Abstract: The objective of this study was to evaluate the utility of hyperventilation (HV) as a stimulus for the determination of cerebrovascular reactivity (CVR) in children with cerebral vasculopathy. Breath hold (BH) has been a useful and effective technique for determining CVR (Thomas et al., 2013). Some children however are unable to perform BH successfully while still able to perform HV. In order to determine whether HV is an effective stimulus for CVR it was compared to BH in a series of 5 patients. These patients had various degrees of Moyamoya, a progressive cerebral vasculopathy.

Seven CVR studies were performed in five children in order to monitor the effect of their vasculopathy on their cerebrovascular reserve capacity. The children ranged in age from 11 to 16 (3 girls) mean age = 13.6 ±2.51 years). Two of the patients had revascularization surgery to improve their cerebral circulation. CVR was determined using an MRI technique which detects the BOLD signal change and reflects the hemodynamic change produced by BH induced CO2 alteration. BH studies involved epochs of 17-25 sec of BH followed by periods of normal breathing for a total of 5 epochs during the BOLD image acquisition. Two BH studies were performed and compared in each CVR study except one. HV studies were performed by instructing the patients to breathe fast and deep for 20 -30 sec followed by normal breathing for a total of 6-9 epochs over 6 minutes. The images were analyzed by comparing the MR signal during the task with that during normal breathing. The images were processed using STIMULATE software (Strupp, 1996). The signal change produced by the task (BH or HV) was expressed as a percent of the MR signal during normal breathing. The parametric images of each study were judged normal or abnormal by visual inspection.

The mean signal changes for the 2 BH studies were 2.2% (1.7-2.8%) and 2.4% (1.5-3.1%), respectively. These means did not differ significantly (Wilcoxon sign rank test; $p>0.05$). The mean signal change for HV was 2.7% (1.7-3.9%) and it did not differ from BH ($p>0.05$). Two CVR BH studies were normal, three were abnormal and two were slightly abnormal. There was a 100% concordance for the six replicate BH studies. The HV studies were concordant with the BH studies except in one patient where the CVR on HV study was slightly abnormal while that based on BH was found to be abnormal.

In conclusion, HV can produce a MR signal change comparable to that produced by BH and appears to be an effective technique for determining CVR in those children who cannot successfully perform BH.

Title: Whole brain and brainstem morphological changes in chronic hemiparetic stroke

Authors: *H. KARBASFOROUSHAN[1], J. P. A. DEWALD[2];
[1]Neurosci., [2]Physical Therapy & Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Previous studies using functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have frequently reported increased motor-related neural activity in motor areas of both ipsilesional and contralesional hemispheres in stroke patients compared to healthy subjects. The neuroimaging studies over the past two decades have found this increased brain activity in more impaired chronic stroke patients more evident in contralesional than ipsilesional hemisphere. More recent studies have suggested that this relative shift in cortical activity to contralesional sensorimotor cortex in individuals with stroke is correlated to the shoulder abduction loading level in the paretic upper limb. This alternative brain activity in individuals with chronic stroke over an extended period of time, may lead to brain structural changes. However, which gray matter regions of brain and brainstem are involved in this cortical shift has not been studied yet. The goal of this study therefore was to use Voxel-Based Morphometry (VBM) analysis on anatomical magnetic resonance images to identify the whole brain and brainstem gray matter density changes over both hemispheres. 10 chronic (>1yr) stroke patients and 10 age-matched healthy controls were recruited to participate in this study and their MRI scans were collected on a 3T Siemens Trio magnetic resonance scanner at the Northwestern University Center for Translational Imaging. High resolution T1-weighted anatomical scans were obtained using a multi-shot gradient echo (GE) sequence with TR = 0.8 s, TE = 2 ms, matrix size = 256 x 256 x 176, and voxel size = 1 x 1 x 1 mm. VBM 8 on SPM12 was used to segment structural images to gray matter, white matter and CSF tissues. Segmented images were modulated and normalized to MNI space while preserved for the total amount of tissue. Normalized gray matter images were smoothed with 6 mm FWHM Gaussian kernel and then used in a between-group two sample t-tests to compare the voxel-wise gray matter density changes in stroke patients compared to control group. Using

voxel-wise corrected p value < 0.05 and p cluster-level corrected < 0.05, the brain and brainstem regions with increase/decrease gray matter density were identified. The stroke patients compared to healthy controls showed significant gray matter density changes in sensorimotor cortices, premotor area, thalamus and bulbar nuclei. Subsequent work will test the relationship between changes in neural morphology in the lesioned and non-lesioned hemispheres and shoulder abduction induced reductions in reaching and hand opening and grasping in individuals with chronic stroke.

Title: Neurite orientation dispersion and density imaging revealed the brain microstructural ischemic damage of moyamoya disease

Authors: *S. HARA[1], T. NARIAI[1], S. MURATA[2], K. TSURUTA[2], Y. TANAKA[1], M. HORI[2], T. MAEHARA[1], S. AOKI[2];
[1]Dept. of Neurosurg., Tokyo Med. and Dent. Univ., Tokyo, Japan; [2]Dept. of Radiology, Juntendo Univ., Tokyo, Japan

Abstract: *Purpose:* To investigate the microstructural damage of the brain elicited by long-standing chronic ischemia in patients with moyamoya disease, we underwent a newly developed diffusion imaging named neurite orientation dispersion and density imaging (NODDI). *Methods:* 12 patients with moyamoya disease (MMD) ranging from 19-61 yrs old (mean age, 44) and 8 normal healthy volunteers (controls) ranging from 27-64 yrs old (mean age, 44) were evaluated. Data was acquired using a 3.0-T MRI system (Magnetom Skyra; Siemens AG, Erlangen, Germany) with 3 b values (0, 700: 30axes, 2850: 60 axes) and then fitted to the NODDI model by using the NODDI Matlab Toolbox5. Created maps of orientation dispersion index (OD) and intracellular volume fraction (Vic) were fitted to standard template by SPM12. Cortical infarction, cerebral hemorrhage and the white matter lesions visible on conventional MRI and b=0 images were deleted from each map by drawing volume of interests using MRIcron. FSL was used to calculate regional values of standard atlases of each map. Two-sample t-test was performed by SPM 12 to compare maps of two groups. *Results:* By comparing the regional

values, widespread decrease in Vic was detected in the white matter of MMD compared to controls (average of all ROIs in the white matter, 0.568 vs 0.625). As for cortical regions, some areas equivalent to watershed area of anterior/posterior circulation showed lower Vic compared to controls (e.g. in 50% Juelich visual cortex V5 region, 0.430 in MMD vs 0.550 in controls). OD of white matter tended to be higher in MMD compared to controls (average of all white matter ROIs, 0.317 vs. 0.271). By whole-brain analysis with SPM, significant increase in ODI was observed in the bilateral deep white matter. *Discussion:* Recent MRI study using advanced diffusion imaging to evaluate the chronic ischemic brain structural change in patients with moyamoya disease revealed widespread decrease in parameters of the white matter compared to normal subjects. Our study's results, decreased Vic and increased OD in the white matter were also compatible with them. Unlike existing conventional diffusion images, NODDI model could be applied to the cortex as well as the white matter. By utilizing this novel characteristic, we found some cortical regions (mainly in watershed area) showed decreased Vic in patients with moyamoya disease. *Conclusion:* NODDI would be a promising tool to investigate microstructural changes caused by chronic ischemia in moyamoya disease. We would further accumulate participants, coanalyzed data with neurophysiological test and PET metabolic images, to establish the clinical significance of NODDI in moyamoya disease.

Title: Targeted photothombotic stroke: a method for producing upper extremity impairments in mice

Authors: ***T. MUHAMMAD**[1], T. CLARK[2], C. SULLENDER[3], A. TANG[2], A. DUNN[3], T. JONES[2];
[1]Univ. of Texas At Austin, Austin, TX; [2]Neurosci., [3]Biomed. Engin., Univ. of Texas at Austin, Austin, TX

Abstract: The photothrombotic approach has become widely used as an animal model of stroke because it can be used to create small ischemic infarcts over discrete subdivisions of cortex and

can be easily combined with in vivo imaging techniques. One criticism, however, is its failure to produce a notable ischemic penumbra, the region around the ischemic core with reduced cerebral blood flow (CBF). In the standard photothrombotic method, after injection of the photooxidative dye, Rose Bengal, and laser illumination (~685nm), thrombi formation results in the simultaneous occlusion of numerous vessels in the illumination region. In the present study we combine a micromirror device (DMD) to confine green laser illumination to specific penetrating arterioles branching from the middle cerebral artery and supplying the forelimb region of motor cortex (M1) of adult male and female C57/Bl6 mice. We then assessed whether this variation of the photothrombotic approach was suitable for modeling post-stroke upper extremity impairments in mice. Prior to stroke, mice were trained on a variation of the single seed retrieval task (SSR). Seeds were randomly placed on each trial in one of three positions of varying difficulty. In order to successfully grab the seed, mice needed to change their reach trajectory on every trial. Mice were trained for ten days prior to stroke and then implanted with cranial windows over the motor cortex contralateral to their preferred reaching forelim. For vessel occlusion,. After systemic injection of either Rose Bengal for animals in the stroke condition (n=12) or saline for animals in the control condition (n=8), a 0.15-0.25mm^2 arteriole area was targeted using the DMD for 4 min of green laser illumination. Mice were then probed on their reaching performance on days 3, 5, 10, 20 and 30 following stroke. Mice in the stroke condition performed significantly worse on days 3 5 and 10 post stroke compared to control animals. However, reaching performance improved by days 20 and 30. There were significant correlations between reaching performance decrements and both the area of targeted illumination and lesion volume, as measured histologically. Thus ,this variation of the standard photothrombotic technique can be used to produce focal lesions in mouse motor cortex of varying size that cause measureable impairments in upper extremity function. Title: Structural-functional interactions underlying mirror feedback in cortical and non-cortical stroke

Authors: *T. MANUWEERA[1], S. SALEH[2], M. YAROSSI[1], S. ADAMOVICH[3], E. TUNIK[4]; [1]Rutgers Biomed. and Hlth. Sci., Newark, NJ; [2]Kessler Fndn., West Orange, NJ; [3]New Jersey Inst. of Technol., Newark, NJ; [4]Northeastern Univ., Boston, MA

Abstract: A bilateral fronto-parietal network has been implicated for processing Mirrored Visual Feedback (MVF) when chronic stroke patients move the unaffected hand. In this study we tested dependence of MVF associated function interactions on the remaining white matter integrity within this fronto-parietal network. Subjects were stratified by lesion location to determine if functional-structural relationships underlying MVF are comparable in patients with cortical and subcortical stroke. Functional Magnetic Resonance Imaging (fMRI) and Diffusion Tensor Imaging (DTI) data were correlated to describe the relationship between mirror related functional connectivity and the structural integrity. 18 stroke subjects (10 cortical, 7F, 54±13 yrs old) performed a finger flexion task with the non-paretic hand during fMRI scanning. Visual feedback was presented in real-time virtual reality as either Veridical (same side hand) or Mirrored (opposite side hand). Dynamic Causal Modeling (DCM) was used to test modulatory interactions among regions of interest selected from the contrast between conditions. Bayesian Model Averaging (BMA) was used to determine the connection strength between regions. Fractional Anisotropy (FA), a measure of white matter integrity, was correlated with the BMA parameters of intrinsic connectivity (BMA.A) and modulatory connectivity (BMA.B) scores. In line with past results, group-level analysis revealed MVF-related activation in ipsilesional fronto-parietal regions in the absence of affected hand movement. Structural integrity (FA) of the ipsilesional parietal cortex (iPar) to ipsilesional M1 (iM1) connection was positively correlated with MVF induced modulation (BMA.B) of iPar to iM1 connectivity ($r=0.654$, $p=0.056$), and negatively correlated with modulation of connectivity from contralesional parietal cortex (cPar) to iM1 ($r=-0.713$, $p = 0.047$). Analysis comparing the cortical and sub-cortical stroke groups revealed that lesion-dependency for processing MVF may be rooted in the structural integrity of fronto-parietal connections. FA of iPar-iM1 tractography was significantly smaller in cortical stroke patients ($p=0.006$), possibly resulting in a weaker iPar-to-iM1 intrinsic modulation (BMA.A) ($p=0.051$). Collectively, these results suggest that MVF modulates iM1 through both iPar and cPar, and that cPar modulation is dominant when structural integrity between iPar-iM1 is compromised. A larger sample size in each group, and a matched healthy subject data set, would strengthen interpretations about these neural mechanisms underlying mirror feedback processing in stroke.

Title: Remote effects of stroke on brain function and motor cortex connectivity

Authors: *B. J. MCMAHAN[1], J. M. CASSIDY[2], C. O'BRIEN[1], G. BRENTLINGER[3], R. SRINIVASAN[4], S. C. CRAMER[5];
[2]Neurol., [1]Univ. of California, Irvine, Irvine, CA; [3]Med. Ctr., Univ. of California, Irvine, Orange, CA; [4]Cognitive Sci., [5]Neurology, Anat. & Neurobio., Univ. of California, Irvine, Irvine, CA

Abstract: OBJECTIVE: Stroke is a leading cause of adult disability that occurs from compromised blood flow to the brain. Post-stroke behavioral deficits result from a combination of structural injury and functional injury, which can be remote from the stroke infarct. The objective of this study was to determine the association between measures of motor system injury and motor cortex (M1) function and connectivity in patients hospitalized with stroke.**MATERIALS AND METHODS:** Twelve individuals (62.1 ± 13.7 years; 4 females) 3-28 days post-stroke admitted to an acute rehabilitation unit completed a 3-minute bedside resting electroencephalography (EEG) recording. EEG power and coherence measures in delta (1-3 Hz) and beta (20-30 Hz) frequency ranges from ipsi- and contralesional M1 were acquired with a high dense array (256-lead) EEG system. Bilateral corticospinal tract integrity was assessed in 9 of the 12 subjects with diffusion tensor imaging. Fractional anisotropy (FA) values at the cerebral peduncle level were computed. This area was unaffected by the stroke. A physical therapist assessed motor impairment and stroke severity using the Upper-Extremity Fugl-Meyer (UEFM) exam and NIH Stroke Scale (NIHSS), respectively. Associations between EEG, FA, and clinical measures were determined using Spearman's rho values.**RESULTS:** Ipsilesional FA values were negatively associated with relative delta power in ipsilesional M1 ($\rho = -0.783$; $p = 0.012$) and delta coherence between ipsi- and contralesional M1 ($\rho = -0.933$; $p < 0.001$). A ratio of ipsi/contralesional FA values negatively correlated with NIHSS score ($\rho = -0.8938$; $p < 0.001$). No significant findings were found in the beta frequency range. **CONCLUSIONS:** These findings show how the remote effects of stroke on the motor system affect ipsilesional M1 function and its interaction with contralesional M1. Importantly, stroke infarct location did not involve M1 in any of the subjects. Significant correlations involving EEG measures in the delta frequency range may reflect early neural injury more than measures in the beta frequency range.

Expanding EEG measures to include premotor and parietal motor regions may provide further understanding of the remote effects of stroke on motor system function.

Title: Interhemispheric morphology of diffusion properties in the brainstem provides new insight to clinical assessment of chronic ischemic stroke patients with upper limb impairment

Authors: ***M. OWEN**[1], C. INGO[2], J. DEWALD[2];
[1]Physical Therapy & Human Movement Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: PURPOSE: Ischemic damage from stroke causes disruption of neural pathways; however, less is known about the resulting changes in normal appearing white matter in individuals that experience upper limb impairment. In this study, we used Diffusion Tensor Imaging to quantify microstructural integrity changes in sub-cortical regions contralateral to the lesion and in the brainstem in stroke subjects when compared to healthy controls. Additionally, we used these imaging measurements to predict impairment by Fugl-Meyer assessment (FMA), 0 (severely impaired) - 66 (not impaired).**METHOD AND MATERIALS:** MPRAGE (1.0mm³ isotropic) and spin-echo echo-planar (SE-EPI) DTI (1.5mm³ isotropic, b=1000 s/mm², 60 directions, 9 b=0 s/mm² averages) were performed on 12 moderately to severely impaired stroke individuals (FMA 11-33) and 14 healthy age-matched controls. For stroke participants, FMA was taken to quantify upper extremity impairment. Tract-based spatial statistical (TBSS) analysis was performed using fractional anisotropy (FA), radial diffusivity (RD), and axial diffusivity (AD) measures.**RESULTS: We demonstrate widespread decreased FA and increased AD and RD in sub-cortical regions contralateral to the lesion in stroke when compared to control; however, we observed the opposite trend in the midbrain. Surprisingly, for the stroke subjects, increased FA in the midbrain significantly correlated with FMA (r=.64, p=.032). Corticospinal tract AD also negatively correlated with FMA (r=-.69, p=.02),**

suggesting that corticospinal tract and brainstem microstructural properties may be important factors for clinical outcome.CONCLUSION: Our results describe the widespread structural changes that occur post-stroke, but highlight the importance of the diffusion properties within the corticospinal tract and midbrain in predicting an individual's clinical impairment level in chronic stroke.

Title: Stroke infarct volume estimation: Comparison of diffusion kurtosis imaging compared to diffusion weighted imaging and histology

Authors: V. BAY[1], M. ARDALAN[1,2,3], B. F. KJOELBY[1], I. K. MIKKELSEN[1], S. N. JESPERSEN[1], J. R. NYENGAARD[2,4], B. HANSEN[1], *K. R. DRASBEK[1];
[1]Ctr. of Functionally Integrative Neurosci., [2]Stereology and Electron Microscopy Lab., [3]Translational Neuropsychiatry Unit, [4]Ctr. for Stochastic Geometry and Advanced Bioimaging, Aarhus Univ., Aarhus C, Denmark

Abstract: In stroke treatment, diffusion weighted MRI (DWI) is an important diagnostic tool for detection and delineation of the infarct and is widely used in treatment planning. However, improvement to these MRI techniques would further aid diagnosis and treatment. In contrast to commonly used diffusion weighted imaging (DWI) protocols, a newer DWI technique, called diffusion kurtosis imaging (DKI), takes deviation from Gaussian diffusion into account, potentially providing better microstructural sensitivity, thereby supplementing the information contained in traditional DWI diagnosis based on diffusivity estimates such as mean diffusivity

(MD). The added benefit of DKI in combination with DWI in stroke is the subject of this study where infarct volume estimates based on MD and mean tensor kurtosis (MKT) are compared to histological staining. Male Sprague Dawley rats (n=7) were subjected to transient middle cerebral artery occlusion (MCAO) for 60 min and reperfused for 24 h before perfusion fixation. The fixed brains were subjected to ex-vivo high-field MRI allowing standard DWI analysis and fast DKI estimation. Brains were sliced in 40 μm cryosections for histology (hematoxylin) for infarct volume estimation using Cavalieri estimator and 2D nucleator and immunohistochemistry (IHC) using anti-GFAP (glial fibrillary acidic protein) for visualization of morphological changes in astrocytes.No differences were seen between whole brain volume estimations by DWI and histology. Likewise, the estimated infarct volumes by MD and histology did not differ. In contrast, substantially larger infarct volumes were estimated using MKT. To investigate if the larger MKT infarcts could be correlated with microstructural changes, sections were stained with anti-GFAP. This revealed a larger area of ischemia-affected tissue than seen by histology. The anti-GFAP stained tissue was separated in three different zones: an advanced infarcted zone containing astrocytes with necrotic features, a penumbra-like-area containing astrocytes with vaguely appearing branches and non-ischemic tissue. This study shows that MD-based infarct volume estimations in perfused-fixed tissue are comparable to estimations based on histological stainings and stereology of cryosections in experimental stroke. Intriguingly, the newer MKT-based infarct volume estimations might include a zone surrounding the infarct area showing astrocyte abnormality in what is thought to be the penumbra. Further studies will elucidate whether DKI in combination with DWI can be used to estimate both the penumbra and the infarct core, and thus, give an estimate of the salvageable tissue in a clinical setting.

Title: Rapid EEG of acute ischemic stroke in the emergency room

Authors: *A. KAUR[1], L. SHREVE[6], C. VO[6], A. P. NGUYEN[6], J. WU[2], J. M. CASSIDY[1], K. M. WU[1], N. L. CHIU[1], R. J. ZHOU[1], W. YU[3], I. VELARDE[4], S. GEHAN[4], B. CHAKRAVARTHY[3], W. HOONPONGSIMANONT[3], E. BARTON[3], R. SRINIVASAN[5], S. C.

CRAMER[2];
[1]Neurol., [2]Anat. & Neurobio., [3]Univ. of California-Irvine Med. Ctr., [5]Cognitive Sci., [4]Univ. of California-Irvine, Irvine, CA; [6]Univ. of California-Irvine, Sch. of Med., Irvine, CA

Abstract: INTRODUCTION: Treatment of acute stroke requires rapid, accurate diagnosis. An additional challenge is to identify candidates for acute reperfusion. EEG detects cerebral ischemia immediately and might have diagnostic utility in this setting. Application of EEG in the acute disease setting has historically been limited by technical limitations. These may be overcome by advances in EEG hardware and software, motivating the current study, which hypothesized that rapid EEG would be feasible and would rapidly detect acute ischemia among patients transported to an Emergency Room (ER) for possible stroke.
METHODS: Patients with suspected acute stroke seen in the UC Irvine Medical Center ER consented to a 3 min resting EEG using a 256 lead dense-array system (EGI, Eugene, OR) that uses a saline lead cap. EEG recordings were obtained in parallel with ER assessments and therapy. The two EEG metrics of interest were power in the delta (1-3Hz) frequency range and the high beta frequency range (20-30Hz), in a frontal and an occipital lead over each hemisphere.
RESULTS: EEG was obtained in 25 subjects (mean age 63 yr), 12 with radiologically confirmed acute ischemic stroke (median NIHSS=4; 4 got IV tPA); 13 were discharged with a non-stroke diagnosis such as TIA, seizure, and encephalopathy. Time from signed consent to EEG averaged 12.2 min and with practice was as short as 5 min. EEG was acquired as early as 1.6 hr after stroke onset, and was readily captured during IV tPA drip. In the C3, C4, O1, and O2 leads, delta power was 1.78-1.96 fold higher in subjects with stroke vs. non-stroke ($p<0.05$ to 0.003); no differences were significant for beta power. Findings for the ipsilesional findings (C3 and O1) were not attributable to injury to underlying cortical regions.
CONCLUSIONS: Dense array EEG can be obtained easily, rapidly, and safely in the ER acute stroke setting. Increased delta power, an established marker of brain injury, performed well in identifying stroke. Interestingly, delta power increases were widely distribute, beyond sites of injury, providing a measure of the network-wide effects resulting from focal stroke injury. This finding extended to the contralesional hemisphere--unilateral acute injury produced bilateral derangement in cortical function--indicating that EEG measures of altered brain function in the acute stroke setting provide information not apparent from structural imaging.

Title: Specificity of neural system injury in relation to motor and proprioceptive deficits post-stroke

Authors: *M. L. INGEMANSON[1], J. B. ROWE[2], V. CHAN[3], D. J. REINKENSMEYER[3,1,2], S. C. CRAMER[1,4];
[1]Anat. and Neurobio., [2]Biomed. Engin., [3]Mechanical and Aerospace Engin., [4]Neurol., Univ. of California Irvine, Irvine, CA

Abstract: *Background*: Somatosensory function is a highly distributed neural network. However, while brain regions that support proprioception are known, neural correlates of proprioceptive deficits after CNS injury remain poorly understood. Here, we aimed to understand the specificity of neural system injury in relation to motor and proprioception behavioral deficits post-stroke.
Methods: Subjects with unilateral chronic stroke were recruited. Contralesional proprioceptive function was assessed using a robot-based measure of passive finger joint position sense. Upper extremity motor function was assessed using the Fugl-Meyer Scale.
High-resolution T1-weighted and T2 FLAIR images were used to quantify motor system and sensory system injury. Each subject's infarct was outlined, and extent of overlap calculated for three gray matter regions of interest: primary motor cortex hand area (M1), primary somatosensory cortex hand area (S1), and secondary somatosensory cortex (S2). White matter injury was quantified as degree of overlap between each infarct and a canonical corticospinal tract (CST) or thalamocortical sensory tract (TST), each generated from healthy controls using diffusion tensor tractography.
To quantify total sensory system injury, S1, S2, and TST injury measures were each standardized then averaged together for each subject. For total motor system injury, standardized injury measures of M1 and CST were averaged.
Results: 27 subjects completed the study (mean age 58 yrs; Fugl-Meyer: 45 out of 66; 30 mo post-stroke). Proprioception deficits were found in 66% of subjects. There was no correlation between proprioception and motor function measured with the Fugl-Meyer score (p=0.3).

Individual injury measures for S1, S2, and TST did not significantly correlate with proprioception function. However, total sensory system injury was strongly associated with greater proprioceptive impairment (r=0.57, p=0.009). In contrast, total motor system injury and M1 injury did not correlate with motor function, but rather more severe injury to the motor tract (CST) was associated with greater motor impairment (r=0.45, p=0.04).
Conclusions: These results suggest that proprioceptive function relies on a neural network that is more distributed than that for motor function, and is less sensitive to focal tract injury than motor function. This enhanced understanding of the specific association between brain injury and proprioceptive dysfunction could lead to advances in diagnosis and treatment after stroke.

Title: Neural substrates supporting compromised hand function in the chronic phase of stroke

Authors: *K. P. REVILL[1], J. FREEMAN[1], G. KOWALSKI[1], M. HAUT[2], S. BELAGAJE[1], C. M. BUETEFISCH[1];
[1]Emory Univ., Atlanta, GA; [2]West Virginia Univ., Morgantown, WV

Abstract: Ischemic stroke often impacts the integrity of primary motor cortex (M1) and its corticospinal projections (CST) resulting in incomplete recovery of hand function. The neuronal substrate supporting compromised hand function in the chronic phase of stroke is not well understood. The objective of this fMRI study is to determine the relationship between hand function and performance related activation in ipsi- and contralesional M1. Seventeen patients with chronic stroke (9M, age = 61.4 ± 12.2 years, months since stroke = 33.5 ± 35.1) participated in the study. The score on a standardized time-based hand function test (Jebsen test contrast ratio = 0.50 ± 0.2) and the mean peak acceleration recorded across five ballistic wrist extension movements were used as measures of affected hand motor and kinematic function. In a block design fMRI task, participants performed cued wrist extension movements with the affected

hand. Structural MRI images were acquired to determine lesion size and location. Following enantiomorphic normalization, BA 4 maximum probability masks were used as anatomical ROIs, masked with lesion location where appropriate. Mean percent signal change (PSC) values from each ROI were dependent variables in a regression model with age included as a covariate. Peak acceleration and Jebsen scores were negatively correlated, with higher peak acceleration predicting a lower score (less impairment) on the Jebsen test. Peak acceleration significantly predicted PSC in both ipsi- and contralesional BA 4, with reduced activation when peak acceleration was high. Higher Jebsen scores were associated with higher PSC in contralesional but not ipsilesional BA 4. Exploratory analyses (FWE-corrected) in the contralesional hemisphere showed an additional positive correlation between the Jebsen score and PSC in the cerebellum and negative correlations between peak acceleration and PSC in BA 5 and 6. Conclusions: In chronic stroke, superior hand function is associated with less activity in contralesional BA 4. Activity in contralateral BA 4 is typically low for simple motor tasks in healthy controls. Likewise, patients with good hand function do not depend on contralesional BA 4 activity when executing a simple motor task. Similarly, the negative correlation between less activity in ipsilesional BA 4 during the execution of a simple motor task and better hand kinematic function supports the notion of more effective processing of the motor command. Like measures of ipsilesional CST structure and function, ipsilesional BA 4 activity is not correlated with Jebsen score, suggesting that more complex motor tasks depend on reorganization of additional brain areas.

Title: High-dimensional therapeutic inference in the focally damaged human brain

Authors: T. XU[1], H. R. JÄGER[1], M. HUSAIN[2], *G. E. REES[1], P. NACHEV[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: The functional architecture of the human brain is known from neuroimaging to be highly complex yet remarkably consistent across individuals. This makes the inverse inference from brain structure to behaviour insecure when simple, low-dimensional models of the brain are used, but potentially powerful where complex, high-dimensional models are combined with large-scale data. Focusing on the consequences of acute stroke, here we use the largest reported set of anatomically registered human focal brain lesions (N=1333) to show that the low-dimensional lesion-deficit modelling implicit in conventional evaluations of focal brain damage obscures positive treatment effects. High-dimensional modelling, however, is shown to leverage complex architectural regularities in the brain to unveil substantial effects invisible to other inferential methods. The common failure to replicate in humans positive findings from animal studies may thus have a remediable inferential cause, and need not reflect physiological differences. A wholesale re-evaluation of therapeutic inference in focal human brain damage is thereby compelled.

Title: Enlarging the penumbra with a slight variation of the standard photothrombotic technique: targeted artery occlusion

Authors: *T. CLARK[1], C. SULLENDER[2], S. KAZMI[2], A. DUNN[2], T. JONES[1];
[2]Biomed. Engin., [1]Univ. of Texas At Austin, Austin, TX

Abstract: Photothrombotic stroke is a popular stroke model due to its ability to produce reliable, small infarcts that can be placed within distinct functional subdivisions of cortex, and its ability to be easily combined with *in vivo* imaging techniques in order to monitor stroke over time in the living brain. However, this approach has been criticized for its failure to produce a substantial ischemic penumbra, the region around the ischemic core with reduced cerebral blood flow (CBF). Here we assess the extent of the ischemic penumbra using both the traditional photothrombotic stroke approach and a variation allowing for patterned light illumination that targeted only pre-selected portions of surface arterioles. Photothrombotic lesions were

introduced by intravenous or systemic delivery of Rose Bengal followed by either patterned laser power (685nm, 20mW) over mouse motor cortex for 4 minutes, or unfocused laser power (20-24mW) for 12-15 minutes. Slight variations in the timing and delivery of Rose Bengal ensured equal lesion sizes between approaches. Cerebral blood flow was monitored with multi-exposure speckle imaging prior to and immediately following ischemia; and then again at 6 hours, 2 days, and 5 days following occlusion. Speckle imaging of cerebral blood flow (CBF) was analyzed using a custom made MATLAB script to estimate relative CBF changes from baseline. Parenchymal CBF was analyzed at each imaging time point at selected regions of interest (ROI) binned within various distances (<100um, 100-250um, 250-500um, >500um) from the ischemic core, defined as the area of parenchyma with CBF below 20% of baseline CBF at 2 days post stroke. At 2 days post occlusion, CBF in both groups was significantly reduced between 20-60% of baseline CBF within 250um of the ischemic core. However, animals that received the traditional photothrombosis showed near baseline levels of CBF at distances greater than 250um from the core whereas animals that received targeted photothrombosis showed decreased (40-80%) levels of baseline CBF even in parenchymal regions greater than 500um from the ischemic core. By 5 days, CBF in both groups returned to 60-80% of baseline blood flow within 250um of the ischemic core. However, animals that received traditional photothrombosis showed suprabaseline CBF at distances greater than 250um whereas animals that received targeted photothrombosis retained decreased (60-80%) CBF more than 500um from the core. These data demonstrate that patterned illumination during photothrombosis, creates a substantial ischemic penumbra, which makes it a more clinically relevant stroke model than the traditional photothrombotic method.

Title: Analysis of evoked potentials during successful treatment of carotid artery disease

Authors: ***M. KELLY**[1], L. PEELING[2], K. MEGURO[2], J. NORTON[2];
[1]Neurosurg., [2]Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Carotid artery stenosis is a leading cause of stroke, and therefore disability. Removing the stenosis through either open surgery or endovascular treatment has been shown to reduce the risk of subsequent stroke. Open surgical treatment involves the occlusion of the artery for the period of time in which the plaque is being removed. In endovascular surgery stents and catheters are placed into the artery and there is often a period of blood flow occlusion during angioplasty. To forewarn of impending neurological damage it is common to use somatosensory evoked potentials to assess brain function during the period of occlusion. All patients were monitored with bilateral median nerve SSEPs recorded with either a Cadwell Cascade or Medtronic NIM-Eclipse, both with the same filter and stimulation settings. Data was exported for post-hoc analysis in the Matlab environment. In this study we examined the SSEP velocity and acceleration during phases of the procedure related to both blood flow occlusion and restoration. None of the cases in the study (14 surgical and 11 endovascular) resulted in changes in the SSEP according to the traditional criteria (decrease in amplitude of 50% or increase in latency of 10%). The analysis focused on the initial slope of the cortical SSEP leading to the N20 peak. Both the open and endovascular procedure resulted in an increase in the amplitude of the SSEP (7.4% and 5.2% respectively, [$p<0.05$ in both cases, paired t-test]) compared to the baseline recordings. In open surgery the clamp time resulted in a slower velocity of the potential, whilst following the clamp release it rebounded to above baseline values. This was a short-lived event, and at the end of the procedure, although the potential was higher in amplitude, there were no differences in velocity compared to baseline. In contrast, the endovascular approach did not show any significant changes in velocity. In the absence of changes in amplitude or latency that are indicative of neural damage there are other changes in the brain function that can be detected in the evoked potential. The clinical significance of the changes is not known at present. Differences between the two procedures may influence differences in neurophysiological functions.

Title: Damage to white matter bottlenecks contributes to chronic language impairments and disrupts semantic network function in patients with left middle cerebral artery stroke

Authors: *J. C. GRIFFIS[1], J. P. SZAFLARSKI[2];
[1]Psychology, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Neuroimaging evidence indicates that the normalization of processing in pre-existing language networks enables language recovery after left hemisphere stroke. Damage to white matter (WM) connections among language areas might be expected to impede recovery by disabling long-range communication and preventing the re-integration of surviving areas into coherent networks for language processing. Indeed, chronic language impairments have been linked to WM damage near regions that may correspond to bottlenecks where fibers from multiple long-range tracts converge. However, the effects of damage to verified WM bottlenecks on long-term language outcomes and language network function in stroke patients have not been investigated.

We first validated predictions of the current model of language recovery after stroke by showing that task-driven fMRI activity in the pre-existing semantic network (identified in 43 healthy individuals) during semantic decisions predicts naming, fluency, and comprehension abilities independently of damage to the network in 43 patients with chronic post-stroke aphasia. Diffusion MRI tractography of the healthy individuals verified the presence of 2 *a priori* WM bottlenecks involving (1) callosal, arcuate, inferior fronto-occipital, and inferior longitudinal fibers in the WM underlying posterior temporal regions, and (2) anterior thalamo-cortical, uncinate, and inferior fronto-occipital fibers in the WM underlying anterior prefrontal regions. Using multiple regression to control for lesion volume effects, we found that damage to the posterior bottleneck predicts chronic deficits in fluency, naming, and comprehension, while damage to the anterior bottleneck only predicts deficits in fluency. Results from a multivariate lesion-behavior analysis corroborated these findings. Whole-brain fMRI analyses revealed that damage to the posterior bottleneck was associated with reduced task-driven activity throughout the bilateral semantic network, while damage to the anterior bottleneck was associated with reduced activity only in left inferior frontal cortex.

Our results support the current model of language recovery after stroke. They also show that damage to WM bottlenecks, specifically in the WM underlying posterior temporal regions, contribute to chronic language impairments in multiple domains and disrupts function in bilateral portions of the semantic network. Damage to WM bottlenecks may represent an under-recognized source of chronic language deficits after stroke, and may underlie previous associations between damage to the posterior temporal WM and poor prognosis in patients with post-stroke aphasia.

Title: Visualizing reorganization of cholinergic projections from the nucleus basalis after photothrombotic stroke.

Authors: *D. M. BETZ, A. BECKER, M. P. GOLDBERG;
Neurol. and Neurotherapeutics, UT Southwestern Med. Ctr., Dallas, TX

Abstract: Stroke is a devastating event with long term functional deficits. Many stokes affect the somatosensory cortex, causing specific deficits that never fully recover. Cholinergic pathways are known to modulate plasticity in many different modalities. If the cholinergic system itself is damaged or modified by stroke, it could hold important implications for stroke recovery. We hypothesize that the cholinergic projections from the nucleus basalis (NB) undergo changes in axonal density and distribution after stroke. We examined cholinergic pathways in transgenic mice expressing EYFP-tagged channelrhodopsin in cholinergic cells. We bred these mice by crossing mice with a cre transgene under the choline acetyltransferase promoter (**B6;129S6-*Chat*$^{tm2(cre)Lowl}$/J**)with mice containing a channelrhodopsin-EYFP transgene with a floxed stop cassette under the CAG promoter (**B6;129S-*Gt(ROSA)26Sor*$^{tm32(CAG-COP4*H134R/EYFP)Hze}$/J**), both obtained from Jackson Laboratories. Mice received either sham surgery or photothrombotic stroke of the left sensorimotor cortex. Behavioral function was assessed by Rotarod testing. Mice were housed in enriched environments beginning 3 weeks prior to stroke and were sacrificed at day 3, week 2 or week 4 after stroke or sham surgery. Evolution of cholinergic projections in fixed brains was visualized by high-throughput fluorescence microscopy using either whole slide imaging of cryostat sections (Nanozoomer, Hamamatsu) or serial two-photon tomography of whole brains (TissueCyte 1000, TissueVision). Cholinergic pathways were well visualized with both imaging systems. Projection axons were especially intense within brainstem nuclei, but cholinergic cell bodies and proximal processes were also well seen within basal forebrain and cerebral cortex. NB projections were best seen in sagittal sections. Results from stroke and control mice will be presented. With the diffuse characteristics of the cholinergic pathways, we anticipate disruptions in axonal density and innervation. Understanding and modulating circuits involved in plasticity after stroke may be crucial to developing new therapeutic methods.

Abstract: Improvements in optical imaging and availability of model animals with genetically encoded calcium indicators have opened up new avenues to explore a variety of conditions in the brain. In particular, new methods for longitudinal wide-field brain imaging in awake behaving mice allows high-resolution, multi-modal recording of functional changes during disease development and progression. Here, we present an experimental model utilizing wide-field, high-speed optical imaging of Thy1-GCaMP mice during photothrombotic stroke to determine the second-by-second progression of acute ischemia and associated waves of ischemic depolarization. Our technique allows for simultaneous acquisition of hemoglobin oxygenation dynamics, GCaMP fluorescence and laser speckle blood flow data over the course of 2-4 hours following stroke induction. Our analysis reveals that prior to ischemia, bilateral waves of neuronal activity spontaneously traverse the cortex. Soon after ischemia, waves of depolarization can be seen spreading radially across the ischemic hemisphere. Simultaneous hemodynamic and blood flow measurements reveal a profound vasoconstriction coincident with the CSD, and allow for the analysis of neurovascular coupling during these events. These methods provide an important new platform for understanding acute and longitudinal brain disease, and can provide previously inaccessible links between neural, vascular, and behavioral deterioration and recovery, as well as responses to therapy in a wide range of disease states.

Title: DTI analysis in patients with sickle cell disease

Authors: *J. COLOIGNER[1], D. SACCHETTO[1], J. TANEDO[1], T. COATES[2], N. LEPORE[1], J. C. WOOD[3];
[1]Radiology, [2]Hematology, [3]Cardiol., Children's Hosp., Los Angeles, CA

Abstract: *Introduction* - Sickle cell disease (SCD) is a genetic disorder characterized by a mutation in the beta hemoglobin gene causing hemoglobin to polymerize upon deoxygenation, leading to chronic microvascular damage and strokes. Furthermore, recent studies have demonstrated that cognitive impairment occurs even in the absence of overt stroke on conventional imaging. We hypothesized that subtle cerebral injury might be visible with diffusion tensor imaging (DTI) in these patients.
Methods - DTI scans were obtained in 30 directions using an EPI sequence with a b-value of 1000s/mm2. 3D T1 and T2 images were collected for volumetric assessments and detection of white matter strokes. The population sample consists of 18 SCD patients and 20 healthy controls (CTL) subjects. The DTI data were processed with the Diffusion Imaging in Python (DiPy) toolbox. Images were processed to provide fractional anisotropy (FA) and mean diffusivity (MD) maps. All maps derived from the DTI images of the SCD and CTL groups were compared by paired Student's t-test. White matter strokes were found in 5 patients.
Results - Right hand figures demonstrate the cumulative white matter stroke map across all patients as a binary mask. Across frontal and parietal lobes, SCD patients had significantly higher MD and lower FA than controls. In the frontal lobe, the distribution of reduced FA matched regions of increased MD, and corresponded brain regions at high risk for stroke.
Conclusions - Although silent strokes are common in SCD, their number and location are highly variable. In contrast, our DTI data showed widespread systematic white matter abnormalities in patients with SCD in regions at risk for stroke. This suggests chronic axonal injury is occurring, even in patients who don't have overt strokes. Interestingly, regions of increased FA and decreased MD were also found in regions of the brain typically spared by silent strokes. These

may represent axonal remodeling in compensation for the frontoparietal damage. We are currently exploring the impact of these lesions on neurocognitive function.

Title: Changes in corticospinal tract microstructure are associated with motor performance improvement in chronic stroke

Authors: *B. KIM[1], D. B. KAY[2], N. SCHWEIGHOFER[1,2], J. P. HALDAR[3,4], R. M. LEAHY[3,4], B. FISHER[1,5], C. J. WINSTEIN[1,5];
[1]Div. of Biokinesiology and Physical Therapy, [2]Neurosci. Grad. Program, [3]Ming Hsieh Dept. of Electrical Engin., [4]Brain and Creativity Inst., [5]Dept. of Neurol., USC, Los Angeles, CA

Abstract: Background: Microstructure of corticospinal tract (CST) characterized by diffusion tensor imaging (DTI) has been shown to be a significant predictor of motor recovery after stroke in both acute and chronic stroke. While CST microstructural change during the early phase has been shown to be associated with motor recovery, there is no study showing a significant relationship between the change in CST microstructure and the change in motor performance in chronic stroke. **Purpose:** This study aims to determine if a change in ipsilesional CST (iCST) fractional anisotropy (FA) is associated with improvement in paretic upper extremity (UE) motor performance over a three-month intervention period. These data are a subset of a longitudinal Phase-I clinical trial of rehabilitation in chronic stroke (ClinicalTrials.gov ID: NCT01749358). **Methods:** Those with mild-to-moderate UE motor impairment participated (N=28, chronicity range = 0.47 to 14.38 years). MRI scans and clinical assessments were acquired at baseline and post a 3-month period. Imaging data were processed using BrainSuite14a (http://brainsuite.org/). CST tractography was reconstructed for both ipsi- and contra-lesional sides, and 3-dimensional CST masks were generated for each side. Average FA values of each voxel within CST mask was calculated for each side, and CST FA asymmetry index (FAAI) was derived. The primary motor outcome was average Wolf Motor Function Test (WMFT) log time score of distal control items. Significant changes in DTI and motor performance variables were assessed using repeated measures ANOVA. Relationship between change in DTI variables and change in motor performance was assessed using linear regression. **Results:** There was a significant decrease in WMFT log time score over a 3-month period (mean ± standard deviation of changes = -8.4±10.8 %, $p < 0.05$). Changes in the iCST FA and FAAI were not significant ($p = 0.82$ and $p = 0.15$, respectively). However, the linear regression revealed that changes in iCST FA and FAAI explained 35 % ($p < 0.0001$) and 33 % ($p < 0.01$) of the variance in change in log time score of WMFT distal items, respectively. **Discussion:** This is the first study in a chronic stroke population that has demonstrated a significant relationship between CST microstructural change and motor performance improvement. However, we did not set covariates in the linear regression, such as age and chronicity that can affect FA value, due to the small sample size. We need more studies with larger sample size to develop a better model for the relationship between brain microstructure and motor behavior.

Title: Improving arm function in chronic stroke using myoelectric-computer interface

Authors: *E. M. MUGLER[1], S. HAMEED[1], J. E. GAIDE[1], R. D. FLINT[1], M. W. SLUTZKY[2]; [1]Neurol., [2]Neurology, Physiology, Physical Med. and Rehabil., Northwestern Univ., Chicago, IL

Abstract: Stroke can cause impaired arm function due to weakness, impaired sensation, and abnormal patterns of muscle activation. We have designed a myoelectric-computer interface (MCI) paradigm that maps activations of a pair of abnormally coupled muscles to orthogonal components of computer cursor movement. MCI users can learn to decouple these muscles by moving the cursor to targets along the mapping directions in an interactive game. In this study, we investigated improvement in arm function of chronic stroke survivors before, during, and after MCI training of 3 different muscle pairs in the upper arm over 18 sessions. We evaluated the effects of training duration and isometric vs. movement-based training conditions. We measured clinical outcome metrics as well as the degree of co-activation and arm joint kinematics during free reaching. Our first 16 subjects demonstrated improvement from baseline to the end of training and sustained improvement 4 weeks post-MCI use. Co-activation levels declined in all subjects in the targeted muscles, and elbow extension improved substantially in all subjects. Subjects showed modest improvement (Fugl-Meyer: 3.4 for 60-minute group, 3.6 for 90-minute group). Arm function, as measured by the Wolf Motor Function Test, also improved moderately (by 4.9 s and 10.3 s for 60- and 90-min groups, respectively). Arm function also improved outside of the lab (Motor Activity Log “How Often”: 4.1 and 4.9; “How Well”, 3.1 and 4.9 for the 2 groups, respectively). Spasticity decreased consistently across groups (-5.3 for 60-minute group, -4.21 for 90-minute group on MAS). Overall, longer MCI training showed improved functional outcomes. These results suggest that MCI training can reduce abnormal co-activation and spasticity and improve upper arm function in chronic stroke survivors. If successful, this paradigm could have a broad impact, and could be made into an inexpensive and portable device that many survivors could incorporate into their daily routine.

Title: Hemisphere specific motor deficits in bilateral coordination

Authors: *C. MAENZA[1,2], D. GOOD[1], R. L. SAINBURG[1,2];
[1]Neurol., Penn State Col. of Med., Hershey, PA; [2]Kinesiology, Pennsylvania State Univ., University Park, PA

Abstract: We have demonstrated hemisphere specific motor deficits in the ipsilesional arm of stroke patients that are most severe in patients with left hemisphere damage (LHD) and with severe contralesional impairment. LHD produced deficits in predictive features of coordination, initial trajectory direction, and intersegmental coordination. Right hemisphere damage (RHD) produced deficits in the ability to achieve and stabilize the final position of movement, possibly related to impedance control deficits. Stroke patients with mild to moderate contralesional impairments are able to use both arms for bilateral performance, a requisite for many activities of daily living. We hypothesize that right and left hemisphere lesions should differentially affect bilateral coordination. Specifically that LHD should produce deficits in predictive aspects of coordination, while RHD might produce deficits in feedback mediated aspects of coordination. We present a virtual object manipulation task, in which forward movement of the object trajectory depends upon lateral motions of the hands, predominantly elbow extension. Maintaining the object (bar) in midline requires the lateral trajectories, compensate one another, or are negatively correlated. Lack of such covariation produces lateral deviations in the trajectory of the virtual object. Because this task does not induce mechanical interactions between the arms, such coordination is completely dependent on neural control mechanisms. Our preliminary findings indicate that the movements of LHD patients were less coordinated than those of control participants or RHD patients in the early phase of motion. In contrast, RHD produced deficits in coordination in the later, stabilization phase of motion, but not in the early phases. Our results indicate hemisphere specific deficits in bilateral coordination.

Title: Characterization of long-term gait deficits in mouse dmcao model of stroke, using the catwalk system

Authors: *E. CABALLERO-GARRIDO[1], J. PENA-PHILLIPIDES[1], Z. GALOCHKINA[2], E. ERHARDT[2], T. ROITBAK1[1];
[1]Neurosurg., [2]Dept. of Mathematics and Statistics, Univ. of New Mexico, Albuquerque, NM

Abstract: Assessment of functional deficits after experimental stroke has become increasingly important for clinical relevance of the proposed animal models or treatments. Stroke Therapy Academic Industry Roundtable (STAIR) recommends multiple endpoints (at least 2 or 3 weeks or longer after the insult) for behavioral studies in pre-clinical stroke research, to demonstrate a sustained benefit and sufficient clinical relevance. We evaluated mouse locomotion and gait impairment for four consecutive weeks after direct (distal) middle cerebral artery occlusion (dMCAO), a widely utilized model for experimental cortical ischemia. Different behavioral tests have been used to characterize somatosensory deficits after dMCAO. CatWalk test has been proposed as a sensitive tool for evaluation of the animal locomotion and gait impairment. The main goal of the present study was to provide a detailed characterization of the long-term functional recovery in dMCAO model of mouse stroke, using CatWalk automated system. C57BL/6 mice were subjected to dMCAO or sham surgeries (ten animals per group). The gait was analyzed at 7, 14, 21, and 28 days after surgery. Temporal, Spatial, Kinetics and Interpaw-coordination parameters have been assessed during the testing. Rigorous statistical analysis revealed significant differences in several parameters, including Run Duration, Average speed, and the Number of steps during the run, between dMCAO and Sham groups of animals at 7 days after dMCAO. These differences dissolved by 14 days after dMCAO. Spatial parameters including Print width, length and area, were significantly different between two groups, at 7 and 21 days after surgery. At 28 days, there were no significant differences in the above-mentioned parameters, probably due to a spontaneous post-ischemic recovery. Some of the kinetics parameters such as Body speed or Swing speed were significantly impaired at 7 days after dMCAO. The interpaw coordination parameters (such as Print positions) were significantly different between dMCAO and Sham groups at 28 days, while Stride length (for front and hind paws) was significantly affected at 7 days after dMCAO. In summary, we identified several specific gait and locomotion parameters, which are significantly affected by dMCAO-induced

brain damage at different time points after cerebral ischemia. These parameters can be used in the future studies for the assessment of the recovery after proposed treatments in dMCAO mice model of experimental ischemia.

Title: Electrophysiological assessment of the cervical spinal cord of the Long Evans rat following stroke injury

Authors: *L. MOORE[1,2,3], J. E. DUARTE[4], D. SCHWERZ DE LUCENA[4], H. ZHONG[5], R. R. ROY[5,6], D. J. REINKENSMEYER[4,7,8], V. R. EDGERTON[5,6], D. C. LU[2,3];

Abstract: A stroke injury results in rewiring of long descending tracts that relay motor commands from the brain to motor pools in the spinal cord. To begin to determine whether physiological changes in the spinal cord coincide with post stroke impairments, the behavioral performance of Long Evans rats (n = 11) was evaluated in a reaching task for success rate and utilization of select forelimb muscles while the electrophysiological properties of the cervical spinal cord networks to the same forelimb muscles were evaluated using epidural stimulation. Prior to injury Long Evans rats, trained to perform a reaching task, were implanted with bilateral intramuscular electrodes in select forelimb muscles and with epidural electrodes at spinal cord levels C4, C6, and C8. Following behavioral and electrophysiological evaluation, rats received a unilateral photothrombotic stroke to the forelimb region of the sensory/motor cortex. Post injury rats showed impairments in reaching and grasping ability and reduced amplitudes in EMGs recorded from forelimb muscles involved in the task. These impairments coincided with an increase in the amplitude of evoked responses from multiple cervical spinal cord networks to the

impaired limb. The data presented here suggest that a cortical stroke affects the connectivity between the spinal cord and motor pools that activated impaired muscles.

Title: The effects of conditioning startling acoustic stimulus in healthy and stroke subjects - a TMS study

Authors: *Y.-T. CHEN, S. LI, P. ZHOU, S. LI;
Physical Med. and rehabilitation, Univ. of Texas Hlth. Sci. Ctr. at Houst, Houston, TX

Abstract: Startling acoustic stimulus (SAS) is a useful tool to examine reticulospinal excitability. It is known that a conditioning SAS at 50ms prior can cause a transient suppression of transcranial magnetic stimulus (TMS)-induced motor evoked potential (MEP) at rest in healthy subjects. The induced MEP reduction was attributed to reticulo-cortical inhibition. However, it is unknown whether this phenomenon persists in stroke and during voluntary contraction. Therefore, the purpose of this study was to determine whether a conditioning SAS has different effect at rest and during voluntary contraction in healthy and stroke subjects.
TMS was delivered to the hot spot with and without a conditioning SAS (50ms prior) for left biceps in eleven healthy and non-impaired biceps in nine stroke subjects. TMS-induced MEP, TMS-induced force increment and silent period were used to determine the effect of conditioning SAS. A two-way mixed ANOVA [2 Groups (Healthy V.S. Stroke) × 2 Conditions (with V.S. without SAS)] with repeated measure on conditions was used to determine the difference between and within groups
At rest, the MEP was smaller with a conditioning SAS for both healthy (0.49 mV ± 0.37 mV V.S. 0.70 mV ± 0.55 mV, $p < 0.05$) and stroke (0.50 mV ± 0.52 mV V.S. 0.72 mV ± 0.73 mV, $p < 0.05$) subjects. During voluntary elbow flexion tasks, there were no significant differences in the induced force increment and MEP for both healthy and stroke subjects with and without a conditioning SAS. However, a conditioning SAS resulted in a significant shortening of the MEP silent period for both healthy (187.22 ms ± 22.99 ms with SAS vs. 200.56 ms ± 29.71 ms without SAS) and stroke (164.75 ms ± 22.18 ms with SAS vs. 184.63 ms ± 29.32 ms without SAS) subjects ($p < 0.05$). There were no significant Group × Condition interactions for all

parameters.
Our results showed that a conditioning SAS imposes a significant transient suppression of TMS-induced MEP at rest but not during voluntary contraction for both healthy and stroke subjects. The results of shortening of SAS effect on silent period in healthy and stroke subjects suggest that a conditioning SAS has a separate facilitatory effect on spinal motor neurons via activation of descending reticulospinal projections during sustained voluntary contraction. Similar results between stroke and healthy subjects that reticulospinal projections on the contralesional side are not likely impaired in stroke.

Title: Does contralesional motor cortex contribute to voluntary contraction of the impaired elbow flexors in stroke survivors

Authors: Y.-T. CHEN, 77030[1], S. LI[1], C. DITOMMASO[2], P. ZHOU[1], *S. LI[3];
[1]Univ. of Texas-Houston, Houston, TX; [2]Baylor Col. of Med., Houston, TX; [3]Physical Med. and Rehabil., Univ. of Texas Hlth. Sci. Ctr. - Houston, Houston, TX

Abstract: BACKGOUND: Reorganization of the lesioned hemisphere plays a major role in recovery after stroke, while the contribution of the contralesional motor cortex during voluntary contraction of the paretic limb is still not clear. Transcranial magnetic stimulus (TMS) to the primary motor cortex (M1) primarily induces muscle contraction and increase in force (or force increment) in the contralateral limb. The greater TMS-induced force increment in the ipsilateral limb could be indicative of contributions from the contralesional M1. Therefore, the purpose of this study was to compare the TMS-induced force increment between healthy and stroke subjects. METHODS: Eleven healthy and eight stroke subjects performed isometric elbow flexion (right side of healthy subjects and impaired side of stroke subjects) at 10%, 30% and 60% of their maximum voluntary contraction (MVC). TMS was delivered to M1 ipsilateral to the contracting biceps at rest and during three contraction tasks. TMS-induced MEP in the contralateral non-contracting biceps and TMS-induced elbow flexion force increment in the ipsilateral contracting side were quantified. Two-way ANOVA analyses were used with a between group factor (Group x2) and a within group factor (Force x3). RESULTS: For both health and stroke subjects, the contralateral MEP normalized to the MEP at rest showed force-

level dependent increase (for health: 10% MVC: 130% ± 42%, 30% MVC: 157% ± 58%, 60% MVC: 258% ± 119%; for stroke: 10% MVC: 177% ± 31%, 30% MVC: 235% ± 19%, 60% MVC: 294% ± 64%; $F(2,34)=24.81$ $p<0.05$). Furthermore, the normalized MEP is higher in stroke subjects (235% ± 18%) compared with healthy subjects *(*182% ± 15%*;* $F(1,17)=5.21$, $p<0.05$). There were no significant effects of Group or Group × Force interactions. The TMS-induced force increment (percent change from baseline force) was significantly greater in stroke subjects (8.02% ± 9.38%) than healthy subjects (1.61% ± 0.99%; $F(1,17)=5.18$, $p<0.05$). Furthermore, there was a main effect of Force. Stroke subjects exhibited higher TMS-induced elbow flexion force compared with healthy subjects only during 10% MVC contraction tasks (14.43% ± 17.75% V.S 1.01% ± 0.46%), but not during higher force levels. SUMMARY: Our findings of force level dependent increase in contralateral MEP and non-force level dependent change in the ipsilateral force increment indicate that there are bilateral M1 activations during unilateral voluntary activation of elbow flexors. However, contralesional activation is not likely contributing to voluntary force production of the impaired biceps muscles in stroke subjects.

Title: Split belt walking increases neurovascular response during gait coordination task in stroke

Authors: *V. AMBATI[1], T. RAND[1], J. FUJAN[2], P. FAYAD[3], M. MUKHERJEE[1];
[1]Dept. of Biomechanics, Univ. of Nebraska At Omaha, Omaha, NE; [2]Biomechanics Res. Building, Univ. of Nebraska at Omaha, Omaha, NE; [3]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: The purpose of this project was to analyze the neurovascular responses of stroke survivors during split belt treadmill adaptation task. In this ongoing study, ten chronic stroke survivors walked on an instrumented split belt treadmill while being exposed to different belt speeds for each leg. The affected leg was on the fast/slow belt if its stride length was shorted/longer than the less affected side respectively. Functional near infra-red spectroscopy was used to measure hemodynamic changes in the cerebral cortex. We determined the changes in neurovascular responses due to immediate learning, late learning of split belt paradigm and transfer effects of split belt training to tied belt condition. Changes in mean oxyhemoglobin

values were determined from filtered data in regions of interest. There was a significant main effect of split belt condition on changes in oxyhemoglobin concentration in the supplementary motor area (p=0.007) and post central gyrus (p=0.008). Post-hoc analysis revealed significant decrease in change of oxyhemoglobin concentration from late learning to transfer stage in the supplementary motor area (p=0.033). This indicates a higher neurovascular response in our group of stroke survivors due to split belt protocol. Specifically, changes were observed in the planning and execution of the motor learning task.

Title: An MRI-compatible, split-crank pedaling device to prevent motor compensation after stroke

Authors: ***S. M. SCHINDLER-IVENS**[1], B. D. SCHMIT[2], B. ARAND[2], B. CLELAND[3]; [1]Physical Therapy, [2]Biomed. Engin., [3]Clin. and Translational Rehabil. Hlth. Sci., Marquette Univ., Milwaukee, WI

Abstract: Motor compensation after stroke is a behavior in which the non-paretic limb performs tasks normally accomplished by the paretic limb. For example, stroke survivors with right hemiparesis often bear weight exclusively on the left leg when rising from a chair. Compensation improves independence, but it may be detrimental to motor recovery. We have preliminary data suggesting that compensation during pedaling reduces cortical activation, resulting in inferior lower limb movement. Our data also suggest that, when compensation is prevented, cortical activation increases. Thus, we suggest that rehabilitation that suppresses compensation can maximize lower limb movement via improved cortical activation. Here, we describe a novel experimental approach - an fMRI-compatible, split-crank pedaling device - that allows us to test

this hypothesis. The device is designed for pedaling during fMRI. It is fabricated from non-magnetic materials. Subjects lie supine with their feet fastened to the pedals. A crank arm connects each pedal to a crankshaft, which has a distinctive "split" design whereby the crankshaft is split into a left and right half. The two halves are fastened together with a coupler, which can be removed to eliminate the mechanical connection between pedals. Each half of the crankshaft turns an eccentric pulley that enables continuous pedaling despite no mechanical contribution from the contralateral limb. During the downstroke of pedaling, the eccentric pulley stretches an elastic band. Energy stored in the band is released during the upstroke to propel the leg back to top-dead-center. When the coupler is in place, subjects pedal with the paretic and non-paretic legs mechanically connected. Here, the legs are positioned 180° out-of-phase, as in conventional pedaling. Because the non-paretic leg is mechanically coupled to the paretic leg, it can compensate for impaired motor output of the paretic leg. When the coupler is removed, subjects are asked to pedal with both legs moving 180° out-of-phase. In this configuration, there is no mechanical connection between the right and left pedals. To pedal successfully, the paretic limb must accelerate the crank without assistance from the non-paretic leg. Moreover, the two legs must work together to maintain appropriate phasing. Coupled and uncoupled pedaling can be performed during fMRI, and measurements of position, velocity, and torque can be obtained. Consequently, we can examine the relationship between pedaling performance and cortical activation. The device has been tested in stroke (n=19) and control subjects (n=10), all of whom could pedal it after a brief familiarization.

Title: Split-crank pedaling reveals residual lower limb motor capacity after stroke

Authors: *B. CLELAND[1], T. GELTING[2], B. ARAND[3], J. STRUHAR[4], S. SCHINDLER-IVENS[4];
[2]Clin. and Translational Rehabil. Hlth. Sci., [3]Biomed. Engin., [4]Physical Therapy, [1]Marquette Univ., Milwaukee, WI

Abstract: After stroke, compensation is a behavior whereby the non-paretic limb performs tasks normally executed by the paretic limb. For example, during pedaling the non-paretic limb produces the majority of the mechanical work. Compensation occurs because motor output from the paretic limb is abnormal. Compensation allows task performance despite poor motor output from the paretic limb, but also contributes to learned nonuse, which suppresses paretic limb use. Learned non-use is problematic because it prevents increased paretic motor output that may be possible with motor recovery. This study aimed to determine if learned non-use and residual motor capacity are present during pedaling post-stroke. To achieve this aim, we prevented compensation during pedaling with unilateral and split-crank pedaling. We hypothesized that if learned non-use and residual capacity are present, then muscle activity in the paretic limb would increase during unilateral and split-crank pedaling.

Stroke (n=19, 60 ± 10 yrs) and control subjects (n=10, 64 ± 8 years) performed conventional, unilateral, and split-crank pedaling on a custom-designed pedaling device that allows for coupled or decoupled movement of each crank arm. During conventional pedaling, the crank arms were coupled 180° out-of-phase. For unilateral pedaling, the pedals were decoupled, and subjects pedaled with each leg while the other leg relaxed. During split-crank pedaling, the pedals were decoupled and subjects attempted to simultaneously move both limbs 180° out-of-phase. Muscle activity (EMG) was recorded from the tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), and biceps femoris (BF). Velocity and coefficient of variation of velocity (smoothness) were determined.

During conventional pedaling, there were no significant differences in kinematic variables between stroke and control subjects ($p = 0.602$). During unilateral and split-crank pedaling, stroke subjects increased EMG in the paretic TA, MG, and RF ($p \leq 0.001$). However, pedaling smoothness was lower in the paretic limb compared to controls during both conditions ($p < 0.001$). During split-crank pedaling, smoothness was also lower in the non-paretic limb ($p = 0.001$) and velocity was slower in both limbs ($p \leq 0.014$) compared to controls.

Our results suggest that learned non-use and residual motor capacity are present during pedaling post-stroke. Kinematic deficits that emerge when compensation is prevented might reflect remaining impairments of motor output from the paretic limb or the influence of increased demands on interlimb coordination.

Topic: C.09. Brain Injury and Trauma

Title: Inhibitory dysfunction in contralateral motor cortex following pediatric traumatic brain injury

Authors: J. NICHOLS[1,2], J. NEWBERN[2], *T. R. ANDERSON[1];
[1]Univ. of Arizona-College of Med. Phoenix, Phoenix, AZ; [2]Sch. of Life Sci., Arizona State Univ., Phoenix, AZ

Abstract: Traumatic brain injury (TBI) affects over 1 in 5 children by 15 years of age and accounts for almost half a million emergency room visits each year. In children, TBI may be particularly problematic as they have been shown to take longer to recover and have worse outcomes after injury. Previous work from our laboratory has shown that pediatric TBI induces a preferential loss of cortical inhibition near the site of injury. However TBI patients often report symptoms related to dysfunction in brain areas contralateral to the site of injury. The consequence of TBI on the contralateral cortex remains poorly understood and is the focus of this study. To model TBI, we performed a unilateral CCI in juvenile transgenic mice with fluorescently labelled interneurons (VGAT-cre; Ai9). Following CCI we observed an overall 20% loss of GABAergic neuron density in contralateral motor cortex. Specifically, a detailed analysis of neurochemical markers of inhibitory interneurons revealed that CCI induced a 67% loss of parvalbumin (PV) expression with no change in somatostatin (SST). To assess the functional consequences of these changes we performed whole-cell patch clamp of cortical layer V fast-spiking (FS) interneurons. Layer V FS interneurons were chosen as they predominantly express PV and are known to regulate corticospinal output through axosomatic targeted inhibition. Following CCI the frequency of inhibitory synaptic events (sIPSCs) was significantly decreased by 52%. This was accompanied by a significant CCI induced increase in sIPSC charge and decay time. In contrast, the frequency of excitatory synaptic events (sPSCs) onto FS neurons was significantly increased by 55% and exhibited faster decay kinetics in CCI animals. Intrinsic properties including resting membrane potential, input resistance and firing frequency remained intact in FS neurons. These results indicate that inhibition in the contralateral motor cortex is significantly affected by a unilateral CCI in juvenile mice. The ability of TBI to disrupt the contralateral cortex may expand the consequences of brain injury well beyond the initial site of injury. The preferential loss of cortical inhibition may significantly contribute to the pathophysiology of TBI including known alterations in network excitability and disruptions in neurodevelopment.

Title: Measuring recovery of limb symmetry in subacute stroke using a robotic object hit task

Authors: *J. A. SEMRAU[1], S. H. SCOTT[2], S. P. DUKELOW[1];
[1]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada; [2]Queen's Univ., Kingston, ON, Canada

Abstract: Many everyday tasks require the use of both upper limbs. Yet some rehabilitation techniques (constraint-induced movement therapy) promote use of only the more affected limb after stroke. Little attention has focused on the relationship between the limbs throughout recovery. Recent work in our lab has developed a robotic task to evaluate bimanual function after stroke. Here we aimed to characterize the relationship of how combined use of the affected and unaffected arms evolves over the first 6 months of stroke recovery.
One hundred sixty-one subjects with first-time, unilateral stroke were evaluated at four time-points post-stroke (1, 6, 12, and 26 weeks) on a robotic object hitting (OH) task, as well as several clinical measures. For the OH task, subjects viewed both index fingers as paddles and were instructed to hit objects (red balls) away from their body that fell from the top of the screen with both hands. As the task progressed, difficulty increased, with balls falling more frequently and at a faster rate. Elapsed time for the task was approximately 3 minutes.
We found that between 1-week and 6-months post-stroke, subjects improved the average number of total hits they made (1wk: 138.6 ± 43.7 balls, 6mo: 182.8 ± 41.4), the number of hits with the affected arm (1wk: 52.14 ± 26.9, 6wk: 78.7 ± 28.6), as well as hits with the unaffected arm (1wk: 86.5 ± 25.6, 6mo: 104.0 ± 22.2). Further, when we examined the relationship between the affected and unaffected arms for movement speed and movement area throughout recovery, we found consistent increases in limb symmetry over time (R-values: Movement speed: 1wk = 0.53, 6wk = 0.54, 12wk = 0.56, 26wk = 0.65; Movement area: 1wk = 0.46, 6wk = 0.48, 12wk = 0.47, 26wk = 0.58).
Overall, we found that subjects continued to improve the number of objects hit with both the

affected and unaffected arms throughout 6 months of recovery. Further, we found that both speed and area of limb use became increasingly more symmetrical over 6 months of recovery, suggesting that when subjects are given an environment that engages limb interaction, they will utilize both the affected and unaffected limbs, despite impairment of the affected limb. This has important implications for understanding inter-limb coordination throughout stroke recovery.

Title: The inability to compensate for proprioceptive deficits using vision after stroke: a lesion analysis

Authors: *S. E. FINDLATER[1], J. A. SEMRAU[2], J. M. KENZIE[2], A. Y. YU[2], T. M. HERTER[3], S. H. SCOTT[4], S. P. DUKELOW[2];
[1]Clin. Neurosciences, [2]Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of South Carolina, Columbia, SC; [4]Queen's Univ., Kingston, ON, Canada

Abstract: Background: An estimated 50-70% of stroke patients have upper limb proprioceptive impairments. Proprioception is our sense of limb position and movement. Proprioceptive impairments have been associated with incomplete upper limb recovery after stroke. Vision is widely believed to be a viable means of compensating for proprioceptive deficits. However, our group has recently demonstrated that this strategy is only successful in a small number of subjects within the first few weeks post-stroke. The aim of this study is to identify stroke lesions

that impair the ability to compensate for proprioceptive deficits using vision.
Methods: Proprioceptive deficits were quantified using a KINARM robotic exoskeleton. To assess position sense, the exoskeleton moved the subject's stroke-affected arm to one of nine spatial locations. The subject moved their unaffected arm to mirror-match that location. Subjects matched each location in a pseudo-randomized order over 6 blocks for a total of 54 trials. This task was run twice – first with a screen preventing vision of the arms and then with full view of the arms.
All subjects received anatomical neuroimaging. Lesions were marked by trained researchers, verified by a stroke neurologist, and normalized to MNI-space using SPM8. Lesion volume analysis and subtraction analysis was completed using MRIcron.
Results: One-hundred and seventy-two subjects with ischemic stroke were tested within two weeks of stroke onset. Fifty-eight percent of these subjects had right hemisphere damage and demonstrated a higher incidence (74%) of proprioceptive deficits in the no-vision task compared to those with left hemisphere damage (35%). Lesion volume was significantly greater ($p = 0.07$) in subjects who were unable to compensate for proprioceptive deficits using vision (mean 49ml ± 58) compared to those who were able to compensate (26ml ± 45) or those who didn't have deficits (10ml ± 15). Subjects unable to compensate using vision more frequently sustained damage to the occipital, parietal and sensorimotor cortices.
Seventy-nine subjects completed a follow-up assessment at 6 months post stroke. Twenty-nine of these subjects were unable to compensate with vision at the first timepoint. Of these subjects, twenty-two remained unable to compensate with vision 6 months after their stroke.
Conclusions: A significant proportion of stroke subjects are unable to compensate for proprioceptive deficits using vision. Preliminary analysis indicates that lesion hemisphere, volume and stroke location may be important considerations. These findings may provide prognostic information and guidance to rehabilitation practitioners.

Abstract: Introduction: Many objective assessments have used to measure the motor function in stroke patients. However, there was a lack of studies for the appropriate assessments to represent the current motor function or to predict the motor function in stroke patients. In this study, we aimed to investigate the optimal objective assessments at subacute phase to predict the motor function in stroke patients. **Methods:** Sixty-one subacute stroke patients (mean age 59.7 yrs) were recruited in this study. At 2 weeks after stroke onset, all patients took three different assessments; anatomical T1-weighted MRI to measure the stroke lesion volume, diffusion tensor imaging (DTI) to measure the preservation of anatomical corticospinal tract (CST), and transcranial magnetic stimulation (TMS)-induced motor evoked potentials (MEPs) to measure the preservation of functional CST. The upper limb scores of Fugl-Meyer assessment (FMA-UL) were measured at 2 weeks and 3 months after stroke onset. Multiple regression analysis was performed to determine the significantly independent assessments for motor function at 2 weeks and 3 months after stroke. **Results:** FMA-UL at 2 weeks and 3 months after stroke showed the significant relationship with stroke lesion volume, the preservation of functional and anatomical CST, respectively ($p<0.05$). The preservation of functional CST and the stroke lesion volume showed the significantly independent variables with motor function at 2 weeks after stroke. However, the preservation of functional and anatomical CST showed the significantly independent variables to predict motor function at 3 months after stroke. **Conclusion:** These results suggest both DTI and TMS-induced MEPs at subacute stage could be used to predict the upper extremity motor function at 3 months after stroke. In addition, the preservation of corticospinal tract at subacute stage may reveal the potentials of motor recovery in stroke patients (Supported by the NRF grant funded by the Korea government (MSIP) (NRF-2014R1A2A1A01005128)).

Title: Motor unit discharge characteristics differ among proximal and distal muscles of the upper limb in healthy and post-stroke individuals

Authors: *L. M. MCPHERSON[1], F. NEGRO[2], C. K. THOMPSON[3], D. FARINA[2], C. HECKMAN[4], J. DEWALD[4];
[1]Florida Intl. Univ., Miami, FL; [2]Univ. Med. Ctr. Gottingen, Gottingen, Germany; [3]Temple Univ., Philadelphia, PA; [4]Northwestern Univ., Chicago, IL

Abstract: Proximal and distal arm muscles serve different roles during functional tasks. Proximal muscles are typically used for postural control, and distal muscles are typically used for fine motor control. Differences in neural control of the muscles likely exist, and analysis of motor unit (MU) discharge can help elucidate them. It has not been feasible to efficiently measure MU discharge in multiple muscles until recently. High-density surface EMG is a novel approach for extracting MU discharge that provides improved efficiency and automation. Using this approach in healthy controls (N=8) and those with chronic hemiparetic stroke (N=12, moderate-to-severe impairment), we examined MU discharge characteristics (discharge rate, rate modulation) in proximal and distal arm muscles. The tested arm was placed in an isometric apparatus to measure shoulder, elbow, and finger joint torques. 64-channel EMG grids were placed on the surface of deltoid (DELT), biceps (BIC), and finger flexors (FF). Separate isometric contractions of shoulder abduction, elbow flexion, and finger flexion were performed at efforts ranging from 10 - 40% maximum torque. EMG data were decomposed into MU spike trains. Mean MU discharge rate (MDR) was calculated and compared against torque to estimate rate modulation. Differences in MU behavior were found among DELT, BIC, and FF, and the relationships between the muscles changes post-stroke. Overall MDR values were similar across muscles in controls (DELT: 13.7, BIC: 13.9, FF: 13.4 pps) but decreased from proximal to distal post-stroke (DELT: 11.4, BIC: 10.7, FF: 8.5 pps). Differences in rate modulation were also observed between groups. In controls, rate modulation increased from proximal to distal (DELT: 7.2, BIC: 16.1, FF 19.7 pps/%MVT). In stroke, however, rate modulation decreased from proximal to distal, and it was absent in finger flexors (DELT: 6.7, BIC: 4.0, FF: -0.4 pps/%MVT). Differences in rate modulation across muscles and groups may be due to differences in the balance of excitatory and inhibitory synaptic input, which significantly impacts rate modulation (Powers et al, 2012). Findings underscore the need to record from multiple muscles when using MU analysis to examine neural organization to the upper limb.

Title: Real time biofeedback training improves gait and plantar pressure distribution following 8 weeks of gait training in post stroke individuals.

Authors: *J. GONZALEZ PLAZOLA[1], I.-H. KHOO[2], P. MARAYONG[3], K. DEMARS[4], V. KRISHNAN[4];
[2]Dept. of Electrical Engin., [3]Dept. of Mechanical and Aerospace Engin., [4]Dept. of Physical Therapy, [1]California State Univ. Long Beach, Long Beach, CA

Abstract: Introduction: Asymmetry in a person's gait is a predominate factor when hemiparesis is present. The effects of asymmetrical walking patterns can be associated with irregularities in plantar pressure in the affected limb. Many commercial devices can evaluate the gait parameters relating to gait; however, using our biofeedback device, Walk-Even, a person's gait asymmetry can be both evaluated and corrected in real-time.
Methods: A total of 11 subjects, 6 males and 5 females, with chronic stroke participated in an 8-week intervention study. Six subjects were in the experimental group and the other five participants were in the control group. Both groups received strength and gait training for 40 minutes, two times per week for a total of 8-weeks. For the gait training, the experimental group was given auditory biofeedback to increase their stance time on their affected side, while the control group underwent a traditional gait training with verbal or visual cues. The subjects' average velocity, time taken to shift from heel to toe, average heel pressure, average metatarsal pressure, center of pressure (COP) trajectory, and stance and swing percentage was collected using the F-Scan device. The participants were tested before and after the intervention.
Results: Univariate ANOVA did not show any interaction, or main effect between the groups (experimental and control) and time (pre- and post-intervention) in the following variables even though the results showed a positive trend in the experimental group when compared to the control group in: COP trajectory, average velocity, average heel, average force, stance and swing percentage. Time taken to shift from heel to toe, maximal metatarsal pressure and stride time showed a significant interaction ($p<0.05$) and time effect ($p<0.05$). In addition, average metatarsal showed a significant interaction ($p<0.05$). The interaction effect in the above parameters of gait confirmed that both groups improved after 8 weeks, but the improvement was greater in the experimental group. In particular, the experimental group placed more weight onto

the forefoot during walking and also the speed of transfer was much faster than the control group.
Conclusion: This study suggests that gait training with real-time feedback using Walk-Even might reduce asymmetry while walking and increase weight-bearing on the affected side in chronic stroke survivors.

Title: Deficits of coordination, sensation, and strength predict motor dysfunction after stroke

Authors: *L. A. MROTEK[1,2], M. C. BENGTSON[2], T. STOECKMANN[3], C. P. GHEZ[4], J. MCGUIRE[5], R. A. SCHEIDT[2,6];
[1]Dept Kinesiology, UW-Oshkosh, Oshkosh, WI; [2]Biomed. Engin., [3]Physical Therapy, Marquette Univ., Milwaukee, WI; [4]Neurosci., Columbia Univ., New York, NY; [5]Neurosci., Med. Col. of Wisconsin, Milwaukee, WI; [6]Physical Med. and Rehabil., Northwestern Univ., Evanston, IL

Abstract: An unresolved question in the field of neurorehabilitation is how deficits of motor coordination, sensation, strength, and cognition impact activities of daily living after stroke. We investigated the extent to which these deficits can predict motor function.
Fourteen stroke survivors (>6 mo. post-stroke, 34-70 yr, 5 F) consented to participate; all were able to follow 2-step instructions. Subjects completed 2 lab-based experiments and a battery of clinical tests. In the 1st lab experiment, they sat comfortably with the more affected arm secured to a load cell measuring elbow flexion-extension torque. Maximal voluntary torque generation was determined. Subjects then tracked step changes in elbow torque using visual and auditory cues. In each 60 s trial, participants alternated between relaxing and creating torque (flexion or extension) at a moderate level (20% of maximal torque). From these data we computed several measures of motor control: reaction time, peak rate of torque change, torque change jerk, torque target acquisition error and torque target hold variability.
The 2nd laboratory experiment was a robotic test of proprioceptive acuity that determined the participant's threshold of movement detection. Participants grasped the handle of a 2D robotic

arm as it applied force perturbations ranging from 0 to 4 N in magnitude. Perturbation magnitude was adjusted until subjects could just begin to feel movement. This test estimates the likelihood that proprioception is intact based on the mean and variability of multiple movement detection estimations.
A licensed physical therapist administered tests of motor coordination [upper extremity Fugl-Myer motor (FMm)], sensation [upper extremity Fugl-Myer sensory (FMs)], muscle tone in the wrist, elbow, and shoulder [Modified Ashworth scale (MAS)], cognitive function [Montreal Cognitive Assessment (MoCA)], and sensorimotor function [13-item Chedoke Arm and Hand Activity Inventory (CAHAI)]. We used multilinear forward regression to determine the extent to which deficits of motor control/coordination, sensation, and cognition predict motor function, as quantified by CAHAI.
Regression found that 96% of the variance of CAHAI scores was predicted by 4 variables: the FM test (motor component), 78%; elbow proprioception [FM test (sensory component)], 8%; peak torque rate, 8%; and maximum elbow torque, 2%. These data indicate that coordination, sensation, and strength are all highly important for performing functional motor tasks and activities of daily living. Of these, coordination and sensation training may be the most impactful targets for therapeutic intervention.

Title: Characterising post-stroke cortical plasticity in humans

Authors: *M. C. RIDDING[1], B. HORDACRE[1], M. N. MCDONNELL[3], S. A. KOBLAR[2], T. J. KLEINIG[4], N. S. WARD[5], J. C. ROTHWELL[5];

Research, Sch. of Hea, Univ. of South Australia, Adelaide, Australia; [4]Dept. of Neurol., Royal Adelaide Hosp., Adelaide, Australia; [5]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Background: Animal models provide evidence of enhanced cortical plasticity after ischaemic stroke. Evidence for such a change in plasticity following stroke in humans is limited. The aim of this project was to examine the timeline of changes in cortical plasticity in patients following ischaemic stroke using non-invasive neurophysiological techniques.
Methodology: Patients were recruited following a first ever ischaemic stroke with motor involvement. Experimental sessions were performed at 7 days, 14 days, 21 days, 1 month, 3 months, and 6 months post stroke. A comparator group of healthy adults were tested three times over 12 months. At each session, functional recovery was assessed with the Action Research Arm Test (ARAT) and Functional Independence Measure (FIM). Transcranial Magnetic Stimulation (TMS) was applied to the lesioned M1 (stroke patients) or left M1 (control). Paired trains of continuous theta burst stimulation (cTBS) were used to induce a plastic response which was measured using single pulse TMS at baseline and at 4 time points following the second train of cTBS (5mins, 15mins, 30mins, 45mins).
Results: Thirteen stroke patients (8 male) aged 71.6 ± 16.5 and 16 healthy adults (10 male) aged 67.1 ± 6.3 years were recruited. There was a significant decrease in MEP amplitude following cTBS ($p=0.05$) in healthy control subjects that did not change between the 3 testing sessions. There was no significant response to cTBS (ANOVA, $p>0.05$) and no difference in the cTBS response over the 6 sessions (ANOVA, $p>0.14$) in the stroke patients. Using the 1-month post stroke ARAT score patients were then categorised into "excellent recovery" (n=7 (57/57 on ARAT) or "suboptimal recovery" (n=9, mean ARAT 35.2 (range 0-55)). There was a significant difference in cTBS response between testing sessions for the excellent recovery group, with a significant cTBS response at the 3-week time-point. There was no significant difference in cTBS response between sessions for the suboptimal recovery group and no significant response to cTBS on any testing occasion.
Conclusion: These results suggest that the cTBS induced plasticity response is reduced in stroke patients when compared to healthy aged matched controls. However, in contrast to the suboptimal recovery group, patients with excellent recovery at 1-month after stroke had a significant response to cTBS at 3 weeks post stroke. These preliminary data suggest greater plasticity is present in the acute phase following ischaemic stroke in patients who recover well. This novel human data is essential to understand when rehabilitation or regenerative medical therapies may best be administered to post-stroke patients.

Title: Relation of cortico-muscular coherence and finger motor performance following stroke

Authors: *L. H. LARSEN[1], I. C. ZIBRANDTSEN[2], T. W. KJAER[2], M. S. CHRISTENSEN[1], H. LANGBERG[1], J. B. NIELSEN[1], T. WIENECKE[2];
[1]Univ. of Copenhagen, Copenhagen N, Denmark; [2]Zealand Univ. Hosp., Roskilde, Denmark

Abstract: *Objective:* Stroke is the most common cause of physical disability in the world today. It is widely assumed that damage of the motor cortex or corticospinal tract is a major cause of impaired motor function. The role of adaptations in the corticospinal drive for motor recovery is still not well understood.
Methods: Here we examined 16 patients (mean age 62 years, range 32-87 years) with clinically diagnosed stroke. The patients had unilateral mild to moderate motor impairment of the hand (8 dominant hand affected). Each patient attended two sessions at approximately 5 and 38 days post stroke. In both sessions electrophysiological recordings were obtained during three blocks of 50 precision pinch movements using the affected hand. Data recorded during movements included electroencephalographic (EEG) activity from the contralateral primary motor cortex (M1) and electromyographic (EMG) activity from first dorsal interosseous (FDI) and abductor pollicis brevis (APB) muscles in the affected hand. Changes in the corticospinal drive were evaluated from coupling in the frequency domain (coherence) between EEG and EMG.
Results: Preliminary results suggest that EEG_{M1}- EMG_{APB} coherence increases significantly in the beta band (15-30 Hz) within the first 38 days following stroke. EEG_{M1}- EMG_{FDI} coherence did not change significantly within the same period. However, the most distinct individual change in coherence was directly correlated to follow-up performance (Figure) ($p<0.01$). These results should be interpreted with caution as currently only 11 patients have been through follow-up examinations.
Conclusions: Finger motor performance 5 weeks post stroke is correlated with improvement in coherence. We propose that the changes in coherence reflect plastic changes in the corticospinal drive to the spinal motor neurons related to optimization of task performance. Individual task strategies may explain why EEG_{M1}- EMG_{FDI} coherence was not improved after 5 weeks. We

speculate that changes in the corticospinal drive may be an important part of the mechanism of motor recovery after stroke.

Title: A tablet-based tool for accurate measurement of hand proprioception after stroke

Authors: ***H. J. BLOCK**[1,2], J. L. MIRDAMADI[1], S. RYCKMAN[1], A. K. LYNCH[1], R. WILSON[1], D. UDAYAN[3], C. L. MASSIE[4];

Abstract: Position sense, or proprioception, plays an important role in motor control, motor learning, and functional activities. Proprioceptive deficits following stroke have been linked to motor control impairment and recovery, although the nature of this relationship is unclear. Our understanding is in part limited by the fact that current methods of measuring proprioception in the clinical setting are subjective, imprecise, and unreliable. We recently developed a portable tablet-based apparatus to measure static proprioception in the hand using an adaptive staircase procedure. In healthy individuals, the tool demonstrated better construct validity and inter-rater and test-retest reliability compared to two common clinical tests: passive motion direction discrimination (PMDD) and position matching. An additional advantage of this method is that it assesses both proprioceptive bias and sensitivity, which may provide additional insight into the nature of proprioception deficits in clinical populations. Here, we evaluate the effectiveness of the tablet-based tool in chronic ischemic stroke survivors. We quantified proprioception at the metacarpophalangeal joint of the index finger of each hand using three methods: the tablet, PMDD, and the proprioception subsection of the Fugl-Meyer (FM). To investigate how these proprioception measures relate to tests of other sensory modalities and motor function, we also assessed primary tactile sensation (light touch, two-point discrimination), upper limb motor impairment (Fugl-Meyer Upper Extremity) and hand dexterity (Box and Block Test). We hypothesized that the tablet would better discriminate proprioception differences between the affected and unaffected hand, and that it would be more strongly correlated with hand dexterity compared to PMDD and FM. 3 chronic stroke survivors have been tested to date, all with an MRC score of 4 or 5 in the affected hand and FM Upper Extremity scores of 51, 55, and 62, indicating mild motor impairment. All had indications of impaired tactile sensation, with worse two-point discrimination on the affected side. The tablet-based tool indicated greater proprioceptive bias (n=3) and worse sensitivity (n=2) in the affected hand compared to the unaffected hand. In contrast, PMDD did not indicate any consistent pattern, and both hands scored as unimpaired in the FM test of proprioception. Overall, these preliminary data suggest that the tablet-based tool is better able to detect subtle differences in proprioception than current clinical methods.

Title: Alterations in spatial electromyogram patterns of hand muscles in hemiparetic stroke survivors

Authors: *G. RASOOL, B. AFSHARIPOUR, N. L. SURESH, W. Z. RYMER;
Rehabil. Inst. of Chicago, Chicago, IL

Abstract: We investigated high-density electromyogram (EMG) patterns recorded from the first dorsal interosseous (FDI) of hemiparetic stroke survivors. We analyzed spatial EMG patterns, i.e., muscle activity maps by comparing stroke-affected and intact muscles in the contralateral hands. We hypothesized that alteration in the neuromuscular system resulting from the stroke would be evident in muscle activity maps and an analysis of these maps in spatial domain will provide us greater insight into the nature of post-stroke alterations.We recorded 64-channel (8x8) EMG data from both FDI muscles (left/right) of a mildly impaired hemiplegic chronic stroke survivor (age 59 years, Fugl-Meyer 52) and an intact subject. We also recorded isometric contraction force using a force transducer. After performing the maximum voluntarily contraction (MVC) on each side, we recorded the EMG data at different contraction levels, i.e., 5%, 10%, 20% to 60% of the MVC. The raw EMG data were bandpass filtered 20-400 Hz and root mean square (RMS) values were calculated for each channel resulting in RMS maps (8x8) for each contraction level. We compared RMS maps from opposite hands using two parameters, i.e., the Euclidean distance and the Pearson product-moment correlation.We observed greater Euclidean distance and less correlation between muscle activity maps of the stroke survivor (impaired vs. intact) as compared to the intact participant. Our statistical analysis performed using the analysis of variance revealed significant differences for the Euclidean distance $F(1,24) = 8.39$, $p=0.008$ as well as for the correlation $F(1,24) = 33.58$, $p<.001$.We found differences (quantified using the Euclidean distance and correlation) between muscle activity maps at all contraction levels for the stroke survivor. However, no such differences were observed in the intact participant.We believe that the altered neural control after brain injury and potentially later neuroplasticity resulted in substantial changes in the neural control strategy, i.e., changes in the motor unit recruitment as well as firing rates. Furthermore, the local soft tissue may also have changed substantially after the injury. The combined effect of these alterations led to the altered spatial muscle activity patterns. In future, we plan to collect data from a larger group of stroke survivors as well as intact participants. We also plan to perform textural analysis on these maps to find how individual EMG channels are changed in relation to their neighbors after the injury.

Title: An algorithm to predict recovery of independent ambulation after stroke

Authors: *M.-C. SMITH[1], J. W. STINEAR[2], P. A. BARBER[1], C. M. STINEAR[1];
[1]Dept. of Med., [2]Dept. of Exercise Sci., Univ. of Auckland, Auckland, New Zealand

Abstract: Predicting the recovery of independent ambulation after stroke may help guide expectations for recovery and assist in realistic goal setting. The prediction of gait recovery has been limited to predicting whole group outcomes, or multivariable regression analyses which aim to explain the variance in recovery after stroke, but do not provide a means for predicting recovery in individual patients in a clinical setting. This study investigated a combination of clinical, neurophysiological and imaging assessments within 1 week of stroke as potential predictors for independent mobility at 12 weeks. The aim was to create an algorithm to predict which patients will recover independent ambulation. An initial cohort of 35 patients with lower limb weakness was recruited within 3 to 7 days of ischaemic or haemorrhagic stroke (16 men, mean age 70 years, 19 right hemisphere). Baseline clinical assessments were conducted at 3 days and 1 week after stroke. These included stroke severity, strength, lower limb impairment, trunk control, balance and current ambulation. In addition to clinical measures, transcranial magnetic stimulation (TMS) was used between days 5 - 7 to assess the functional integrity of the corticospinal tract (CST) by attempting to elicit a motor-evoked potential (MEP) in the affected tibialis anterior muscle. Magnetic Resonance Imaging (MRI) was conducted at 7-10 days after stroke to assess structural integrity of the CST. The primary endpoint was independent mobility at 12 weeks, defined as a Functional Ambulation Categories (FAC) score of 4 or 5. At 1 week after stroke, 16 patients had an FAC score of 0 (unable to mobilise or requiring at least 2 people to assist), 10 required assistance or supervision to mobilise (FAC 1,2,3) and 7 had already regained independent mobility (FAC 4,5). At 12 weeks, 23 were mobilising independently, 4 required assistance and 2 were unable to mobilise. Six patients were lost to follow up due to death or illness. Preliminary data analysis indicates that an algorithm based on clinical assessments alone at 1 week after stroke may predict which patients will or will not recover independent ambulation. This differs from previous work in the upper limb in which a combination of clinical assessment, TMS and MRI is recommended. A second cohort of 18 patients (8 men, mean age 70 years, 9 right hemisphere) was recruited to test the proposed algorithm. Patients in the second cohort are currently completing primary endpoint assessments.

The findings from this study are expected to provide evidence for the use of a simple, clinically useful algorithm for predicting which patients will recover independent ambulation after stroke.

Title: PREP2: A refined algorithm for Predicting REcovery Potential of upper limb function after stroke

Authors: ***C. M. STINEAR**, W. D. BYBLOW, M.-C. SMITH, S. J. ACKERLEY, P. A. BARBER;
Univ. of Auckland, Auckland, New Zealand

Abstract: Independence after stroke depends largely on the recovery of motor function. Accurate prediction of motor recovery may help clinicians and patients manage expectations, set realistic rehabilitation goals, and use their resources efficiently. However, accurate prediction is difficult for individual patients. We have previously described an algorithm for predicting potential for recovery of upper limb function for individual patients after stroke. The Predicting REcovery Potential (PREP) algorithm begins with a simple assessment of paretic shoulder abduction and finger extension strength (SAFE score out of 10), followed by transcranial magnetic stimulation (TMS), and magnetic resonance imaging (MRI), as required. Patients are predicted to have potential for a Complete, Notable, Limited or None recovery of upper limb function within 12 weeks. The PREP algorithm was developed with a dataset from 40 patients with first-ever ischaemic stroke. The aim of this study was to evaluate and refine the algorithm with a larger, more heterogeneous cohort. Inclusion criteria were confirmed stroke (ischaemic or haemorrhagic), new upper limb motor symptoms, and age at least 18 years. Previous stroke, thrombolysis and thrombectomy were allowed. Exclusion criteria were cerebellar stroke, contraindications to TMS and MRI for those patients who required these tests, reduced capacity for consent, and residing out of region precluding follow-up. The PREP algorithm was used to predict recovery of upper limb function for each patient. The Action Research Arm Test was used to measure paretic upper limb function 12 weeks post-stroke. A sample of 192 patients was recruited within 3 days of stroke (106 men, mean age 72 y, 100 right hemisphere), and 157

patients completed the 12 week assessment. The algorithm made correct predictions for 80% of patients. Of those with a Complete prognosis, 26% under-achieved and were in the Notable category at 12 weeks. Of the patients with a Notable prognosis, 42% over-achieved and were in the Complete category at 12 weeks. Using this information the algorithm was then refined by combining the SAFE score with age (<80, ≥80 years) to more accurately distinguish between patients with a Complete or Notable prognosis (88% accuracy). With the revised algorithm, only patients with a SAFE score < 5 now require TMS, reducing the proportion of patients who need this test from over half, to around one third. The revised algorithm is therefore more accurate and more efficient. The implementation of the PREP algorithm in clinical practice is described, with its potential clinical and economic benefits.

Title: Somatotopic motor mapping in the internal capsule and its implication to capsular infarct modelling in rat

Authors: H. SONG[1], W. JEONG[1], E. LEE[1], R. KIM[1], J.-Y. PARK[1], M.-C. LEE[2], *H.-I. KIM[3]; [1]Dept. of Biomed. Sci. and Engineering, Inst. of Integrated Technol., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of; [2]Dept. of Pathology, Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of; [3]GIST, Gwangju, Korea, Republic of

Abstract: The essence in creating the motor deficit-stroke model is to destroy the part of corticospinal tract along its pathway at the target level. For creating the capsular infarct modelling, somatotopic motor mapping (SMM) of corticospinal tract is critical in the internal

capsule. In contrast to human studies, there is a lack of SMM in rodent, which leads to the absence of unanimous target for capsular infarct lesioning. In this study, we tried to define the somatotopic location of forelimb and hind limb motor tract in the internal capsule, and we compared them with the previously published targets, to provide the better stereotactic coordinates in creating capsular infarct modelling. Twenty-nine male Sprague Dawley rats were used for this study. We used the neural tracing for SMM of forelimb and hind limb in the internal capsule. We co-injected (1μl/10min) AAV-CamKII-GFP (forelimb area) and AAV-CamKII-mCherry (hind limb area) at a titer of $2x10^{12}$ (N=9). After 3 weeks of viral expressions, rats were sacrificed for histological examinations. In addition, 20 rats were subject to capsular infarct lesioning according to previously published target: 10 for lesioning in antero-inferior target (AIG) and 10 for postero-middle target (PMG) in internal capsule. Daily behavioral tests (Single Pellet Reaching Task, Beam Walking Test, Cylinder Test and Ladder Rung Walking Test) were performed preoperatively and postoperatively to determine the motor deficit following infarct lesioning. Neural tracing showed that forelimb motor tract (FMT) was traced obliquely along the axis of corticospinal tract whereas hind limb motor tract (HMT) were traced more vertically since the forelimb area is located anterior to hind limb in the motor cortex. In the internal capsule, FMT was arranged in the ventromedial portion of the internal capsule whereas HMT in ventrolateral part of internal capsule, and superior to FMT. The overlapping of FMT and HMP were observed at the junctional area and increased more in the posterior part of internal capsule. However, area of overlapping was less than 30% in anterior part and 50 % in posterior part, respectively. AIG exhibited the severe degree of motor deficits immediately following infarct lesioning, and the motor deficits were maintained up to 14 days of observation ($p<0.001$). In contrast, motor performances were not significantly changed in PMG following infarct lesioning. In conclusion, FMT and HMT are arranged in ventromedial and ventrolateral part of internal capsule, respectively and FMT was located inferior to HMT. Accordingly, infarct lesioning in these areas is considered to be ideal target for capsular infarct modelling.

Title: Continuous multi-joint myoelectric control of an upper-limb robotic exoskeleton in stroke patients

Authors: *N. IRASTORZA LANDA[1,2], A. SARASOLA SANZ[1], F. SHIMAN[1], E. LÓPEZ LARRAZ[1], M. SPÜLER[3], N. BIRBAUMER[1], A. RAMOS MURGUIALDAY[1,4];

Abstract: In recent years there has been an increasing progress in the development of upper-limb multi-joint robotic exoskeletons for motor rehabilitation designed for the training of functional arm and hand combined movements. Myoelectric control constitutes an intuitive interface for such robot-aided motor rehabilitation therapies for patients with motor impairment such as stroke. Recent research succeeded at classifying residual muscle activity of stroke patients during upper-limb discrete movements suggesting that electromyographic (EMG) signals can be a promising source for the control of rehabilitation robots in these patients. The myoelectric control of robotic exoskeletons based on the classification of residual EMG can serve to provide proprioceptive feedback to the patients based on the inferred motor intention. The development of robust pattern recognition algorithms based on EMG activity from stroke patients for simultaneous multi-joint movements and suitable training protocols for this purpose are nevertheless still challenging. Unfortunately, most of the current classification systems are limited to control a single degree of freedom (DoF) at a time, which does not allow multidimensional control of a multi-DoF rehabilitation robot for carrying out simultaneous multi-joint functional movements. In this study six healthy participants (age 20-28, right-handed) and two stroke patients underwent EMG recordings from the right and affected upper- and fore-arm muscles, respectively. They performed reaching movements in different directions combined with supination and finger extension while wearing the ISMORE 7-DoF robotic exoskeleton (Tecnalia, San Sebastian, Spain). We analyzed the EMG data and tested offline a novel pattern recognition strategy towards an online myoelectric control of the exoskeleton based on parallel working feed-forward artificial neural networks (FF-ANN) for the classification of functional combined arm and hand movements. The classifiers were fed with time-domain features extracted from the EMG signals and trained with a backpropagation algorithm. Average offline

classification results using FF-ANN for the discrimination of reaching movements in different directions and six different hand movements in healthy subjects resulted in accuracies above 66%. This classification strategy is proposed and tested offline as the decoding method for the continuous myoelectric control of a multi-DoF robotic exoskeleton. Moreover, we carried out a pilot experiment with one stroke patient using the proposed method for an online myoelectric control of the multi-DOF exoskeleton in a realistic rehabilitation scenario.

Title: Robotic assessment of modified constraint induced movement therapy in cynomologus macaques following middle cerebral artery occlusion

Authors: ***M. C. POOLE**[1], J. Y. NASHED[1], J. LECLERC[1], D. J. COOK[1,2];
[1]Ctr. for Neurosci. Studies, [2]Dept. of Surgery, Div. of Neurosurg., Queen's Univ., Kingston, ON, Canada

Abstract: Constraint induced movement therapy (CIMT) has emerged as a potential rehabilitation therapy for stroke. However, its efficacy at inducing recovery is unclear due to stroke heterogeneity in humans and the use of subjective neurological outcomes. Recently, studies have demonstrated the success of non-human primate (NHP) models of stroke. Findings in a NHP stroke model have the potential to translate effectively to human clinical trials because the sample population is more controlled. Additionally, robotic assessment can provide objective determination of motor deficits and recovery. The purpose of this study was to use robotics to assess the effect of modified CIMT on stroke recovery in NHPs following middle cerebral artery occlusion (MCAO).
Stroke was induced in two cynomologus macaques by 90-minute MCAO. Associated upper limb deficits were quantified using a bilateral KINARM^{TM} exoskeleton robot to measure hand, shoulder and elbow movements in the horizontal plane as sensorimotor tasks were performed. In the perturbation posture task, the NHP must keep their hand at a central target and counter mechanical loads that are applied in varying directions to quantify proprioceptive feedback for motor actions. In the centre-out reaching task, the NHP stabilizes their hand within a central target and after an unpredictable time one of eight peripheral targets lights up which the animal

must reach to. This task quantifies control mechanisms and determines range of motion.
At 2.5 years post-stroke the two MCAO and two control NHPs were trained to saturation on the tasks described above and baseline data was collected for 30 days. We noted that MCAO NHPs used compensation strategies to accomplish tasks in the paretic arm by using the unaffected limb. Modified CIMT was then employed for 30 days by restricting movement of the unaffected arm so that it could not interfere with affected arm movements. Initially, MCAO NHPs were unable to complete tasks with the affected arm but began to overcome their maladaptive learnt non-use to make successful movements without assistance from the other limb resulting in a 31.10% increase in good trials over the intervention course. CIMT lead to a 43.02% decrease in initial direction error in one MCAO NHP and a 75.40% decrease in trial competition time in the other, suggesting improvements in range of motion and efficiency of motor behaviour, respectively. These results quantify the reversal of maladaptive compensation strategies following CIMT and suggest that robotic technology can be used to assess and implement rehabilitation strategies in a NHP model of chronic stroke.

Title: Lateral balance control after stroke: A comparison of voluntary and perturbation induced stepping reactions

Authors: *V. L. GRAY, C.-L. YANG, A. OBAH, S. MCCOMBE WALLER, M. W. ROGERS; Univ. of Maryland, Baltimore, MD

Abstract: Balance stability and recovery in persons post-stroke are compromised by limitations in limb motor control which adversely affect protective stepping. After stroke, a significant number of falls occur when weight is transferred laterally with an equal and likely number of

falls from either external factors such as slips, trips and pushes to instances during voluntary movements. Therefore, understanding stepping strategies is important for reducing falls. The purpose of this study was to compare the performance of lateral voluntary steps and reactive stepping in response to lateral waist-pull perturbations in people with chronic stroke and healthy controls. Five subjects >6 months post-stroke and 5 healthy controls (age and gender matched) participated in the study. Subjects performed 6 randomly ordered lateral external waist pull perturbations trials (2 directions x 3 repetitions), and 10 choice reaction voluntary lateral steps (2 directions x 5 repetitions) in response to a light cue. Stepping characteristics were determined from an ankle marker using 3D motion analysis. The first step characteristics including step onset time, global step length, and step height were compared between stroke (paretic, non-paretic) and controls (left, right) & voluntary and reactive steps. The perturbation-induced reactive steps did not differ for the paretic (521ms) and non-paretic leg (556ms); yet, the onset times were earlier than the voluntary steps (paretic 1000ms; non-paretic 905ms). In contrast, the voluntary steps for controls had an earlier step onset (left 420ms; right 380ms) relative to the reactive steps (left 486ms; right 488ms). The reactive steps showed an increased global step length of the paretic, 54% and non-paretic leg, 21% over voluntary trials. The voluntary trials resulted in a similar global step length of the paretic and non-paretic leg, although, it was reduced by 31% compared to controls. The step height of the non-paretic limb was similar to controls, however the paretic limb step height was increased for the voluntary (25%) and reactive (29%) steps compared to controls. Compared with healthy controls, voluntary step initiation after stroke was characterized by reduced step length and longer step initiation time, suggesting difficulties with lateral balance stability. It was evident that the capacity for initiating a quicker and longer step was indicated during perturbation-induced reactive stepping. The present results can be used to lead therapeutic approaches for improving lateral balance stability through protective stepping following stroke.

Title: Exploring functional outcomes and cortical plasticity following middle cerebral artery occlusion in a Non-Human Primate

Authors: *J. Y. NASHED, J. GALLIVAN, D. J. COOK, J. LECLERC;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Stroke is a leading cause of death and disability worldwide. There is a high degree of variability in the recovery of stroke survivors. The reasons for the disparate recovery amongst similar patients are unclear. We hypothesize that preservation of cortical areas that support functional remapping after stroke may enhance recovery. One possibility is that the preservation of local cortical areas may mediate improved functional recovery via remapping. An alternative hypothesis is that long-range compensatory connections form and mediate recovery. Here we investigate the cortical re-organization of a translatable monkey model of stroke. To examine cortical re-organization we utilized a non-human primate model of stroke. Fourteen cynomolgus macaques underwent transient 90-minute MCAO. Perfusion, Diffusion and T2-MRI images were obtained following MCAO occlusion and at 48h and 30d. Total stroke volume and regional stroke volumes were quantified in 180 regionsof the brain. Neurobehavioural outcomes were evaluated using the Non-Human Primate Stroke Scale (NHPSS). Animals were dichotomized into good (NHPSS<9, n=7) and poor recovery (NHPSS≥9, n=7) by 30d NHPSS score. Comparisons between the good and poor recovery groups showed no difference in penumbra (PWI-DWI) and stroke core volume at baseline and no difference in total stroke volume at 48h ($P>0.05$), but differences were observed at 30 days ($P<0.05$). Functional connectivity maps were generated 30 days post-stroke. Interestingly, the poor group had stronger inter- and intra-hemispheric functional connectivity as compared to the good group. This suggests that the degree of remapping in the cortex following stroke maybe dependent on the amount of salvageable tissue in the ipsilesional cortex and penumbra.

Title: The effects of reactive and voluntary step training on balance recovery during lateral perturbations in individuals with chronic stroke

Authors: *C.-L. YANG, S. MCCOMBE WALLER, M. W. ROGERS, V. GRAY;
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Background: Falls are reported as high as 73% within the first 6 months after stroke. Many falls happen while transferring weight laterally. A protective stepping strategy is commonly used to recover balance during external challenges to balance control. However, current rehabilitation practices mainly focus on intentional voluntary actions to improve balance control.
Objective: The purpose of this study was to determine the effects of perturbation-induced reactive (RST) and voluntary step training (VST) on balance recovery during lateral perturbations in individuals with chronic stroke.
Methods: Twelve community dwelling individuals >6 months post-stroke were recruited. Subjects were randomized to RST or VST group. All subjects attended a 60 minute session, 3 times per week, for 6 weeks. For RST, a motorized treadmill (the Active Step™) was used to perturb standing balance in lateral, forward, and backward directions. For VST, voluntary stepping including lateral, crossover, forward, and backward steps were practiced during each training session. The primary outcome measure was the stepping performance following lateral waist-pull perturbations (24 randomly applied trials: 2 directions × 3 repetitions × 4 magnitudes). Outcome variables included first step type, step count, and the Community Balance & Mobility Scale (CBM).
Results: When pulled toward the paretic side, an increase over baseline trials of lateral (14.5 % increase) and crossover (13.6% increase) steps and a decrease of medial steps (17.4% decrease) were found in the RST group whereas no changes were found in the VST group. When pulled toward the non-paretic side, an increase of lateral steps (RST: 24.6%; VST: 31% increase) and a decrease of medial steps (RST: 14.7%; VST: 26.2% decrease) were found in both RST and VST groups. A decreased step count after training was found in RST group regardless of pull direction, and for pulls to the non-paretic side in the VST group. Significant improvements in balance and mobility as measured by CBM were observed in both RST and VST groups (P=0.018 and P=0.043 respectively).
Conclusions: Both RST and VST can modify stepping performance as shown by an increased use of more stable step types (e.g., lateral steps) and a decrease in step count in response to external lateral perturbations. However, RST appeared to be more beneficial when perturbed toward the paretic side. These findings have implications for the development of optimal rehabilitation interventions to improve balance function and prevent falls in individuals with chronic stroke.

Title: A pilot study using the walkeven biofeedback device to improve gait symmetry after a single training session in chronic stroke survivors

Authors: C. RODRIGUEZ[1], N. BALAGTAS[2], O. ROJAS[2], I.-H. KHOO[2], P. MARAYONG[1], *V. KRISHNAN[3];
[1]Mechanical and Aerospace Engin., [2]Electrical Engin., [3]Physical Therapy, California State Univ. Long Beach, Long Beach, CA

Abstract: Introduction: In chronic stroke, asymmetric gait pattern is predominant due to muscle imbalance between the affected and non-affected lower limb muscles. We used a biofeedback device, called the Walk Even, to provide real time feedback to actively correct the asymmetrical gait pattern in subjects with chronic stroke. Our pilot study showed that the subjects' gait symmetry and stance percentage on the affected limb improved after 20 minutes of single session of training. **Methods:** A total of five chronic stroke survivors (3 males and 2 females) participated in a 20 minutes of single training session. The participants in the study were at least 6 months post-stroke, and were capable of walking 10 meters without assistance. During the gait training, the Walk Even device provided auditory feedback to encourage subjects to increase their stance time on the affected side while walking. The Walk Even device collected data from pressure insoles and processed it through a microcontroller to determine the gait parameters. The targeted stance time was based on the stance time of the normal limb. Immediately before and after training, the subjects walked 8 meters to measure gait parameters such as stance percentage and asymmetric ratio. Asymmetric ratio is the ratio between stance times of the affected and the unaffected limb. A ratio of zero implies that the subject has perfect gait symmetry. **Results:** Three subjects had increased stance percentage time (10.72%, 14.4%, and 25.47%) and a decreased swing percentage time (12.17%, 14.01%, and 24.44%) on the affected leg after one session of training. Four subjects showed a decrease in asymmetric ratio (24.72%, 35.21%, 55.13%, and 68.59%). One subject improved in all of the collected measures, and was noted to have the largest change in asymmetric ratio (68.59%). **Conclusions:** A single session of the Walk Even training improved the affected limb's stance time substantially in four chronic stroke survivors. Further randomized controlled investigation is needed in order to confirm the effectiveness of the Walk Even device on a larger population of chronic stroke survivors with asymmetrical gait patterns.

Title: EEG phase synchrony reflects the severity of left unilateral spatial neglect after stroke

Authors: ***T. KAWANO**[1], N. HATTORI[1,2], M. HATAKENAKA[1], Y. UNO[2], K. KITAJO[2], H. YAGURA[1], H. FUJIMOTO[3], T. YOSIOKA[1], M. NAGASAKO[1], I. MIYAI[1];
[1]Neurorehabilitation Res. Inst., Morinomiya Hosp., Osaka-Shi, Japan; [2]Rhythm-based Brain Information Processing Unit, RIKEN BSI-Toyota Collaboration Ctr. (BTCC), Riken Brain Sci. Inst., Saitama, Japan; [3]Dept. of Neurol., Osaka Univ. Grad. Sch. of Med., Osaka, Japan

Abstract: Objective: Focal brain lesions due to stroke can impair neural network functions. By using EEG phase synchrony index (PSI), we have reported that the PSIs between the hemispheres (IH-PSI) and between the sensorimotor areas (C3C4-PSI) showed significant correlations with motor-related clinical scales in stroke patients. The aim of the current study is to investigate the association between PSIs with electrodes placed inter-parietal lobes as well as ipsilesional fronto-parietal lobes and the left unilateral spatial neglect (USN) in stroke patients. **Methods:** Forty first-ever stroke patients with right hemisphere lesions, admitted for post-acute inpatient rehabilitation, were enrolled. Twenty subjects (mean age 65.5) presenting USN were assigned to the USN group, and twenty subjects (mean age 63.0) without presenting USN were assigned to the non-USN group. All subjects signed written informed consent, and were assessed with the Mini Mental State Examination (MMSE) for general cognitive functions. Subjects in the USN group were assessed with a USN clinical scale, which consisted of cancellation tests in the Behavioral Inattention Test. We obtained 2.5 minutes of eye-closed EEG signals according to the international 10-20 system, and inter-parietal PSI (PSI between P3 and P4 electrodes) and ipsilesional intra-hemispheric PSI (average of the PSIs the following fronto-parietal electrode pairs: P4-Fp2, P4-F4 and P4-F8) were computed in three frequency bands including theta (θ) (4-7Hz), alpha (α) (8-13Hz), and beta (β) (14-30Hz). Then, we compared the PSI values between the USN and non-USN groups, and, in the USN group, we examined the correlations of the USN scale with the inter-parietal and intra-hemispheric PSIs. For the statistical analysis, Spearman's rank correlation analysis with Bonferroni correction was used.

Results: In each electrode pair, the PSI value in the USN group was significantly lower than the non-USN group. The inter-parietal PSI significantly correlated with the USN scale in the α and θ band ($p<0.01$). The ipsilesional intra-hemispheric PSI correlated with the USN scale in the θ band ($p<0.05$). No significant correlation was observed with the MMSE scores. Since these correlations were frequency and spatially selective, the inter-parietal and ipsilesional intra-hemispheric PSIs were likely to reflect the pathophysiology of USN.
Conclusion: EEG PSI can be a useful biomarker for both motor and cognitive deficits after stroke.

Title: Cellular mechanisms influencing corticospinal and sensory axonal regeneration into neural stem cell grafts after spinal cord injury

Authors: ***J. N. DULIN**[1], A. F. ADLER[1], H. KUMAMARU[1], M. H. TUSZYNSKI[1,2];
[1]Dept. of Neurosciences, UCSD, La Jolla, CA; [2]Veterans Affairs Med. Ctr., San Diego, CA

Abstract: Injured corticospinal tract axons regenerate robustly into caudalized neural progenitor cell (NPC) grafts and form functional synaptic connections with graft-derived neurons. However, the developmental fate of grafted NPCs, and whether those differentiated graft-derived neural subtypes might influence the regeneration of host axonal projections, remain unexplored. We demonstrate that upon maturation, embryonic spinal cord NPCs grafted into the injured, adult spinal cord contain clusters of dorsal spinal cord sensory interneurons that are potent zones of exclusion for regenerating corticospinal axons, but receive dense innervation by host $CGRP^{+}$ sensory axons, reflecting the normal topographical projection patterns of these axons into distinct spinal cord laminae. Notably, these sensory neuron clusters form curved, layered structures

populated by neuronal subtypes normally present in superficial dorsal horn laminae I-III, revealing the endogenous self-assembly of spinal cord dorsal horn-like structures within dissociated NPC grafts. These findings reveal a previously unknown barrier to corticospinal axon regeneration into otherwise highly permissive neural grafts, and more generally that axons of adult central and peripheral neurons reinnervate topographically appropriate regions of newly-born neurons after spinal cord injury. Moreover, these findings demonstrate the ability of transplanted dissociated embryonic NPCs to recapitulate assembly of adult spinal cord cytoarchitecture following engraftment into the injured, adult CNS.

Abstract: Reactive oxygen species (ROS) contribute to tissue damage and remodelling mediated by the inflammatory response after injury. Here, we show that ROS, which are believed to promote axonal dieback and degeneration after injury, are required for axonal regeneration and functional recovery after spinal injury. We found that CX_3CR1-dependent recruitment of inflammatory cells is required for ROS and NOX2 induction in the injured sciatic nerve and dorsal root ganglia. NOX2 is released from monocytes within exosomes and incorporated in injured axons via endocytosis. Next, active NOX2 is retrogradely transported in axonal

endosomes towards the cell body via an importin-ß1/dynein dependent mechanism. Endosomal NOX2 oxidizes PTEN, leading to PTEN inactivation, stimulating PI3K-pAkt signalling and regenerative outgrowth. Challenging the view that ROS are exclusively involved in nerve degeneration, we propose a novel role for ROS in axonal regeneration and recovery of function via a NOX2-PI3K-pAkt signalling pathway.

Abstract: Olfactory ensheathing cells (OECs) are unique glia that support axon generation and outgrowth in the olfactory system and have shown some success as a cellular transplant therapy for the recovery of sensorimotor control after spinal cord injury. A pilot study was designed in which 10 female Sprague-Dawley rats received acute transplantation of skin fibroblasts (FB, control, n=5) or OECs (n=5) after a complete mid-thoracic spinal cord transection. All rats were implanted with epidural stimulating electrodes at spinal cord levels L1 and S2 and trained to climb an inclined grid while receiving sub-threshold stimulation for 20 min., 3 times/week for 6 months. We injected the Bartha-152 (EGFP-expressing) strain of pseudorabies virus (PRV) into the soleus and/or tibialis anterior muscles 6 days before termination to identify hindlimb motor circuits and assess connectivity across the injury site. Viral transport to cholinergic somatic motor neurons and premotor interneurons was detected in 8 rats (4 FB, 4 OEC). Three rats (2 FB,

1 OEC) had evidence of viral labeling rostral to the transection site (T3-T7), including cholinergic and Chx10-positive V2a interneurons. Serotonergic axons crossed from the rostral to the caudal stump on GFAP-positive astrocyte bridges in 2 of the 3 rats with evidence of PRV-EGFP labeling above the injury site (1 FB, 1 OEC). Together these data imply that long-term axonal regeneration occurred in two of our complete spinal rats after epidural stimulation, climb training, and olfactory ensheathing cell or fibroblast transplantation.

Title: A combinatorial repair strategy to promote regeneration and improve urinary function in rats with chronic thoracic contusive spinal cord injury

Authors: C.-Y. LIN[1], K. LI[1], J. SILVER[3], *Y.-S. LEE[2];
[2]Neurosci, [1]Cleveland Clin., Cleveland, OH; [3]Case Western Reserve Univ., Cleveland, OH

Abstract: In our previous studies, we have demonstrated the long distance functional regeneration of supraspinal axons in acute SCI in adult rats using a spinal cord bridging technique that incorporates peripheral nerve grafts, acidic fibroblast growth factor (aFGF) and chondroitinase ABC (ChABC). However, there is no effective treatment to promote robust nerve regeneration to restore function after chronic SCI, which is a major unmet goal. Intracellular sigma peptide (ISP) which blocks the CSPG receptor RPTPs has been shown to dramatically enhance serotonergic fiber sprouting and improve functional recovery after acute contusive SCI. Here, we investigated the effects of combining ISP with our bridging technique in facilitating nerve regeneration and bladder control after chronic SCI. Adult rats were divided into 5 groups: (1) Sham control, (2) T8 contusive SCI+PNG+ISP (3) T8 contusive SCI+aFGF+ChABC+ISP (4) T8 contusive SCI+PNG+aFGF+ChABC and (5) T8 contusive SCI+PNG+aFGF+ChABC+ISP. ISP treatment (subcutaneous injection) started 8 weeks after the original SCI for 7 weeks. The

bridging treatment was performed at 10 weeks after the original SCI. The observation period was 6 months after the original SCI. The PNG+aFGF+ChABC+ISP group showed improvements in urodynamic patterns, significantly lower bladder weights and healthier bladder morphology than the other groups. Re-lesion of the spinal cord above the injury site abrogated the improvements in urodynamic patterns in the PNG+aFGF+ChABC+ISP group. Our anatomical analyses revealed regeneration of serotonergic fibers into the PNG and also beyond the caudal end of PNG-host interface only in the PNG+aFGF+ChABC+ISP group. The intensity of serotonergic fibers at the lumbar level of the PNG+aFGF+ChABC+ISP group was significantly higher than the other SCI groups. In addition, the serotonin transporter and presynaptic markers were identified in regenerated serotonergic fibers indicating the likely functionality of these fibers. Thus, the combinatorial treatment of ISP with our bridging technique leads to induced regeneration and/or sprouting of serotonergic (and possibly other) fibers that may play an important role in improving bladder function after chronic contusive SCI.

Title: The microtubule associated protein 1b is required to overcome myelin inhibition of axon regeneration in the adult central nervous system

Authors: *F. NOTHIAS[1,2], C. BOUQUET[1], L. VINCENSINI[1,2], M.-N. BENASSY[1,2], M. VERON-RAVAILLE[1], S. SOARES[1,2];

Abstract: Unsuccessful axonal regeneration in the central nervous system (CNS) is closely linked to the non-permissive environment, which is mainly due to reactive glial cells that expose inhibitory signals such as extracellular matrix proteins, myelin-associated proteins, but also due to poor trophic support. However, even if a favorable environment is provided, axon regeneration in mammalian CNS remains partial. Cell-autonomous factors also play a substantial role in determining the capacity for axonal regeneration, and several signaling pathways involving molecules such as cAMP, mTOR, and PTEN have been shown to be involved. Current

attempts to elicit axonal regeneration in the injured spinal cord include interference with extrinsic growth-inhibitory factors present in CNS myelin and scar tissue, their receptors, the implicated signaling pathways, and more recently, by targeting the cytoskeleton, onto which signaling pathways converge. Particularly and according to our present study, we have largely demonstrated in vitro and in vivo that MAP1B, a “juvenile” microtubule-associated protein, plays a key role in integrating signals that lead to cytoskeleton remodeling and determine axonal fate. Inhibition of axon growth by myelin components depends on neuron intracellular concentration of cAMP: embryonic neurons, with high levels of cAMP overcome myelin inhibition, contrarily to adult neurons with low levels of cAMP. Here, we investigated whether MAP1B is required for cAMP-induced axonal regeneration in a non permissive environment. In vivo, prior to a dorsal column injury on adult wildtype (wt) and MAP1B-ko mice, we performed a conditioning lesion through crush of sciatic nerve that results in increased cAMP levels in axotomized DRG neurons. Under such conditioning lesion, central projections of DRG neurons were able to re-grow across the dorsal column injury site in wt mice spinal cord, while axon regeneration was not stimulated in MAP1B-ko mice. We then compared the neurite regeneration capacity in vitro of wt- vs MAPB-ko DRG neurons plated on adult myelin. Regeneration of wt DRG neurites is poor, but significantly enhanced when cAMP is added to the medium. In MAP1B-ko DRG, however, increased cAMP levels do not promote neurite growth. These data strongly suggest that MAP1B is a key player required to overcome myelin-induced inhibition of axon regeneration in the adult CNS. We are currently investigating whether MAP1B promotes axon regeneration by modulating microtubule stability, since we have recently shown that the latter is affected by MAP1B phosphorylation.

Title: A combinatorial approach to CNS regeneration using activated transcription factors

Authors: *S. MEHTA, J. L. BIXBY, V. P. LEMMON;
Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Axonal regeneration after spinal cord injury (SCI) is inhibited by neuronal intrinsic growth limitations as well as external factors. One major intrinsic limitation on axon regeneration is the altered expression and activation state of regeneration-associated transcription factors (TFs) in mature neurons of the central nervous system (CNS). In contrast, axons in the peripheral nervous system (PNS) may regenerate long distances following injury. TFs that play roles in successful PNS regeneration such as cJun, Smad1, and Stat3 have been shown to promote limited axon regeneration in the CNS. Additionally, the activities of TFs can be boosted by the addition of transcriptional activation domains such as the viral activation domain VP16. This strategy has been used with TFs Klf7 and CREB to improve CNS regeneration *in vivo*. Furthermore, previous findings from our lab show that, at least in vitro, overexpression of two or more TFs can significantly enhance neurite outgrown in CNS neuron*s*. Despite these experimental advances, the number of axons that regenerate past CNS injury sites remains low. Moreover, functional recovery is elusive; few axons remake connections to their original targets. We hypothesize that combined expression of modified TFs may serve to promote more effective CNS regeneration after injury. To test this hypothesis, we selected four TFs with vital roles in PNS regeneration - Stat3, Smad1, cJun, and Stat6 - and one developmentally downregulated TF - Klf7. We generated various “activated” forms of these TFs using exogenous activation domains and constitutively active mutants, and determined which modified TFs were best able to neurite outgrowth in cultured postnatal cortical neurons. Finally, we tested the modified TFs in combinations of twos, threes, fours, and five to find the combination that most substantially promotes neurite outgrowth in cortical neurons. Although dual combinations of these modified TFs did not appear more effective than single TFs in vitro, we found that overexpression of several 3-TF combinations promoted neurite growth more strongly than overexpression of any single TF.

Title: Evaluating the effect of targeting ryanodine and IP3 receptors on axonal dieback following laser-induced spinal cord injury

Authors: *B. OREM[1,2], G. NALLY[1,3,2], S. BRYANT[1,3,2], D. P. STIRLING[1,3,2,4];

Abstract: Axons of the central nervous system fail to regenerate following spinal cord injury but instead retract or dieback away from the injury site. The precise mechanisms underlying acute axonal dieback remain poorly understood. Here we investigate the role of the axoplasmic reticulum, a major calcium store within axons, in mediating acute axonal dieback. To observe axons undergoing dieback in real time we use a laser-induced spinal cord injury model. Briefly, the spinal cords are isolated from transgenic mice that express yellow fluorescent protein in axons of the Gracile fasiculus, perfused in artificial cerebrospinal fluid (aCSF), and ablated using an 800 nm laser while being imaged continuously using two-photon excitation microscopy in real-time. We chose to target two different types of receptors in the axons by introducing the drugs ryanodine or 2-APB to measure their effect on axonal dieback. Either drug was dissolved in the aCSF 1 hour post injury and continuously perfused for the remainder of the imaging session. The transected axons retracted both distal and proximal from the lesion as expected. Using Dunn's method for multiple pairwise comparison, there was no significant difference in dieback length at 5 mins or 2 hours post injury, $p > 0.05$ for both. We did find a significant difference in dieback lengths beginning at 4 hours post injury with distal axonal dieback being larger. At 6 hour post injury, the distal axons (n=800) still had significantly larger axonal dieback compared to proximal axons (n=924, $p < 0.001$). We found that targeting ryanodine receptors with ryanodine significantly reduced proximal ($p < 0.001$) and distal axonal dieback ($p < 0.001$) compared to controls at 6 hour post injury. In contrast, targeting IP3 receptors with 2-APB failed to reduce axonal dieback, but rather increased dieback lengths distal to the lesion compared to control (n=207 with 2-APB, n=215 for control, $p <0.001$). Together, these results suggest that targeting ryanodine receptors may reduce axonal dieback following SCI.

Title: Identification of a novel binding domain for heparin in RPTPα, but not LAR or RPTPδ: Implications for proteoglycan signaling

Authors: Y. KATAGIRI[1], A. A. MORGAN[2], N. J. BANGAYAN[2], R. JUNKA[2], H. NAGASE[2], *P. YU[3], H. M. GELLER[2];
[1]Natl. Lung, Heart, and Blood Inst., Bethesda, MD; [2]Natl. Heart, Lung, and Blood Inst., Bethesda, MD; [3]GHMICR, Jinan Univ., Guangzhou, China

Abstract: Type IIa Receptor protein tyrosine phosphatases (RPTPs) have been shown to modulate neural regeneration and development. All members of this family (RPTPσ, RPTPδ, and LAR) have a cell adhesion molecule-like extracellular domain that includes three N-terminal Ig domains and four to nine fibronectin type III (FNIII) domains, as well as tandem intracellular tyrosine phosphatase domains. Compelling evidence suggests that both heparan sulfate (HS) and chondroitin sulfate (CS) are the ligands for RPTPσ and LAR, and the Lys-loop located in the first Ig domain is responsible for the ligand binding. We now demonstrate that all RPTP type IIa members display high affinity binding for heparin, CS-E, and dermatan sulfate (DS) with similar nanomolar dissociation constants. However, the reason for the different functional outputs of HS and CS binding to RPTPσ (respectively promotion and inhibition of axonal growth) remains a mystery. Although attributed to the differential oligomeric state of RPTPσ upon binding to HS, but not to CS, our data indicate that both HS and CS can cluster RPTPσ. Furthermore, we demonstrate a differential contribution of FNIII domains required for high affinity binding to glycosaminoglycans (GAGs). In particular, binding of PTPσ to heparin was not completely abolished by disruption of the Lys-loop. This, along with a decrease in binding with deletion of the fourth FNIII domain, leads us to hypothesize that there is a greater contribution of the FNIII domain in binding to GAGs than previously believed. In addition, the fourth FNIII-containing domain alone binds to heparin independently of the three Ig domains and does not bind to CS-E or DS. Thus, we speculate that this novel binding domain specific for HS on RPTPσ plays an important role in controlling the different biological actions of HS and CS.

Title: ChABC treatment changes the expression of PTPσ and Akt after spinal cord injury in lamprey

Authors: ***J. HU**[1], W. RODEMER[1], G. ZHANG[1], S. LI[1,2], M. E. SELZER[1,3];
[1]Shriners Hosp. Pediatric Res. Ctr. (SHPRC), [2]Dept. of Anat. and Cell Biol., [3]Dept. of Neurol., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Paralysis following spinal cord injury (SCI) is due to axon interruption and failure of regeneration. Removal of chondroitin sulfate proteoglycans (CSPGs) with chondroitinase ABC (ChABC) enhances axon growth and functional recovery after SCI, but in mammalian partial injury models, it is not clear whether this involves true regeneration of injured axons (as opposed to collateral sprouting by spared axons), nor how this treatment affects the expression of CSPG receptors and their downstream signalling pathways. To get around the limitations of mammalian models, we used complete transection of lamprey spinal cord to assess the effect of ChABC on regeneration of spinal-projecting neurons, and on retrograde neuronal death. Using the fluorescence-labelled inhibitor of caspases (FLICA) method, activity was seen primarily in the "bad-regenerating" identified reticulospinal neurons. The number of all neurons showing caspase activity increased significantly at 2, 4 and 8 weeks post-TX, compared to untransected controls. ChABC application to a fresh TX site reduced the number of caspase-positive reticulospinal neurons significantly at 2 weeks. ChABC also greatly enhanced axon regeneration at 7 and 10 weeks post-TX. Correspondingly, PTPσ mRNA expression in the perikaryon was reduced significantly, suggesting that PTPσ is involved in signalling retrograde neuronal death. PTPσ mRNA expression was positively correlated with caspase activation in neurons, and inversely correlated with regeneration of their axons at 10 weeks post-TX. We also found that Akt activation (pAkt-T308) was greatly elevated after ChABC treatment. Thus, ChABC may both enhance axon regeneration after SCI, and protect neurons from delayed retrograde death by reducing PTPσ expression and enhancing Akt activity. **Keyword:** Neuronal Death, FLICA, SCI, ChABC, PTPσ, Akt, Axon Regeneration, Lamprey **Acknowledgements:** Supported by grants R01-NS092876 (NIH, **M.E. Title: Combinatory treatment with hepatocyte growth factor and neural progenitor cells reduces astrogliosis and pro-inflammatory microglial activation *In vitro*

Authors: *R. DRAGAS[1,2], A. SIDDIQUI[1], M. CHAMANKHAH[1], J. HONG[1,2], M. KHAZAEI[1], M. G. FEHLINGS[1,2,3];
[1]Genet. and Develop., Krembil Res. Institute, TWH, Toronto, ON, Canada; [2]Inst. of Med. Sci., [3]Div. of Neurosurg. and Spinal Program, Univ. of Toronto, Toronto, ON, Canada

Abstract: Reactive astrogliosis and neuroinflammation adversely contribute to the hostile microenvironment present after spinal cord injury (SCI), posing significant challenges to regeneration and cell transplantation strategies. Hepatocyte growth factor (HGF) is a multifunctional cytokine with immunomodulatory and regenerative capabilities that may compliment neural progenitor cell (NPC)-mediated trophic support. We hypothesize that combinatorial treatment of NPC conditioned media with HGF will result in a synergistic reduction of astrogliosis and neuroinflammation after SCI. Female Wistar rats were subjected to clip-compression SCI at C5-6 or T6-7 levels. Temporal RNA-seq was used to quantify HGF expression 3-56 days post-injury. Primary rat astrocytes were activated using TGFβ1 (10 ng/mL) and a rat-derived microglial cell line was treated with LPS (1 μg/mL) to induce M1 pro-inflammatory activation. Cells were treated with either HGF protein (10, 20, or 50 ng/mL), rat NPC 4 day conditioned media (rNPC-CM), or both HGF and rNPC-CM for 24 hours. Immunocytochemistry (ICC) and qPCR were used to assess M1/M2 activation state. ICC and Western Blot were used to assess astrocytic GFAP and CSPG production. RNA-seq revealed no significant change in endogenous HGF expression up to 56 days after cervical or thoracic SCI. Combinatorial treatment, as well as HGF alone (50ng/mL), reduced CSPG expression in reactive astrocytes. HGF alone (50ng/mL) also showed a reduction in GFAP expression. Combinatorial treatment resulted in reduced NOS-2 (M1 pro-inflammatory) and increased Arg1 (M2 anti-inflammatory) expression after M1 microglial activation. For the first time, we have shown reduced CSPG deposition, astrogliosis, and pro-inflammatory microglia with HGF-rNPC-CM combinational treatment. These findings have profound translational implications as astrogliosis and neuroinflammation are largely detrimental to stem cell therapeutic efficacy and recovery after SCI and other central nervous system injuries.

Title: Insulin-like growth factor-1 receptor signaling involve the survival & migration of grafted neural stem cells in the injured spinal cord

Authors: *D. HWANG[1], H. SHIN[1], H. SUH-KIM[2], B. G. KIM[1,3];
[2]Anat., [3]Neurol., [1]Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Therapeutic impact of neural stem cell (NSC) transplantation for spinal cord injury is constrained by poor survival and migration ability of grafted NSCs. We have previously demonstrated that survival of NSC grafts rapidly declines after transplantation in the lesioned spinal cord and that combined treadmill locomotor training (TMT) increased the NSC survival in part via insulin-like growth factor-1 (IGF-1) signaling. The current study aimed to provide genetic evidence that IGF-1 receptor (IGF-1R) in NSCs may critically regulate graft survival following transplantation into the injured spinal cord in mice. Neurospheres obtained from E14 IGF-1R (+/-) mice showed size and proliferation rate similar to those from littermate wild type (WT) embryos. However, IGF-1R (+/-) NSCs were more susceptible to cellular stresses induced by reactive oxygen or nitrogen species than those from WT embryos. The survival of IGF-1R (+/-) NSC grafts was significantly attenuated after transplantation into lesioned spinal cord when compared WT NSC grafts. TMT enhanced the extent of NSC migration from the injection site allowing more intimate contacts with host spinal cord circuitry. However, most NSCs derived from IGF-1R (+/-) mice were confined around the injection site regardless of TMT. We also observed that the IGF-1R (+/+) NSCs were highly motile with frequent formation of lamellipodia or filopodia during culture. This motility and migration ability was markedly decreased in IGF-1R (+/-) NSCs. Combination of TMT and WT NSC transplantation enhanced behavioral recovery. This TMT effect was not observed when IGF-1R (+/-) NSCs were grafted. These results indicate that the IGF-1 receptor signaling may play a central role in regulation of the survival and migration of NSC grafts after SCI.

Title: Effects on neural progenitor cell grafts on neuropathic pain outcomes in models of spinal cord injury

Authors: *C. LEE-KUBLI[1], R. SHIAO[2], K. KADOYA[2], P. LU[2,5], W. CAMPANA[3,4], M. TUSZYNSKI[2,5];
[1]UCSD, LA Jolla, CA; [2]Neurosciences, [3]Anesthesiol., [4]Program in Neurosciences, UCSD, La Jolla, CA; [5]Veteran's Admin. Med. Ctr., San Diego, CA

Abstract: Neural progenitor cells (NPCs) grafted into sites of spinal cord injury (SCI) survive and differentiate into neural cells, including neurons that extend axons in very large numbers over long distances, resulting in improved motor functional outcomes (Lu et al, 2012; Kadoya et al, 2016). An important step in the clinical translation of NPC therapies for use in the treatment of SCI is to evaluate their impact on neuropathic pain outcomes in models of SCI, particularly as there have been previous reports of stem cell therapies for SCI generating neuropathic pain (Hoftetter et al., 2005). To address this question, female Fisher 344 rats received either 1) a C4 dorsal column lesion; 2) a C4 over-quadrant lesion or 3) a T3 complete transection SCI followed by NPC grafts and serial assessment of sensory outcomes. NPC grafts were obtained from GFP-expressing rat embryonic day 14 spinal cords, and were implanted into lesion sites with growth factor cocktail 1 or 2 weeks after SCI. Forelimb sensory outcomes were evaluated up to 3 months post-grafting. Neither C4 dorsal column lesion nor over-quadrant lesion (without graft) led to alterations in forelimb sensory outcomes, and implantation of NPC graft had no impact on either tactile or thermal withdrawal thresholds; thus, NPC grafts directly into spinal cord segments innervating the forepaws did not *cause* neuropathic pain.
T3 complete transection lesions resulted in the development of forelimb neuropathic pain behaviors, including forepaw spontaneous lifting, tactile allodynia and cold sensitivity, as we previously described (Lee-Kubli et al., 2016). Implantation of NPC grafts into the T3 lesion had

no effect on the development and maintenance of these neuropathic pain behaviors. The impact of NPC grafts on previously identified markers of SCI-induced neuropathic pain (Iba1, GFAP and CGRP) were also evaluated. Notably, rats that received an NPC graft showed significantly increased CGRP fiber sprouting in the cervical spinal cord segments, but did not impact the extent or magnitude of lesion-induced sensory function.
A consideration of great importance in this work is whether implants of NPC grafts can modify, either beneficially or detrimentally, SCI-related pain outcomes. These findings indicate that NPC grafts after SCI do not generate or worsen neuropathic pain states, supporting the safety and feasibility of this approach for potential clinical translation.

Med. Ctr., New York, NY; [7]Sumitomo Dainippon Pharma, Osaka, Japan

Abstract: Background: The use of induced pluripotent stem cell-derived neural precursor cells (iPS-NPCs) represents a promising strategy for generation of cells with the ability to repopulate and repair the injured spinal cord. The possibility of using autologous or syngeneic cells for tailored therapy with no need for immunosuppression would represent a significant improvement over currently used allogeneic cell replacement protocols which require immunosuppression. In

our current study, we have tested the engraftment of porcine iPS-NPCs after transplantation into the lumbar spinal cord of syngeneic non-injured pigs or in allogeneic transiently-immunosuppressed recipients with spinal (L3) injury. Material and Methods: Porcine iPS were derived from skin fibroblasts of MHC-inbred pigs and reprogrammed with Sendai virus. NPCs were isolated by harvesting of the group of cells (5-10 cells), with star-like morphology and emerging from induced neural rosettes. NPCs were further expanded, characterized in vitro by calcium imaging and immunofluorescence staining. Clones of SYN-GFP expressing NPCs were then prepared and used in vivo for grafting into the: i) striata of immunodeficient rats, ii) lumbar spinal cord in syngeneic non-injured pigs without immunosuppression, and iii) lumbar spinal cord in allogeneic transiently-immunosuppressed pigs with previous spinal cord injury. After cell grafting, animals survived for 1-6 months and the presence of grafted cells confirmed with immunofluorescence staining. Results: i) In vitro induced NPCs showed expression of neural/neuronal markers, including DCX, NeuN, GABA and GFAP. ii) After in vivo grafting into the striata of immunodeficient rats, the NPCs showed a robust engraftment and expression of mature neuronal and non-neuronal markers (NeuN, NSE, SYN, GFAP). A preferential GABA-ergic phenotype was seen in grafted neurons. Extensive axonal projection into the host tissue and development of putative synapses with neurons of the host was also seen. iii) Analysis of grafted NPCs in syngeneic recipients showed similar long-term survival and neuronal/glial differentiation. No graft rejection or tumor formation was noted. iv) NPCs grafted into allogenic recipients with previous spinal injury showed comparable robust survival and incorporation into the host-previously injured spinal cord tissue. No signs of graft rejection were seen 3 months after immunosuppression was terminated. Conclusion: These data demonstrate that the use of syngeneic or allogeneic iPS-derived NPCs can successfully be used in large animal models for testing the long-term efficacy of cell-replacement therapy in spinally injured animals.

Title: Transplantation of human embryonic stem cell-derived immature astrocytes promotes long-term survival and functional recovery after spinal cord injury

Authors: *Y. SUN[1,2,3], R. BRADLEY[4], L. DENG[1,2], C. CHEN[1,2], Y. RUAN[5], W. WU[1,2], Y.-P. ZHANG[6], C. SHIELDS[6], S.-C. ZHANG[4], X.-M. XU[1,2];

Institute, Norton Healthcare, Louisville, KY

Abstract: Contusive spinal cord injuries (SCI) often lead to severe and persistent impairments of sensorimotor functions and are clinically the most frequent type of SCI. Transplantation of human embryonic stem cell (hESC)-derived immature astrocytes could be an attractive strategy to improve anatomical reorganization and functional recovery after SCI. However, such an innovative strategy remains to be tested in animal models of SCI. In the present study, we investigated the therapeutic potential of intraspinal transplantation of hESC-derived immature astrocytes into immune deficient rats following a moderate spinal cord contusive injury at the 10^{th} (T10) thoracic vertebral level using a NYU/MASCIS impactor (10 gm dropped from a height of 12.5 mm). Ten days after the injury, hESC-derived immature astrocytes or vehicle medium were injected into the lesion center as well as rostral and caudal to it. Animals received routine behavioral, electrophysiological, and urinary bladder assessments up to 9 months post-transplantation. We demonstrated that transplanted hESC-derived immature astrocytes survived well within the injured host spinal cord for a considerable period of time (up to 9 months), migrated extensively for a long distance, differentiated into mature astrocytes, and integrated into the injured host spinal cord. In addition, transplantation of hESC-derived immature astrocytes enhanced myelin formation and tissue sparing, and decreased the inhibitory molecules associated with glial scar formation as compared to vehicle-treated control animals. Moreover, >80% of rats receiving hESCs-derived immature astrocytes recovered transcranial magnetic motor-evoked potential (tcMMEP) responses, indicating that conduction through axons across the lesion was partially restored. Lastly, transplantation of hESC-derived immature astrocytes promoted long-term recovery of both locomotor and urinary bladder functions. Importantly, no tumor formation was observed in rats receiving hESC-derived immature astrocyte transplantation. Collectively, these findings suggest that hESC-derived immature astrocytes may be a unique cell type for transplantation-mediated reorganization and recovery of function following SCI.

Title: A combinatorial treatment strategy following spinal cord injury: Human stem cell-derived neuronal grafts and local delivery of chondroitinase ABC

Authors: *T. FUEHRMANN[1], P. ANADAKUMARAN[1], S. L. PAYNE[1], M. PAKULSKA[1], B. VARGA[2], A. NAGY[2], C. TATOR[3], M. S. SHOICHET[1];

Abstract: Spinal cord injury (SCI) is a devastating condition leading to loss of sensory and motor function. The initial mechanical injury and subsequent secondary events result in substantial cell loss, and in the formation of an inhibitory environment that prevents endogenous repair. Cell transplantation to replace lost cells is a promising strategy to promote tissue repair and functional recovery following SCI; however, cell survival and integration into host tissue is limited. Although some interventions have shown promising results, it is unlikely that any one strategy, alone, would be able to promote dramatic functional improvements. It is more likely that combined approaches will yield greater benefits. This project focuses on combining the pro-survival effect of an injectable hydrogel on pre-differentiated human induced pluripotent stem cell-derived neuroepithelial cells (hNECs) combined with the local delivery of chondroitinase ABC (ChABC).Previous research indicates that pre-differentiation towards a neuronal lineage enhances cell survival. As a result, hNECs were differentiated into immature neurons, as indicated by the down-regulation of neural stem cell marker (SOX2, Nestin) and the up-regulation of neuronal marker (beta-III-tubulin, doublecortin). Cells were sorted for PSA-NCAM prior to grafting. Additionally, it has been shown that the physical blend of hyaluronan (HA) and methylcellulose (MC) promotes cell survival after grafting. HA is shear thinning and can be delivered through a fine needle, whereas MC is inverse thermal gelling, enabling it to form a gel at 37°C to provide localized delivery. One week following a moderate clip compression injury

(26g) at level T2 animals (female rats) received cell transplants in HAMC (0.75% / 0.75%) at 4 sites around the lesion (160.000 cells in total). Animals were tested for motor (BBB, ladder walk) and sensory function (tail flick) for up to 9 weeks.To promote integration of the neuronal cells, we co-delivered ChABC into the intrathecal space using a crosslinked MC hydrogel modified with the SRC Homology 3 domain for affinity release. ChABC degrades chondroitin sulphate proteoglycans (CSPGs), which are part of the inhibitory environment after injury. It can also degrade perineuronal nets, potentially promoting synapse formation between grafted and endogenous neurons.The combined therapy did not have any deleterious effects on motor or sensory function, demonstrating that the neuronal cells, ChABC and delivery vehicles are safe. Early survival of the hNECs-derived neurons was observed. We are currently evaluating the long term survival of grafted cells and the effect of ChABC on cell integration.

Title: Development and characterisation of PLGA biodegradable nanocarriers for controlled and sustained delivery of Neuregulin-1 in spinal cord injury

Authors: K. SANTHOSH[1], A. ALIZADEH[1], *S. KARIMI-ABDOLREZAEE[2];
[1]Physiol. and Pathophysiology, [2]Physiol., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Spinal cord injury (SCI) leads to significant cell death and tissue degeneration that underlies functional impairments. Pharmacological interventions to promote cell replacement holds great promise for SCI repair. We previously showed the potential of Neuregulin-1 (Nrg1) therapy in enhancing oligodendrocyte differentiation after SCI. Nrg1 is a key growth factor for proliferation and oligodendrocyte differentiation of neural precursor cells (NPCs). Here, we developed an injectable poly (lactic-co-glycolic acid) (PLGA) nanocarrier based system for Nrg1 delivery into the injured spinal cord. Nrg1 peptide was encapsulated into PLGA nanocarriers by water-oil-water double emulsion method. Porosity was introduced by incorporating sodium

bicarbonate and later salt leaching. We assessed the release rate of Nrg1 from PLGA nanocarriers with different degree of porosity. Porosity was directly proportional to the release rate of Nrg1 and inversely proportional to loading efficiency. Distribution analysis showed average particle size was directly proportional to duration of Nrg1 release. Assessment of various PLGA-Nrg1 nanocarrier preparations identified that 1.0 mg $NaHCO_3$ as porogen and 3 min sonication results in a release rate of 255.1±0.9ng/ml and prolonged release of 21 days for preparation with mean particle size of 1.42 μm and for 42 days delivery for mean particle size of 2.37 μm. Using complementary *in vitro* and *in vivo* approaches, we tested the safety and efficacy of PLGA nanocarriers and Nrg1 release. In primary cultures of adult NPCs, the PLGA was found to be non-toxic with no detrimental effects on NPC proliferation and differentiation. Moreover, in primary cultures of mixed astrocytes/microglia, PLGA did not elicit glial reactivity. Interestingly, PLGA-Nrg1 or Nrg1 alone similarly promoted NPCs proliferation and their differentiation into oligodendrocytes suggesting the efficacy of PLGA in releasing bioactive Nrg1. In a clinically relevant model of compressive SCI in rats, intraspinal PLGA-Nrg1 injection maintained significantly higher tissue levels of Nrg1 compared to Nrg1 delivered intrathecally by mini osmotic pumps. Electron-micrographs confirmed the presence of PLGA particles inside the spinal cord with a size range of 0.2-1.87 μm. Our time-point tissue assessments also showed beneficial effects of PLGA-Nrg1 therapy in attenuating scar formation after SCI. In conclusion, our study shows that PLGA nanocarriers can be used for local and sustained delivery of bioactive Nrg1 within the SCI tissue. This system allows simultaneous delivery of multiple agents in pharmacological and cellular therapies for the treatment of SCI.

Title: The effect of mesenchymal stem cells combined with an angiopoietin-1 mimetic on blood spinal cord barrier stabilization after spinal cord injury

Authors: *M. OUDEGA[1], M. M. MARLOW[2], G. J. RITFELD[2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami Dept. of Neurolog. Surgery, Miami, FL; [2]The Miami Project to Cure Paralysis, Miami, FL

Abstract: Bone marrow-derived mesenchymal stem cell (MSC) transplantation is a promising strategy for repair of the injured spinal cord. MSCs elicit neuroprotection associated with partial functional recovery. A possible mechanism underlying MSC-mediated neuroprotection is the promotion of an angiogenic response by secreted angiogenic growth factors, including vascular endothelial growth factor (VEGF). However, newly formed blood vessels may contribute to unwanted inflammatory processes due to an immature blood-spinal cord-barrier (BSCB) that allows leakage. In the present study, we combined MSC transplantation with a mimetic of angiopoietin-1 to accelerate the maturation of the BSCB of both MSC-induced new blood vessels and endogenous blood vessels. In adult female Sprague-Dawley rats we elicited a moderately severe T9 spinal cord contusion. Three days later, we injected 5 x 10^5 MSCs in the contusion epicenter and started a daily systemic treatment for 7 days with angiopoietin-1 mimetic. Spinal cords were collected at 8 days, 17 days, and 4 weeks post contusion. The BSCB was analyzed structurally with antibodies against Occludin and SMI-71 and functionally by antibodies against fibrinogen and albumin. Maturation of the BSCB was correlated with spared tissue volumes, inflammatory markers, and functional recovery. Our data provides detailed information about the feasibility of combining an angiogenic strategy (MSC transplantation) with a BSCB maturation enhancing therapeutic (angiopoietin-1 mimetic) for tissue repair after spinal cord injury.

Abstract: Human embryonic stem cell (H9)-derived neural stem cells (NSCs) were implanted into sites of spinal cord injury in immunodeficient rats and assessed over 18 months. Notably, grafts evidenced continued maturation over this entire time period. Immature neurons labeled with doublecortin appeared as early as 1 month post-grafting, but mature neuronal markers, NeuN, were first expressed three months post-grafting. To assess the total numbers of grafted human cells expressing a neuronal marker at all time points, we selected Hu as an immature and mature neuronal marker. Hu-labeled neurons continued to progressively enlarge in size while total numbers declined at early times and then partially recovered, indicating dynamic neurogenesis. While axons emerged early from grafts in very high numbers and extended over very long distances, only half of these projections persisted by 18 months. Mature astrocytic markers first appeared only after 6 months, while mature oligodendrocyte markers were not present until 12 months post-grafting. Astrocytes slowly migrated out from the graft over time. Graft size was stable over time and few dividing cells remained after 18 months. Thus, human NSCs retain an intrinsic *human* rate of maturation despite placement in the traumatic rodent environment, a finding of great importance in planning and assessing human clinical trials.

Title: Microtissue-derived matrices reveal specific neural niche architectures

Authors: *E. B. EVANS, M. LUMINAIS, D. HOFFMAN-KIM;
Mol. Pharmacology, Physiology, & Biotech., Brown Univ., Providence, RI

Abstract: Background: Several neurological pathologies may benefit from cell transplant therapy; however, enhanced CNS regeneration from successful cell therapy relies on the ability

of the transplanted cells to adhere, survive, and migrate into the targeted lesion site. Given the low viability and poor positional targeting of existing cell transplant methods, there is a need to develop biomaterials, which when co-delivered with grafted cells, improve cell survival and retention at the delivery site. Towards this end, one regenerative biomaterial strategy is to decellularize donor tissues to generate biochemical and physical cues from healthy extracellular matrix (ECM). Although decellularization methods have recently been reported for whole brains, it is unknown whether these methods can be applied to engineered tissues to create neural cell-derived matrices. Here, our goal was to generate three-dimensional cell-derived matrices from microtissues, to recapitulate tailorable ECM architectures.
Methods: Three different types of spheroid microtissues were generated through a self-assembly method using the following cell sources: primary rat cortical cells enriched for neurons, primary rat cortical cells enriched for astrocytes, and Neu7 cells, an inhibitory astrocyte cell line originally derived from rat cortex. We evaluated three existing decellularization protocols, including two developed for brain tissue and one previously used with tissue-engineered constructs, on 6-week old microtissues. To assess the efficacy of each decellularization method in removing cellular and nucleic material from the tissues, cryosections of microtissues were stained with Phalloidin and 4',6-diamidino-2-phenylindole (DAPI), immunostained for laminin, and processed for scanning electron microscopy.
Results: All decellularization protocols evaluated were effective at removing cellular debris from the neural microtissues, however the protocol previously used for tissue-engineered constructs best preserved the structural integrity of the ECM. Within each microtissue type, the patterning of laminin revealed distinct architectures, varying in topography and porosity.
Conclusions: Here, we show that acellular matrices can be derived from engineered neural microtissues. As a proof of concept, we have demonstrated through the culture and subsequent decellularization of three different example microtissues, representative of various cerebral cortex niches, that matrix architecture can be engineered through the inclusion of specific neural cell populations.

Title: Cervical spinal cord injury degenerates distal locomotor central pattern generator (CPG)

Authors: *K. SATKUNENDRARAJAH[1], S. K. KARADIMAS[2], S. GOSGNACH[3], M. G. FEHLINGS[2];
[1]Genet. and Develop., Toronto Western Res. Inst., Toronto, ON, Canada; [2]Genet. and Develop., Krembil Res. Inst., Toronto, ON, Canada; [3]Dept. of Physiol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Spinal cord injury (SCI) is devastating, causing significant locomotor deficits and potential paralysis with no optimal treatment available to date. Thus far, barring SCI directly to the segments housing the locomotor CPG, it is presumed that these networks remain intact after trauma. Stemming from this optimistic presumption, many approaches for restoring motor function below the injury site have focused on reestablishing the necessary excitation by either coaxing axons across the lesion to their synaptic partners, or directly activating the CPG using electrical stimulation. However, the extent to which intrinsic anatomical properties of these distal circuits remain intact following rostral SCI has been conspicuously overlooked. Using mice and human with progressive cervical SCI (cSCI), first we demonstrate significant locomotor deficits such as reduced speed and cadence as well increased stance phase duration compared to uninjured controls. In addition disrupted hindlimb flexor/extensor coordination and decreased ability to initiate and maintain locomotion. These locomotor disruptions were associated with significant loss of neurons (NeuN+) within the ventromedial regions of the distal lumbar spinal cord in cSCI animals. Interestingly, this neuronal loss was also mirrored in human cSCI patients. To further examine this neuronal loss, we initially induced progressive and chronic cSCI in *ChAT-GFP* mice. We found a significant loss of GFP+ cells within lamina IX of the lumbar enlargement in cSCI compared to sham ChAT-GFP mice. Moreover, preserved motoneurons displayed altered morphological characteristics such as decreased dendritic arborizations and decreased soma size. Glutamatergic neurons in the ventromedial area of the lumbar spinal cord are critical for rhythm generation and for initiating and maintaining locomotor activity. Hence, we specifically assessed the integrity of glutamatergic neurons by inducing progressive cSCI in double transgenic *Vglut2::cre; tdtomato* mice. Unbiased stereology and 3D reconstruction demonstrate significant loss of tdtomato cells in the ventromedial area of lumbar enlargement in cSCI *Vglut2::cre; tdtomato* compared to sham. While, we did not find differences in the number of inhibitory cells between cSCI and sham GABA(c-aminobutyric acid)/glycinergic ($VGAT^{ON}$) mice. For the first time, we present data showing that progressive and chronic cSCI induces specific anatomical and physiological modifications of the distal locomotor CPG in the lumbar spinal cord. As such, findings of this study dramatically alter the way in which we approach the development of treatments to restore walking in cSCI patients.

Title: Changes in the transmission of spinal lumbar pathways following a contusion (T10) during fictive locomotion in the decerebrate/spinal cat.

Authors: *J.-P. GOSSARD, H. DELIVET-MONGRAIN, M. DEA, L. AHMED, S. ROSSIGNOL;
Dept. de Neurosciences, Univ. de Montreal, Montreal, QC, Canada

Abstract: In the field of neurotrauma, contusion models are collectively accepted to be clinically relevant. In this project, adult cats were submitted to a severe spinal contusion at T10-11 using an Infinite Horizon impactor allowing the application of force of up to 800kdynes (8N) for 30s using a flat tip (5mm). Thereafter, cats were trained to walk quadrupedally on a treadmill 5 times a week on the treadmill for 5 weeks. The recovery process was studied with EMG recordings and kinematic analyses (see poster of Delivet-Mongrain et al). Trained cats could walk unaided on all four limbs. Histological examination revealed the contusions were generally very large affecting all quadrants bilaterally with large cavities leaving almost no residual grey matter.
Contused cats were used for an acute experiment to evaluate plastic changes occurring in spinal pathways below the contusion. Two were used after 5 weeks of training. Four contused cats were further spinalized at T13: 2 recovered for 2 days and 2 for 14 days before the acute experiment. The effects of stimulating supraspinal and/or cutaneous pathways were recorded in selected nerves in both hindlimbs during fictive locomotion after decerebration and curarization.
In the 1st contused cat, we found a coordinated pattern of fictive locomotion in both hindlimbs following decerebration. In the 2nd contused cat, perineal stimulation induced locomotor rhythm in both hindlimbs but bursts were not alternating properly between left and right. Trains of stimuli in the corticospinal tracts in the right pyramids evoked an increased amplitude of locomotor bursts in ankle flexors bilaterally in the 1st cat but impeded the rhythm on the right side in the 2nd cat. Stimulation of left pyramidal tracts impeded strongly the rhythm in both cats. The amplitude of cutaneous reflexes in flexors was increased on the right side as compared to the left in the 1st cat and the opposite in the 2nd. The results indicate clearly that the integrity of the corticospinal tracts was not the same in the 2 contused cats and that cutaneous transmission was also modified differently. Our recent work showed that cats with no previous lesions display left-right symmetry in all of these aspects. In forthcoming experiments using cats with an additional spinalization, locomotor rhythm is induced by clonidine i.v. We expect to see a more coordinated

and robust locomotor pattern and a decreased cutaneous transmission after 2 weeks as compared to 2 days.
Overall the results indicate that plastic changes occurred below the contusion in spinal pathways controlling and generating the locomotor rhythm in the absence of entraining sensory feedback from the moving limbs on the treadmill.

Title: The rat somatosensory corticospinal tract response to spinal injury is comparable to monkeys

Authors: M. M. MCCANN[1], A. LILAK[1], *K. M. FISHER[1], K.-A. IRVINE[2], C. DARIAN-SMITH[1];
[1]Stanford Univ., Stanford, CA; [2]Palo Alto VA Hosp., Palo Alto, CA

Abstract: We have previously shown in monkeys that different lesions of the primary afferent pathway induce very different responses in the motor and somatosensory (S1) corticospinal tract (CST) axons within the cervical spinal cord. Following a cervical dorsal root lesion (DRL), the motor CST remains robust, while the S1 CST retracts by 40% within the dorsal horn. In contrast, when a DRL is combined with a cervical dorsal column lesion (DCL; at C5), both the motor and S1 CSTs sprout dramatically into parts of the spinal grey outside the normal terminal territory. In this study, we asked if these same responses occur in the rat S1 CST following similar cervical DRL and DRL/DCL lesions. Our goal was to determine the suitability of the rat model in studying involvement of the S1 CST in post spinal cord injury recovery.
Rats were divided in to 3 groups (n=5 in each), and all animals underwent an initial laminectomy. Group 1 were controls, Group 2 were given a cervical dorsal rhizotomy at C6-7, and Group 3 received a combined DRL/DCL (where the DCL was made at the border of C5 and C6). Rats were recovered and survived for 6-8 weeks, at which time they were anesthetized, and

their S1 cortex mapped electrophysiologically to locate the region of paw representation contralateral to the lesion. This was the area most affected by the lesion and the region known to reorganize following a DRL or DRL/DCL. Anterograde tracers were injected into the area of digit representation (Lucifer yellow dextran and/or biotin dextran amine), and animals were euthanized 3 weeks later. CST axon terminal territories were then mapped in a series of coronal sections through the cervical and thoracic spinal segments using a Neurolucida system (MBF Bioscience). Results indicate that the S1 CST in the rat also retracts following a DRL but sprouts well beyond normal range when a central dorsal column lesion is included. This is similar to our observations made in the macaque and suggests a cross species response and sprouting of the S1 CST, in addition to the better known motor CST response, when a central spinal injury occurs. We will discuss the details of these similarities, and their potential role in behavioural recovery of paw function.

Title: Using flow cytometry to characterize morphine-induced changes in immune function following spinal cord injury

Authors: *M. ACEVES[1,2], A. OKOREEH[1], M. N. TERMINEL[1,2], A. R. ACEVES[1], M. A. HOOK[1,2];
[1]Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Opioids are one of few effective analgesics for the treatment of pain following spinal cord injury (SCI). Unfortunately, we have shown that morphine administered in the acute phase of SCI undermines locomotor recovery, increases mortality and pain reactivity, and decreases signs of general health in a rodent contusion model. Our studies suggest that morphine produces these adverse effects by exacerbating the inflammatory response innate to SCI. Indeed, a single

administration of morphine significantly increases IL-1β at the lesion site at 30 min and 24 h post-treatment. Pre-treatment with minocycline also blocks the adverse effects of morphine on locomotor recovery. In the current study, we used flow cytometry to characterize morphine-induced changes in resident and infiltrating immune cell populations. Sham and contused (T12) subjects were implanted with an intrathecal cannula. Twenty-four hours following surgery, subjects were treated with morphine or vehicle. At 24 hours post-treatment (48 h post-surgery), 1 cm of spinal tissue encompassing the injury was collected and dissociated. The resulting cell suspension was plated and stained with markers for CD45, CD11b, IBA1, CD86, and CD68. Cells were quantified using a FACSFortessa flow cytometer, and data were analyzed using FlowJo software. We found significant main effects of surgery and drug treatment on total immune cells present at the injury site, with contused-morphine subjects showing significantly higher numbers than their contused-vehicle counterparts. Importantly, we also found a significant main effect of morphine on total and M1-polarized microglia. Irrespective of surgery, morphine increased the number of inflammatory microglia present at the injury site. Our results support the hypothesis that opioid-immune interactions underlie the adverse effects on recovery observed in our model. Morphine may bind to opioid receptors on microglia, synergistically increasing the release of pro-inflammatory factors after SCI, and producing neurotoxicity.

Abstract: A significant number of FDA approved drugs have demonstrated efficacy in preclinical spinal cord injury (SCI). These studies used thoracic models of contusion, yet less than 5% of human SCI are incomplete thoracic injuries. Most human injuries occur at cervical levels (>65%), half of these are incomplete and this group should benefit the most from neuroprotective treatments. The short windows of intervention used in animal studies (often less than one hour) are difficult to translate in human trials. In addition, many preclinical studies are underpowered, subject to experimenter biases or conflict of interest, which significantly reduces their value as predictors of success in a human trial. We therefore created a team of research staff to assess the effects on functional recovery of the most promising FDA approved drugs when these are administered 3 hours after a cervical spinal cord hemicontusion injury using group sizes of n=14-20.

In experiment 1 we tested riluzole (n =20) administered 3 hours after injury (control = 21) in adult male Sprague Dawley rats. RT-PCR analysis performed at 3 days after injury showed significant reductions in inflammatory markers (CD68 and CD45). In the a priori primary outcome of a skilled forelimb task (Montoya staircase: retrieval of food pellets from a staircase) there were no differences between the riluzole treated group and the control group at any of the post injury time periods (2,4,6 and 8 weeks post injury). In addition, there were no differences in the secondary outcome of proximal limb use as measured by the cylinder rearing task at 3, 5 or 7 weeks after injury.

In experiment 2 metformin (n = 19) and fluoxetine (n = 20) were tested against vehicle controls: (n = 19). In the primary outcome of skilled forelimb use, as assessed by the fruit-loop eating score on the injured side, there were no differences among the groups at 6 weeks post injury. Similarly, in the secondary behavioral outcome of proximal limb use we found no differences in the cylinder rearing task at 2, 4 or 6 weeks post injury.

In experiment 3 we examined rosuvastatin (n = 14) and inosine (n = 17) started 3 hours after injury (control = 17). In the primary outcome of distal forelimb use there were no difference in the Montoya staircase task. Similarly, in the cylinder rearing task we did not observe any differences among the groups at 2, 4, 6, or 8 weeks after injury.

As in previous replication studies, establishing robustness in preclinical models is challenging and possible reasons will be discussed.

Title: Antidepressant efficacy of S-ketamine in spinal cord injury

Authors: *K. BRAKEL[1,2], A. R. ACEVES[1], N. PANCHANI[1], K. NGUYEN[1], M. ACEVES[1,2], M. A. HOOK[1,2];
[1]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Major depressive disorder (MDD) is a significant, but understudied, consequence of spinal cord injury (SCI). Approximately 11-24% of SCI patients experience MDD, compared to 8% in the general population. Unfortunately, however, some of the most effective antidepressants (selective serotonin reuptake inhibitors) have been associated with spasticity and poorer rehabilitation outcomes after SCI. Alternative antidepressant therapies that improve psychological well-being without compromising recovery are needed for the SCI population. To address this, we tested the efficacy of S-ketamine, an NMDA receptor antagonist that has been increasingly used as a short-term antidepressant in the clinical setting. Adult, male Sprague Dawley rats received moderate spinal cord contusion injuries. Twenty-four hours after injury, the subjects were treated with one of 4 doses of S-ketamine: 0, 5, 10, or 20 mg/kg, i.p. Depression-like behavior was assessed with a battery of established tests prior to injury and then on days 2, 9-10, and 19-21 post-injury. Locomotor function was also recorded throughout the 3-week recovery period using the Basso, Beattie, and Bresnahan (BBB) scale. To identify depression, change from baseline (collected two days before injury) scores were calculated for each post-injury test period. The change from baseline scores derived for test days 9-10 and 19-21, after any antidepressant effects of ketamine should have dissipated, were subjected to principal components and hierarchical cluster analyses. These analyses clustered the subjects into two groups: depressed and not-depressed. Thirteen of 32 subjects (41%) displayed depression-like behaviors (decreased sucrose preference and open-field activity). The incidence of depression was similar across S-ketamine dose groups. S-ketamine did not affect the long-term development of depression. However, high doses of S-ketamine (20 mg/kg) had an antidepressant-like effect at day 2, when ketamine should have been biologically active. Specifically, 20 mg/kg of S-ketamine increased social interaction in subjects later characterized as depressed. Importantly, ketamine did not compromise motor function; BBB scores were similar across all groups. While

the molecular mechanisms underlying these effects must be derived, the current study suggests that ketamine may provide a safer alternative for treating depression after SCI than traditional SSRI treatments.

Title: Directed differentiation of corticofugal projection neurons from endogenous cortical progenitors

Authors: ***A. OZKAN**[1,3], H. PADMANABHAN[1], S. L. SHIPMAN[1], P. KUMAR[1], W. EBINA[2], A. N. BASAK[3], J. D. MACKLIS[1];

Abstract: Specific classes of neurons are selectively vulnerable in distinct neurodegenerative, developmental, and acquired diseases of the CNS. In particular, for this work, corticospinal motor neurons (CSMN) degenerate in amyotrophic lateral sclerosis (ALS) and other motor neuron diseases, and loss of motor function in spinal cord injury results from damage to CSMN axons. Directed differentiation of new neurons with appropriate identity, maturity, circuit connectivity and function from endogenous local progenitors offers a potential therapeutic approach for functional repair of diseased or injured neuronal circuitry.
Recent work by our lab and others has begun to identify central elements of a combinatorial "molecular logic" of stage-, state-, and area-specific controls over development of broad classes and specific subtypes of cortical projection neurons. Here, we target endogenous cortical progenitors present in postnatal and adult brain to direct their differentiation into corticofugal (cortical output) projection neurons; CSMN belong to this class. Application of a select

combination of central and complementary transcriptional controls in cultured cortical progenitors directs acquisition of cardinal morphological, molecular, and electrophysiological features of corticofugal projection neurons. We employ synthetic modified RNA technology to enable temporal and dose control to mimic the *in vivo* expression dynamics of the relevant transcriptional regulators. Ongoing work will further assess fidelity of their differentiation, integration, and function within complex cortical circuitry in both developing and the diseased brain.

Title: Ubiquitin Proteasome System alterations within dystrophic axonal endings following spinal cord injury

Authors: T. E. JOHNS[1], J. L. BROWN[1], *C. E. HILL[1,2];
[1]Burke Med. Res. Inst., White Plains, NY; [2]The Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY

Abstract: After spinal cord injury (SCI), axons fail to regrow through the lesion site. Dystrophic axonal endings known as retraction bulbs form at the tips of arrested axons and persist chronically at the lesion margin. The dystrophic endings at the margins of the lesion site may provide a target for chronic SCI repair if the causes of their failure to grow can be identified and therapeutically manipulated. Although they were first described over 100 years ago by Ramon y Cajal, little is known about why retraction bulbs form and what causes them to persist after injury. This limits our ability to develop strategies to prevent their formation or reestablish the growth of chronically injured axons. In other neurological diseases, dystrophic axonal endings are associated with deficits in protein degradation. Protein degradation is necessary for the formation of growth cones following injury and their responsiveness to environmental cues, both of which are important to axonal growth following SCI. In the current study, we examined the

levels of components of the Ubiquitin Proteasome System (UPS), one of the major protein degradation systems in cells, to determine if this system is defective within dystrophic endings. Using immunohistochemistry, UPS levels were examined *in vivo* following rat SCI and *in vitro* using a proteoglycan spot assay for dystrophic ending formation. Elevated levels of the three UPS components examined (free ubiquitin, ubiquitinated protein, and proteasome core protein) were detected within dystrophic endings relative to growth cones. These results indicate that protein degradation may be altered within dystrophic endings. Manipulation of UPS activity in dystrophic endings is a necessary next step in determining whether manipulating protein degradation can overcome dystrophic axonal ending formation and promote the growth of chronically injured axons following spinal cord injury.

Title: Development of a CRISPR-based strategy for high content screening in primary neurons

Authors: *B. CALLIF, N. KRUEGER, M. T. SIMPSON, M. G. BLACKMORE;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Axon growth and regeneration are coordinated by multiple interacting proteins, the identity of which remain incompletely characterized. High content screening (HCS) combines manipulation of candidate genes with rapid image analysis of morphological changes, and has emerged as a powerful technique to identify key proteins that control axon outgrowth. Our previous screens have involved forced overexpression of candidate genes, but a complementary knockout approach is needed to clarify the role of endogenously expressed proteins. A genome editing approach often referred to as CRISPR (Clustered Regularly Interspersed Palindromic Repeats) is a rapidly developing tool for protein knockout. In the CRISPR approach, a DNA-cleaving enzyme called Cas9 is guided to target sequences in the genome by user-created guide RNA (sgRNA), where it causes a double-stranded break that ultimately results in missense mutations. Using cultured postnatal cortical neurons, we verified the ability of CRISPR to

achieve protein-level knockdown using electroporation of plasmid DNA that co-expresses Cas9 enzyme and sgRNA. Targeted proteins included NeuN, not anticipated to affect neurite length, and PTEN, a well-studied regulator of axon growth. Importantly, targeted proteins were eventually undetectable by immunohistochemistry in more than 80% of transfected neurons, but effective knockdown lagged at least four days behind transfection. Consistent with this, anti-PTEN sgRNA produced no changes in neurite outgrowth when assessed 3 days post-transfection. Therefore, we modified the procedure, such that neurons were maintained for a week post-transfection, replated to disentangle overlapping neurites, and assessed for growth after an additional 24 hours. In these replated neurons PTEN knockout produced robust increases in neurite length. These PTEN effects were achieved using multi-well transfection and automated phenotypic analysis, indicating PTEN's suitability as a positive control for CRISPR-based screening efforts. Accordingly, we have initiated a CRISPR-based knockdown screen of 50 transcription factors that potentially regulate axon growth. In addition, using viral delivery of anti-PTEN sgRNA to transgenic mice that express Cas9 we have confirmed a strong decrease in PTEN expression in adult cortical neurons in vivo. Overall these data establish CRISPR-based knockdown as effective in primary neurons, compatible with HCS workflows, and readily translated in vivo. Furthermore, our results suggest that CRISPR represents a powerful tool for discovering genetic regulators of axon growth.

Abstract: *Aims:* The Spinal Cord Injury (SCI) is a condition in which disturbances establish a complex dysfunction. Currently, the treatment of SCI is based on procedures that seek to minimize the consequences, preserve the functionality and enhance the quality of life. In this approach, the use of cells of olfactory ensheathing cells (OEC´s) and soluble factors have been suggested as a intervention for spinal cord injuries, to be recognized, properties involved in the growth of axons of olfactory neurons.
Objective Characterize promoting and inhibitors factors expression of neuroregeneration in OEC´S interaction in vitro model of spinal cord injury.
Method
Isolation of the thoracic and spinal cord of Wistar rats. Section by cross cuts 3-5 mm. Cultured for 5 days. Then mechanical injury was performed. Once the injury was made a trial of variable dosing of previously cultured OEC's and comparison with a control group using conditioned media. Morphological evaluation by electron microscopy and quantification assay was performed by using nanotechnology biosensor.
Results Identifying the presence of promoting and inhibitory proteins (NT-4/5, NOGO-A, MAG) in cell culture and morphological changes in injured neurons pretreated with OEC's determines the involvement of these proteins in axonal regeneration after injury
Conclusion The OEC´s is a population that represents a future therapeutic alternative in the treatment of spinal cord injury because of its regenerative potential. The knowledge of protein interaction represents an approach to the mechanism involved in neuroregeneration process and the future of therapeutic possibilities based on cell therapy *Keywords*

Title: A novel form of neuronal regeneration in *C. elegans* shares links with activity-dependent ectopic axon outgrowth and mammalian lesion conditioning

Authors: S. CHUNG, *C. V. GABEL;
Dept. of Physiol. and Biophysics, Boston Univ. Sch. of Med., Boston, MA

Abstract: During development, a neuron transitions from a state of rapid growth to a stable morphology, and neurons within the adult mammalian central nervous system lose their ability to effectively regenerate in response to injury. Here we identify a novel form of neuronal regeneration that is remarkably independent of the defined and well-conserved axon regeneration pathways involving DLK/p38 and MLK/JNK MAP kinase signaling. This regeneration in *C. elegans* has direct genetic and molecular links to a well-studied form of endogenous activity-dependent ectopic axon outgrowth in the same neuron type that commences during the final stages of development. Both neuron outgrowths are triggered by physical lesion of the sensory dendrite or by mutations disrupting sensory activity, calcium signaling, or genes that restrict outgrowth during neuronal maturation, such as NDR kinase or CaMKII. These connections suggest that ectopic outgrowth represents a powerful platform for gene discovery in neuronal regeneration. Moreover, we note numerous similarities between this *C. elegans* regeneration and lesion conditioning, a phenomenon producing robust regeneration in the mammalian central nervous system. Both regeneration types are triggered by lesion of a sensory neurite via reduction of neuronal activity and are enhanced by disrupting L-type voltage-gated calcium channels, elevating cAMP, or preconditioning. Taken as a whole our study unites disparate forms of neuronal outgrowth to uncover fresh molecular insights into activity-dependent control of the adult nervous system's intrinsic regenerative capacity.

Title: Relationship between clinical and physiological outcomes of quadriceps spasticity after spinal cord injury

Authors: *D. SOLAUN[1], C. A. PLUMLEE[2], M. A. PEREZ[1];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL;
[2]Jackson Mem. Hosp., Miami, FL

Abstract: The Modified Ashworth Scale (MAS) is one of the most widely used clinical exams for assessing spasticity in humans with spinal cord injury (SCI). The extent to which MAS scores relates to other clinical and physiological measurements of spasticity after SCI remains poorly understood. In the present study, we examined spasticity in the quadriceps muscle of the more affected leg in individuals with chronic (13.6±12.6 years post injury) complete and incomplete SCI between C2 and T12 spinal segments by quantifying (i) MAS scores, (ii) the pendulum test, and (iii) input-output recruitment quadriceps H-reflex curves. The MAS assessment was performed by a certified SCI physician. The pendulum test was conducted with the subject in supine position while the examiner hold the subject's foot with the knee fully extended. Then, the examiner dropped the leg and the Vicon Motion Capture System was used to quantify the first angle of the backward swing, swing ratio (defined between the first and second angle of the backward swing), swing time (defined as the time of the first angle of the backward swing), and the total number of leg swing oscillations. The quadriceps H-reflex was tested by stimulating the femoral nerve at the femoral triangle at increasing stimulus intensities (10 pulses of 1 ms duration at each stimulus intensity delivered at 0.25 Hz). Electrophysiological outcomes included quadriceps H-reflex maximum (H-max), maximal motor response (M-max), and H/M ratio. In the pendulum test, we found that MAS scores were negatively correlated with the total number of swing oscillations ($p<0.001$) but not with the first angle of the backward swing and swing time and ratio ($p>0.05$). Physiological measurements showed that MAS scores showed a weaker relationship with quadriceps H-max, M-max and H/M ratio. Altogether, our findings indicate that an aspect of the pendulum test, specifically the total number of swing oscillations, is more likely to reflect changes detected by the MAS clinical exam following human SCI.

Title: Time-dependent discrepancies between assessments of sensory function after incomplete cervical spinal cord injury

Authors: *R. A. MACKLIN[1], P. H. ELLAWAY[2], M. A. PEREZ[1];
[1]Dept. of Neurosurg., Univ. of Miami, Miami, FL; [2]Div. of Brain Sci., Imperial Col., London, United Kingdom

Abstract: We recently demonstrated that the electrical perceptual threshold (EPT) reveals spared sensory function at lower spinal segments compared with the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) exam in humans with chronic incomplete cervical spinal cord injury (SCI). Here, we investigated whether discrepancies in sensory function detected by both sensory exams change over time following SCI. Forty eight participants with acute (< 1 year), chronic (> 1 to 10 years), and extended-chronic (> 10 years) incomplete cervical SCI and 30 control subjects were tested on dermatomes C2 to T4 bilaterally. EPT values were higher in subjects with acute (2.5±0.8 mA), chronic (2.2±0.7 mA), and extended-chronic (2.8±1.1 mA) SCI compared with controls (1.0±0.1 mA). The EPT exam detected sensory impairments in spinal segments above (2.3±0.9) and below (4.2±2.6) the level detected by the ISNCSCI sensory exam in individuals with acute and chronic SCI, respectively. Notably, both exams detected similar levels of spared sensory function in the extended-chronic phase of SCI (0.8±0.5). A negative correlation was found between differences in EPT and ISNCSCI sensory levels and time post injury. These observations indicate that discrepancies between EPT and ISNCSCI sensory scores are time-dependent, with the EPT revealing impaired sensory function above, below, or at the same spinal segment as the ISNCSCI exam over time following SCI. We propose that the EPT is a sensitive tool to assess changes in sensory function throughout time after incomplete SCI.

Title: Transplanted neural precursor cells integrate with the injured cervical spinal cord

Authors: L. V. ZHOLUDEVA, V. M. SPRUANCE, T. G. BEZDUDNAYA, K. M. NEGRON, I. FISCHER, *M. A. LANE;
Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: More than half of all spinal cord injuries (SCIs) occur at the cervical level resulting in some degree of respiratory deficiency. Although there has been increasing evidence for spontaneous neuroplasticity and improvements in respiration, functional recovery remains limited. Thus, there is an urgent need for the development of therapies targeting restoration of respiratory function following SCI. One therapeutic strategy gaining translational recognition is transplantation of neural precursor cells (NPCs) to repair the injured spinal cord. NPC transplants have been shown to survive, differentiate, form synaptic connections between donor and host cells, and enhance functional recovery. However, little is known about the development of donor neurons transplanted into the injured spinal cord, and whether the injured adult spinal cord selects for specific neuronal phenotypes that could limit therapeutic potential. The present work begins to track the development of cultured and non-cultured NPCs 3, 7, 14 and 30 days after transplantation into a lateral, C3/4 contusion injury in the adult rat. Results from these ongoing studies reveal that grafted cells survive and differentiate into mature neurons and glia within the injured spinal cord 14 days post-transplantation. However, cell survival and neurite outgrowth appears to be greater in non-cultured grafts. The neuronal precursor phenotype also differs between cultured and non-cultured donor NPCs. These ongoing experiments are beginning to identify donor cell phenotypes and offer insight into how the internal milieu of the injured spinal cord might select for specific neurons and their outgrowth into host tissue.

Title: Short and long term effects of neural progenitor transplantation following cervical spinal cord contusion injury

Authors: *V. SPRUANCE[1], L. ZHOLUDEVA[2], K. NEGRON[3], T. BEZDUDNAYA[3], M. LANE[3];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Drexel Univ., Philaldelphia, PA; [3]Drexel Univ., Philadelphia, PA

Abstract: Impaired breathing is a devastating consequence of cervical spinal cord injury (SCI) that increases morbidity and the risk of mortality. Injuries at high-to-mid cervical levels (C1-4) result in the most severe deficits as the phrenic motor circuitry - controlling the diaphragm - is directly compromised, typically resulting in dependence on assisted-ventilation. While there is mounting evidence for spontaneous respiratory improvement, the extent of recovery - or functional plasticity - remains limited. Thus, there is a need to develop therapeutic strategies for enhancing repair and recovery of respiratory pathways.
Our ongoing research aims to elucidate spinal and supraspinal changes that may influence respiration post-SCI, and assess whether treatments can harness ongoing neuroplasticity to improve function post-injury. These studies have identified that spinal interneurons represent a potential therapeutic target for enhancing plasticity and recovery of phrenic motor function. With a particular focus on the phrenic motor system, the goal of the present work is to assess whether transplantation of neural precursor and stem cells (NPCs/NSCs) can facilitate repair of the injured adult rat cervical spinal cord and promote lasting, functional recovery. We hypothesize that spinally derived NPCs, rich in interneuronal precursors, will provide a source of neurons that facilitate a novel neuronal relay capable of restoring input to phrenic motoneurons.
Adult, female Sprague-Dawley rats (~250g) received lateralized C3/4 contusions (200 kilodynes, Infinite Horizons Pneumatic Impactor). One week post-injury, NPCs derived from developing rat spinal cord (E13.5 Sprague Dawley or E13.5 Fisher rat, expressing green fluorescent protein) were injected directly into the injury cavity (~1 million cells). Transplanted animals are compared against injured, untreated animals. Four weeks or one year later, a transynaptic, retrograde tracer (pseudorabies virus) was delivered to the ipsilateral hemidiaphragm or directly into the transplant. Tracing revealed synaptic integration between donor neurons and host phrenic circuitry at one month following transplantation. However, evidence for this connectivity is lost at one year following transplantation. Terminal electrophysiology analysis revealed variable phrenic and diaphragm recovery at both time points in those animals that received NPC transplants following cervical contusion injury. These ongoing studies are providing insight into the therapeutic potential for NPC therapy in the injured spinal cord.

Title: Tibialis anterior muscle activity during the paw withdrawal learning paradigm

Authors: *M. S. JOSEPH[1], K. GRIFFIS[1], H. ZHONG[1], R. R. ROY[1,2], N. J. K. TILLAKARATNE[1,2], V. EDGERTON[1,2,3];
[1]Integrative Biol. and Physiol., [2]Brain Res. Inst., [3]Neurobio., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The spinal cord has the ability to learn motor tasks in the absence of supraspinal input. The paw withdrawal learning (PaWL) paradigm represents a simple spinal learning model. In mice whose spinal cords are completely transected (ST) at mid-thoracic level, tibialis anterior (TA) muscle is given a shock to a hind leg when the leg is extended. The master mice learn to maintain the shocked leg in a flexed position while the experimentally coupled yoked group do not. To demonstrate the acquisition of the de novo flexed paw hold is mediated through muscle-specific proprioceptive inputs and a time dependent modification of the spinal interneuronal network associated with the TA motor pool, we measured the TA muscle activity using acute EMG during PaWL in both master and yoked mice. By blocking the proprioceptive muscle and the cutaneous afferents using Lidocaine, we demonstrated that TA- specific muscle afferents are critical in PaWL. In master TA muscle we detected greater activity when compared to the yoked during PaWL. Furthermore, the TA muscle showed significant EMG activity when compared to medial gastrocnemius and vastus lateralis muscles. During maintenance period of paw dorsiflexion within the master group, we find significant increase in paw displacement above the threshold coupled with decreasing iEMG activity suggesting the increase in network efficiency in performing the paw flexion. The significant increase in the EMG amplitude in the TA muscle and time-frequency and power relationships in the master group, but not the yoked, suggests that the successful learning requires temporally mediated engagement of the spinal sensorimotor network.

Title: Use of pact clearing technique to identify and trace activated neurons in the spinal network during locomotor behavior

Authors: *B. N. PHAM, JR, H. ZHONG, N. J. K. TILLAKARATNE, V. EDGERTON; UCLA, Los Angeles, CA

Abstract: The performance of motor tasks such as standing or stepping requires integration of cutaneous and proprioceptive inputs across many spinal segments. The role of these hindlimb inputs on locomotor recovery after spinal cord injury (SCI) has been shown behaviorally and electrophysiolgically, but little is known of the spatial distribution and type of neurons at the network level. Understanding the composition of this network and the changes it undergoes after SCI necessitates the need to analyze the spinal cord on a macro network level that is difficult to interpret using standard histological techniques. To address this difficulty we used tissue clearing techniques to gain a macro-perspective on spinal locomotor networks as they function *in vivo*. Adult C57/Bl6 mice had intramuscular injections of the transynaptic tracer pseudorabies virus (PRV) and the retrograde tracer Cholera Toxin subunit B (CTB) into the tibialis anterior (TA) and soleus (SOL), respectively. After 72 or 96 hrs post-viral injections, these mice were quadrupedally stepped for 60 minutes on a moving treadmill and terminated one hour later. The spinal cords were cleared using the Passive CLARITY Technique (PACT) protocol and subsequently underwent whole tissue immunohistochemistry (IHC) for the c-fos, CTB, and GFP antibodies. C-fos was used to demarcate activated spinal neurons. The tissue was then imaged using a Leica SP5 confocal and rendered using the Vaa3D program.
We found that the locations of Fos+ neurons in PACT-cleared tissue were similar to a previous study in which quadrupedally-stepped rat tissue was processed by standard IHC in 30 μM-thick sections (Ahn et al. 2006). The majority of Fos+ neurons were located in laminae V-VII with sparse labeling in laminae I-III and IX. PACT clearing was able to reveal strong labelling of PRV+ TA neurons, CTB+ SOL neurons, and CTB+ afferent terminals. The spread of PRV+

neurons were similar in PACT and 30 μM-thick tissue, with 72 hr infection labeling mostly motoneurons and that 96 hr infection labeling many interneurons. The localization of CTB+ terminals in lateral laminae II-IV and medial lamina V and VI was similar to that in 30 μM-thick sections (Hirakawa et al. 1992; Tillakaratne 2014). PACT clearing of spinal cord tissue allowed for faster tissue processing times over standard IHC. The combination of neural tracing, IHC, and PACT clearing enables increased three dimensional resolution that better captures complex, neural network connectivity. The application of PACT to analyze mouse spinal cords on a network level will facilitate the identification of network level changes that occur in the mouse spinal cord after SCI and subsequent rehabilitation.

Title: Possible mechanisms underlying conversion of nonfunctional to functional states among spinal networks after spinal cord injury

Authors: *K. A. DEPETRO, S. ZDUNOWSKI, N. J. K. TILLAKARATNE, B. PHAM, H. ZHONG, V. R. EDGERTON;
UCLA, Los Angeles, CA

Abstract: Our previous studies show that epidural and transcutaneous spinal stimulation and step/stand training can restore voluntary control in adult humans with chronic, clinically motor complete spinal cord injuries. However, the mechanism by which voluntary improvements recover seems too early to be attributed to axonal growth across the lesion. We hypothesize that some spinal networks can survive in a nonfunctional state after injury, but can be converted into a functional state and form functional connections to networks below the lesion and to motor pools. Previous studies done in rats have shown that in a hemisection (HX) model, 1-2 weeks post-injury, anatomically intact spinal axons, contralateral to the lesion, show dispersal of voltage-gated sodium channel isoform 1.6 (Nav1.6) and characteristics of demyelination associated with reduced conduction. Nav1.6 is the predominant voltage-gated sodium channel at the nodes of Ranvier in the adult CNS, and is largely responsible for depolarization. The current study seeks to determine whether this mechanism can be a factor in the recovery of voluntary control. Adult female Sprague-Dawley

rats were divided into hemisected, hemisected with step/stand training, and hemisected with ES and step/stand training. Rats were: 1) pre-trained before injury, 2) injected with anterograde tracer into the hindlimb motor cortex, 3) implanted with an epidural stimulator and transcranial stimulator with electrodes placed bilaterally into the soleus (SOL) and tibialis anterior (TA), 4) hemisected, and 5) step trained and stimulated, and 6) tested for stepping ability and motor evoked potentials (MEPs) in implanted muscles. Tissue was analyzed for dispersal of Nav1.6 channels from the nodes of Ranvier and myelin was assessed. Electrophysiological analysis showed bilaterally delayed conduction through the spinal cord post-injury followed by gradual improvement in the SOL and TA, followed by a drastic decline in MEP amplitude at each stimulation intensity (4.0 mA, 2.0 mA, 1.0 mA, and 0.5 mA) at day 15. This is consistent with the previous studies showing dispersal of Nav1.6 from the nodes of Ranvier around weeks 1-2 post-HX. The effect of Nav1.6 channel dispersal with the use of epidural stimulation and training and how these variables relate to the restoration of function will be presented.

Title: Simultaneous application of therapeutic exercise and magnetic stimulation significantly improved cervical spinal cord injury (C-SCI)-induced spasticity and gait parameters

Authors: *J. HOU[1,2], R. NELSON[1], J. WATTS[1], G. MUSTAFA[1,2], J. JOSEPH[1], D. FANTACCIONE[1], F. J. THOMPSON[1,2,3], P. BOSE[1,2,4];
[1]North Florida South Georgia Veterans Hlth. Syst., Gainesville, FL; [2]Physiological Sci., [3]Neurosci., [4]Neurol., Univ. of Florida, Gainesville, FL

Abstract: In human, more than 50% of spinal cord injuries occur at the cervical level. Following C-SCI, spasticity and gait disabilities are two most common complications which can significantly affect quality of life. Recently, we reported that a combination of treadmill (Tm) locomotor exercise with SCI-site magnetic stimulation yielded significant locomotor improvement, and spasticity reduction that was greater than either treatment tested alone (Hou et al., 2014). In order to further improve the efficacy of the therapy, here, we evaluated the

therapeutic effects of simultaneous application of Tm locomotor training with injury-site magnetic stimulation. Moderate C6/7 contusion injuries (200 kdynes, Infinity Horizon Impactor) were produced in 20 anesthetized adult Sprague-Dawley rats. Ten rats were randomly selected and initiated Tm locomotor therapy at post-injury (p.i.) day 8. Started from p.i. week 2, magnetic stimulation was applied at the injury site using a single pulse protocol that we have recently reported (Hou et al., 2014). Magnetic stimulation was provided on every other day for 6 weeks while rats were walking on the Tm. Exercise protocol continued 5 days a week and all treatments ended at p.i. week 8. The velocity-dependent ankle torques and time-locked triceps surae EMGs were recorded at p.i. week 4 and week 8 as a measure of spasticity. Six weeks of magnetic stimulation combined with the Tm locomotor training protocol completely blocked the development of spasticity when compared to data obtained from untreated injured controls. In addition, plantar H-reflex rate-depression was also measured following completion of the treatment to index quantitative changes in inhibitory processes that regulate motoneuron excitability. The combined treatment group showed rate-depression similar to that recorded in the normal controls. Moreover, the combined treatment group showed significantly increases (68.37%) in grip strength, and significantly fewer errors in paw/foot placement on a stepladder compared to corresponding data obtained from the untreated injured controls. Combined treated animals also exhibited an improved and normalized gait (3-D angular kinematics of gait, Vicon) and paw placement (Catwalk, Noldus) patter and normalization of outcome measures for pain compared to corresponding data obtained from the untreated injured controls. Our data to date suggest that combination of Tm and simultaneous magnetic stimulation can be a safe and effective treatment modality for C-SCI induced spasticity and gait impairments. The combination therapy revealed a profound therapeutic reduction of spasticity toward pre-injury levels.

Title: Grafting embryonic raphe nuclei cells into a complete spinal cord injury site reestablishes serotonergic modulation of sympathetic activity and improves cardiovascular regulation

Authors: *S. HOU[1], T. SALTOS[1], T. CONNORS[1], K. C. ELDAHAN[2], A. G. RABCHEVSKY[2], P. LU[3,4], V. J. TOM[1];
[1]Spinal Cord Res. Center, Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]SCoBIRC, Dept. of Physiol., Univ. of Kentucky, Lexington, KY; [3]Dept. of Neurosciences, Univ. of California at San Diego, La Jolla, CA; [4]VA Med. Ctr., San Diego, CA

Abstract: Cardiovascular dysfunction often occurs after high-level spinal cord injury (SCI). Disrupting supraspinal vasomotor pathways (SVPs) affects resting hemodynamics and leads to autonomic dysreflexia (AD) under unpleasant stimulus. Recently, grafting neural stem cells (NSCs) from embryonic (E) brainstem into a high-thoracic (T) SCI site enhanced cardiovascular regulation. We hypothesize that graft-derived serotonergic (5HT) reinnervation of caudal autonomic neurons plays a critical role in the functional recovery. To test this, we transplanted NSCs from raphe nuclei (RN-NSCs) of E14 GFP transgenic rats into an acute, complete T4 SCI cavity of adult wild-type rats. SCI rats grafted with NSCs dissected from E14 spinal cord (SC-NSCs), that contain very few $5HT^+$ neurons, or SCI rats without a graft served as two controls. Biotinylated dextran amine (BDA) was infused bilaterally into the rostral ventrolateral medulla (RVLM) to anterogradely trace host SVPs. A radio-telemeter was implanted into the descending aorta to measure cardiovascular parameters. Following 8 weeks, resting mean arterial pressure (MAP) in rats with injury only was significantly lower than in naïve rats. Grafting RN-NSCs restored basal MAP to normal, pre-injury levels. On the other hand, resting MAP in SC-NSC rats was significantly lower than in either RN-NSC or naïve rats and was similar to that in ungrafted SCI rats. In 24 h hemodynamic recordings, we detected significantly fewer spontaneous AD events in RN-NSC or SC-NSC rats compared to injury only controls. During colorectal distension-induced AD episodes, the magnitude of MAP elevation was remarkably lower in both RN- and SC-NSC groups versus injury controls. Pharmacologically blocking 5HT2A receptors, mainly expressed on sympathetic preganglionic neurons (SPNs), with ketanserin reduced resting MAP and elicited a responsive heart rate (HR) increase in RN-NSC rats but not in SC-NSC rats or SCI controls. Moreover, spinal cord re-transection above the graft abolished all functional recovery in RN-NSC rats, indicating the necessity of supraspinal input. Histological analysis showed that GFP^+ grafted cells survived and integrated with host tissue. BDA-labeled SVPs regenerated into the grafts. We perceived $5HT^+$ neurons in the RN-NSC grafts and dense $5HT^+$ axonal bundles innervating caudal autonomic regions, i.e. SPNs and the gray commissure. Very few $5HT^+$ neurons and axons were found in the graft and caudal cord of SC-NSC rats. Thus, grafting RN-NSCs into a lesion of SCI reestablishes 5HT regulation of sympathetic activity and improves cardiovascular performance.

Title: Investigating the role of cervical propriospinal relays in re-establishing forelimb function after a spinal cord injury.

Authors: *I. S. SHEIKH, Y. LIU, K. M. KEEFE, X.-Q. TANG, G. M. SMITH;
Neurosci., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Propriospinal interneurons (PNs) are found throughout the spinal cord, forming simple and complex circuits between different spinal segments. PNs function by integrating supraspinal motor and sensory information to organize locomotion. Studies postulate that spared PNs can reorganize and contribute to functional recovery by establishing relays between lesioned axons and motor neurons. However, to what extent PNs contribute to recovery of forelimb reaching and grasping following SCI is not known in rodents. In our first study, we examined the number and distribution of supraspinal (cortico-, rubro- and propriospinal) neurons that innervate forelimb motoneurons in C6-T1 spinal levels. We utilized a lentivirus that permits highly efficient retrograde labeling of GFP (HiRet-GFP) to neuronal somas when injected at synaptic terminals near motoneurons. Histological analysis showed C3-C4 PNs bilaterally labeled with GFP in the grey matter with greater numbers ipsilateral to the injection. Rubrospinal neurons were labeled contralateral to the injection with sparse GFP+ neurons in the ipsilateral red nucleus. Very sparse GFP-labeled corticospinal neurons were observed in the contralateral cortex. In our second study, we tested if manipulation of the intrinsic axonal growth program of severed corticospinal tract fibers combined with neurotrophin expression from spared C3-C4 PNs can permit forelimb recovery after a cervical lesion. We promoted upregulation of the PI3K/Akt/mTOR pathway by injection of AAV2-shPTEN-GFP into the primary somatosensory cortex in adult rats several days prior to a C5 dorsolateral quadrant lesion. Immediately after the lesion, we injected HiRet-NT3 at PN synaptic terminals to permit neurotrophin-3 expression from spared interneurons rostral to the lesion. We observed limited recovery of the forelimb in the IBB and grip-strength test. No recovery was observed in the cylinder and single-pellet reaching test. We intend to further explore whether propriospinal relays can influence forelimb functional recovery post injury by expressing inhibitory DREADDs in C3-C4 PNs. We will also examine if changes in axonal sprouting with therapeutic intervention can promote increased plasticity from severed corticospinal fibers onto propriospinal relays.

Title: Mapping propriospinal interneurons and their lumbar connections in a contusive injury model

Authors: ***K. M. KEEFE**, Y. LIU, C. ENEANYA, N. STERLING, G. SMITH; Neurosci., Temple Univ., Philadelphia, PA

Abstract: Spontaneous recovery from a contusive spinal cord injury is thought to involve mechanisms such as remyelination, recovery from spinal shock, and sprouting of damaged axons onto intact circuitry to form adaptive pathways. One likely target of sprouting axons is propriospinal interneurons (PNs), a ubiquitous population of neurons that reside in the intermediate grey matter of the spinal cord. These neurons receive and integrate signals from motor tracts that control locomotion such as the corticospinal, rubrospinal and reticulospinal tracts. One particular group of PNs, the long descending propriospinal neurons (LDPNs), are especially interesting to study after a contusive injury as their axons traverse the lateral funiculi of the spinal cord, and thus represent a potentially preserved population of descending axons. This makes them a likely contributor to spontaneous recovery. As this has never specifically been studied, we first focus on mapping LDPNs with axons bypassing a contusive injury, their supraspinal connections and their connections onto lumbar neurons. 200kD contusions are performed on female Sprague Dawley rats at spinal level T10. Four weeks later, we inject HiRet-GFP lentivirus into the lumbar region for retrograde tracing to the brain and spinal cord. GFP positive neuronal counts were performed on the cortex, red nucleus, medullary and pontine reticular formation, raphe nuclei, locus coeruleus, and lateral vestibular nuclear areas of the brain, and the thoracic and cervical spinal cords. To track supraspinal connections onto LDPNs, we additionally inject AAV-mCherry-WGA into the red nucleus, pontine reticular formation, or medullary reticular formation. This allows us to quantify percentages of neurons bypassing the injury in each pathway, identifying which supraspinal pathways might be involved in the

formation of adaptive circuitry. Future studies will target these populations with synaptic silencing techniques to verify their role in spontaneous behavioral recovery.

Title: Effects of transcutaneous spinal cord stimulation on soleus H- and posterior root motor reflexes: A pilot study

Authors: *B. FARRELL[1], K. HUANG[2], J. JACKSON[1], N. KAUSAR[1], I. SHVARTSMAN[1]; [1]Physical Therapy, [2]Georgia State Univ., Atlanta, GA

Abstract: Studies have shown that spinal cord stimulation (SCS) can decrease spasticity, specifically hyperreflexia, in individuals with spinal cord injury. Traditional epidural SCS is invasive and costly however, similar effects on spasticity using transcutaneous spinal cord stimulation (tSCS) have been seen. In addition, the electrode placement for tSCS can be used to elicit posterior root muscle (PRM) reflexes, which are thought to be analogous to the soleus H-reflex and provide additional insight into the effects of tSCS. Therefore, the purpose of this study was to evaluate how lumbar tSCS alters in the soleus H- and PRM reflexes. Based on the reported data, our hypothesis was that tSCS will reduce reflex amplitude and will demonstrate an enduring effect. Eight healthy subjects with no previous neurological damage were recruited for the study. Each subject had EMG electrodes placed over select muscles in the legs. Stimulation was provided in the popliteal fossa for eliciting H-reflexes and over the T11/T12 spinous processes for eliciting PRM reflexes. Each subject underwent baseline reflex testing followed by 15 minutes of tonic tSCS through the same electrodes on the back. Reflexes were reassessed during (H- only), immediately after, and 10 minutes after the bout of stimulation.
Of the eight subjects, five showed a decrease in peak-to-peak soleus H- reflex amplitude (10% decrease) while one showed no change and two increased (14% increase) immediately after tSCS. After the washout period, we found H-reflexes were reduced in six of the eight subjects (28% decrease), while the same 2 subjects remained elevated 9%). For the PRM reflex the results were different. Only four of the eight showed a decrease but the decrease was greater than that of the H-reflex (51% vs 10% decrease) immediately after the bout of tSCS. The remaining subjects showed an increase (9.05%).

These results provide preliminary evidence in support our hypothesis that tSCS can modulate reflexes with a lasting effect, though larger samples are needed. Interestingly, while the PRM reflexes were less responsive within the group, the changes were significantly greater and the PRM reflex was often absent after tonic tSCS. This may suggests that these PRM reflexes represent activation of different populations of afferents, which are undergoing different modulation.. Future studies will attempt to increase the sample size as well as provide sham stimulation condition to confirm these results.

Title: Spinal neurons from adult mice do not show enhanced excitability after spinal cord injury in reduced calcium saline and elevated temperature

Authors: *B. R. JOHNSON[1], K. LETT[2], S. DIETZ[2], A. HUSCH[3], R. M. HARRIS-WARRICK[2];
[1]Neurobio. and Behavior, Cornell Univ., Ithaca, NY; [2]Neurobio. and Behavior, Cornell Univerisity, Ithaca, NY; [3]Inst. of Genet., Univ. of Bonn, Bonn, Germany

Abstract: Spinal motor neurons and interneurons from neonatal rodents show enhanced excitability and bistable firing properties when recorded in temperatures above 30°C and using saline with 1.2 mM calcium, approximating normal in vivo conditions (Bouhadfane et al 2013. J Neuroscience, 33:15626; Brocard etal 2013. Neuron 77:1047). This increased excitability is thought to contribute to locomotor rhythm generation and plateau properties of spinal neurons. We are investigating the intrinsic firing properties of lumbar motor neurons (MNs), V1 interneurons (INs), and V2a INs from intact and spinal cord injured (SCI) adult (at least 8 weeks old) mice, comparing 2.5 to 1.2 mM Ca and 20 to 30°C, in order to optimize experimental conditions to detect excitability differences between spinal neurons recorded from intact and SCI mice. Perforated and whole cell patch recordings were made from identified lumbar MNs in longitudinal spinal cord slices from ChAT-GFP transgenic mice; V1 and V2a INs were recorded in transverse slices from En1-RFP and Chx10-CFP mice. Most neurons were pharmacologically

isolated from fast synaptic input. Excitability was measured with depolarizing current steps and ramps, and bistability was detected by negative hysteresis on ramps, or prolonged after-discharges following a current step. At 30° C and in 1.2 mM Ca saline, action potential firing in MNs and INs from intact adult mice was generally limited to the depolarizing phase of a symmetrical current ramp current; bistability was not detectable. After SCI, we have only examined excitability in MNs, 4 to 6 weeks after transection of the thoracic spinal cord, with the higher temperature and low calcium saline. MNs from SCI mice did not show signs of enhanced excitability or bistability, confirming our earlier work on MN properties at room temperature and higher calcium concentration. Some SCI MNs even expressed reduced excitability when shifted to higher temperature and 1.2 mM Ca, compared to room temperature and 2.5 mM Ca saline. SCI mice showed rear leg paralysis and other behavioral deficits consistent with complete SCI. Motor neurons from SCI mice were 100-1000-fold more sensitive to serotonin than control MNs, as found previously for V2a INs. These results suggest that the enhanced excitability seen under higher temperature and reduced Ca conditions in MNs and INs from neonatal mice may be lost during postnatal development, and SCI does not restore it, at least in MNs.

Title: Dynamic electrical stimulation modulates spinal reflexes

Authors: *G. TACCOLA[1,4], P. GAD[1], C. CHANG[2], H. ZHONG[1], W. LIU[2], V. EDGERTON[1,3];
[1]Dept. of Integrative Biol. and Physiol., [2]Dept. of Electrical Engin., [3]Brain Res. Inst., UCLA, Los Angeles, CA; [4]Neurosci. Dept., Intl. Sch. for Advanced Studies (SISSA), Trieste, Italy

Abstract: Electrical stimulation of spinal structures represents one of the most promising strategies to restore locomotor functions following neuro-motor disturbances. Animal studies have been useful to assess the best parameters of stimulation intensity, frequency and localization. Nevertheless, as of today, only stereotyped trains of square pulses have been used, while different stimulating patterns and their consequences on locomotion have not yet been explored. However, several studies suggest that critical levels of variable stochastic inputs are important for spinal networks to provide effective neural control, even during highly repetitive motor tasks. Using an *in vivo* rat model and exploiting an innovative array technology that allows independent recordings and stimulations, we concurrently delivered different patterns of intrinsically-variable bio-signals at weak intensity to distinct sites of the lumbosacral spinal cord. We named this innovative approach *dynamic neuromodulation* to distinguish it from canonical stereotyped protocols. Indeed, our stimulating patterns consist in traces previously recorded either during real locomotion from hindlimb EMGs and dorsal cord potentials, or action potential barrage from single motoneurons. Dorsum potentials recorded from the spinal cord and EMG activity recorded bilaterally from the tibialis anterior and soleus muscles were continuously monitored through the concomitant delivery of single square pulses to the spinal cord, at varying intensities. Responses evoked by single pulses at threshold only and not at supra-threshold amplitude, stably increased during dynamic stimulation and remained higher throughout the following resting phase. Moreover, even sub-threshold stimuli elicited responses after about 10s of stimulation. In conclusion, multisite independent stimulation of the cord with weak and intrinsically variable bio-signals efficiently modulates spinal excitability, providing the rationale for exploring new strategies of dynamic neuromodulation to restore muscle leg recruitment after a spinal injury.

Title: Characterization of motor and somatosensory evoked potentials in the yucatan minipig using transcranial and epidural stimulation

Authors: *F. D. BENAVIDES[1], A. J. SANTAMARIA[1], N. BODOUKHIN[1], L. G. GUADA[1], Y. NUNEZ[2], J. P. SOLANO[2], J. D. GUEST[3];
[2]Pediatrics Critical Care, [3]Neurolog. Surgery, [1]Univ. of Miami, Miller Sch. of Med., Miami, FL

Abstract: Introduction: Electrophysiological assessments permit analysis of connectivity in the nervous system. They are a valuable outcome measure bridging animal to human studies. Yucatan micropigs have spinal dimensions similar to humans, useful for spinal cord injury (SCI) studies. Micropigs are readily trained in both open field and treadmill quadruped locomotion and exhibit graded recovery after thoracic SCI. However, they are ungulates, with little neurophysiologic description of their motor and sensory pathways reported. It was necessary to develop such methods and determine normative values. Further, the relative importance of motor pathways such as the corticospinal tract (CST) in pigs must be discerned. We explored the hypothesis that motor and sensory organization would be similar to humans. In addition, we conducted studies based on motor and sensory stimulation and recording from paired epidural electrodes spanning sites of proposed SCI. **Methods**: Juvenile micropigs, trained to both treadmill and open field locomotor tasks were used. Protocols to evoke motor (MEP) and record sensory evoked potentials (SSEPs) from the scalp and spinal surface were developed in anesthetized uninjured animals. Optimal anesthetic conditions were determined to maximize sensitivity and waveform amplitude and consistency. SSEPs were evoked by stimulating peripheral nerves. The cortex was stimulated electrically using trains of pulses and EMG recorded from all limbs. Following laminectomy, epidural electrodes were placed at T8 and T10. **Results**: The response detection frequency, latencies, amplitudes, and variability of evoked potentials were determined. SSEPs were reliable and best detected during stimulation of peripheral nerve and epidural stimulation by referencing the contra-lateral cortex to midline point (Fz). The most reliable hindlimb MEP occurred in tibialis anterior. An inter-limb propriospinal pathway was discovered. Autopsy and direct cortical stimulation studies revealed variations in cortical morphology and optimal stimulation points between animals. Cervical D waves were observed, but stimulation of muscles required multiple pulses, suggesting polysynaptic circuits

were needed to recruit motorneurons. **Conclusions**: This EP study establishes neurophysiologic measures for the Yucatan minipig. Epidural stimulation, while less specific, is more potent to trigger EMG signals. The motor pathway organization requires further study to determine the role of the CST and other systems for limb activity. Yucatans differ from humans in the extent of cortical representation and the pathway to activate motor neurons.

Title: Manipulating chronic inflammation and neural plasticity away from the site of rodent spinal cord injury

Authors: *K. E. TANSEY[1], H. LEE[2], J. CHUNG[2], M. TANSEY[3];
[1]Research/Neurosurg & Neurobio/SCI Clin., Methodist Rehab/U Mississippi Med. Ctr/Jackson VA, Jackson, MS; [2]Neurobio., Univ. of Missisippi Med. Ctr., Jackson, MS; [3]Physiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Lateral hemisection spinal cord injury (SCI) at T10 produces nociceptive hypereflexia in the cutaneus trunci muscle (CTM) reflex and the sprouting of nociceptive afferents in dorsal cutaneous nerves (DCNs), the afferent limbs of the reflex, 6 weeks after SCI, both above (T7) and below (T13) the level of injury, on both sides of the spinal cord. The numbers of Iba1+ microglia/macrophages, but not GFAP+ astrocytes, are also increased at T7 and T13 at this chronic time point following T10 SCI. Because a persistent inflammatory environment following SCI is thought to be related to the development of chronic neuropathic pain, we hypothesized that a selective soluble Tumor Necrosis Factor (TNF) blocker, XPro1595, could modulate chronic inflammation in these spinal segments away from the injury and alter the neural plasticity seen there. XPro1595 has been shown to impact inflammatory cell biology and could impact neural transmission by blocking microglial-derived TNF effects on glutamate and GABA

receptors. Long Evans female rats (n=19) were subjected to a T10 lateral hemisection SCI and injected with either 3 mg/kg or 10 mg/kg of XPro1595 subcutaneously every third day starting the day of surgery. Therapeutic levels of XPro1595 were detected in plasma, cerebrospinal fluid (CSF), brain, and spinal cord segments (T7, T10, T13) 2 weeks after SCI in a dose-dependent manner. Additional animals (n=8) were then treated at 10 mg/kg for 6 weeks following SCI. This chronic XPro1595 treatment reduced the number of Iba1+ microglia/macrophages at T7 to uninjured levels and at T13 to lower than uninjured levels 6 weeks after T10 SCI. XPro1595 treatment also reversed injury induced nociceptive hyperreflexia, returning T7 DCN evoked CTM reflex sizes to uninjured values and causing hyporeflexia relative to the uninjured state in T13 DCN evoked reflexes. The effect of 6 weeks of XPro1595 on nociceptive afferent sprouting in T7 and T13 DCNs is being evaluated. Gene expression levels were also investigated at T7 and T13 in uninjured, T10 SCI, and T10 SCI with XPro1595 treatment animals using qRT-PCR arrays. Groups of genes related to inflammation, neurotrophism, neural transmission, synaptic plasticity, and myelination are being evaluated in particular. This study is the first we know of to examine the relationships between inflammation, reflex physiology, afferent anatomy and genetic changes associated with neural plasticity in the spinal cord away from the site of injury.

Title: Multielectrode array studies with culture models of motor neurons

Authors: ***A. THARANEETHARAN**[1], S. K. CUSTER[2], M. A. HARRINGTON[1];
[1]Delaware State Univ., Dover, DE; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Electrophysiological studies of motor neurons have frequently been approached using rodent models, and usually viewed from the single cell basis of a patch clamp. Recent work has shown that both embryonic chick spinal neurons and NSC-34 (a motor neuron hybridoma) are both robust models with little previous literature on their cellular electrophysiological characteristics, let alone network wide investigation using multielectrode arrays. Due to the

technically difficult and financially strenuous nature of murine models in spinal motor neuron culture, establishing an acceptable primary and secondary culture model via chick and NSC-34 would be of great value for smaller research institutions investigating motor neuron diseases such as Spinal Muscular Atrophy (SMA) or Amyotrophic Lateral Sclerosis (ALS). Spinal ventral horn neurons from embryonic chicks and NSC-34 cells were cultured onto probes for Alpha Med Scientific's MED64 & Axion's 64 electrode Muse system. Spontaneous firing generally appears in both models after 1-2 weeks while synchronized firing appears around 3-4 weeks. Pharmacologic evidence for the presence of active cholinergic and glutamatergic synapses through the use of receptor specific antagonists, such as atropine, oxotremerine, and mecamylamine (acetylcholine receptors) and CNQX and APV (glutamate receptors) were used in combination with optogenetic stimulation. Cholinergic and glutamatergic receptor regulation with myocyte cocultures was also examined. Co-cultures were done with both activated and inactivated astrocytes to mimic reactive gliosis and central nervous system pathology, while studying changes in network synchronicity.

Abstract: Introduction: Spinal cord injury (SCI) is a devastating neurological disease without effective treatment. SCI induced hyperpathia for sustaining neuroinflammation in brain regions regulating pain sensation. But this issue has not been addressed mechanistically. To generate a comprehensive view of the mechanisms involved in brain after spinal cord contusion, we applied

transcriptome analysis to characterize the temporal changes in global gene expression pattern in SCI mouse model.
Methods: This study sequenced brain samples in three groups from sham control, acute and subacute phases (3hrs and 2wks after injury). The samples from the three groups systematically characterized the transcriptome analysis. Differentially expressed genes (DEG), the result of transcriptome analysis, was then analyzed by a program Database of Annotation Visualization and Integrated Discovery (DAVID), which yielded Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway.
Results: The top enriched pathways included oxidative phosphorylation, immune-related pathways. Oxidative phosphorylation was related to the acute model, and immune-related pathways were related to the subacute model. Comparing between subacute phase and acute phase, MAPK signaling pathway was shown as the significantly relative result.
Conclusion: Since following pathways—Oxidative phosphorylation, immune-related pathways and MAPK signaling pathway—have been known as the relative pathways in SCI, when this study found the same pathways at the brain in the SCI model, we suggested the relevance between SCI and brain injury. These results provide a valuable reference data for the better understanding in the brain injury with SCI in acute and sub-acute phases.

Title: Botulinum toxin type a for neuropathic pain in patients with spinal cord injury

Authors: *M. CHUNG[1], Z.-A. HAN[2];
[1]The Catholic Univ. of Korea, Seoul, Korea, Republic of; [2]Natl. Rehabil. Ctr., Seoul, Korea, Republic of

Abstract: Objective: To evaluate the analgesic effect of botulinum toxin type A (BTX-A) on patients with spinal cord injury-associated neuropathic pain. **Methods:** The effect of BTX-A on 40 patients with spinal cord injury-associated neuropathic pain was investigated using a

randomized, double-blind, placebo-controlled design. A one-time subcutaneous BTX-A (200 units) injection was administered to the painful area. Visual analogue scale scores (0-100 mm), the Korean-version of the short-form McGill Pain Questionnaire, and the World Health Organization WHOQOL-BREF quality of life assessment were evaluated prior to treatment and at 4 and 8 weeks after the injection. **Results:** At 4 and 8 weeks after injection, the VAS score for pain was significantly reduced by 18.6 ± 16.8 and 21.3 ± 26.8, respectively, in the BTX-A group, whereas it was reduced by 2.6 ± 14.6 and 0.3 ± 19.5, respectively, in the placebo group. The pain relief was associated with preservation of motor or sensory function below the neurological level of injury. Among the responders in the BTX-A group, 55% and 45% reported pain relief of 20% or greater at 4 and 8 weeks, respectively, after the injection, whereas only 15% and 10% of the responders in the placebo group reported a similar level of pain relief. Improvements in the score for the physical health domain of the WHOQOL-BREF in the BTX-A group showed a marginal trend toward significance ($p = 0.0521$) at 4 weeks after the injection. **Conclusion:** These results indicate that BTX-A may reduce intractable chronic neuropathic pain in patients with spinal cord injury.

Title: Analysis of cortical plasticity after spinal cord injury using resting state-fMRI in awake adults mice

Authors: *K. MATSUBAYASHI[1], A. IWANAMI[2], N. NAGOSHI[2], Y. KOMAKI[3], M. MATSUMOTO[2], N. TAKATA[2], H. OKANO[2], M. NAKAMURA[2];

Abstract: [Purpose] It is recently reported that after spinal cord injury (SCI), neuronal connectivity changes occur not only in the spinal cord, but also in the brain. However, there has been no report investigating the changes of the neuronal functional communication among the regions of the cerebral cortex after SCI .The purpose of this study is to clarify the changes in neuronal functional connectivity of the brain after SCI by taking the resting state-fMRI (rs-fMRI).[Method] C57BL6 female mice were subjected to rs-fMRI without anesthesia. After careful acclimation to environmental stress, rs-fMRI was performed and the data of different

mice brain were standardized with the stereotaxic MRI brain template. By classifying the regions of the brain based on the Allen mouse brain atlas, the neuronal functional connectivity was analyzed among the specific regions. Next, complete transection or contusion SCI was induced at Th10 level in these mice. rs-fMRI was taken at 1,3,7 and 14 weeks after injury and the changes in neuronal functional connectivity of their brain were visualized using SPM12 software and CONN toolbox, and these data were analyzed using graph theory.[Results] First, the normal neuronal functional connectivity was successfully detected in the brain of the awake mice through rs-fMRI., In the comparative analyses before and after the transection SCI, the changes in functional connectivity was observed between the primary and secondary motor cortex. Moreover, by analyzing the brain connectivity of the contusion injury models, we detected the neuronal functional connectivity changes that accompanied motor recovery. Then, the data were analyzed using the graph theory and the network density of each brain region was quantitatively evaluated. The density of the network in the entire brain tended to decrease after SCI, and regarding the community structure in the network, the number of community and a region of the brain to constitute the community change time by time after SCI.[Conclusion] In the current study, we demonstrated the feasibility to take and evaluate the rs-fMRI of mice. We also showed the relative changes in the neuronal functional connectivity in the brain after SCI and identified the regions that were strongly related to the functional recovery after SCI. In addition, we detected that the networks changed in the brain after SCI by the analyses using a graph theory. These networks were divided into small communities and the density of these networks decreases immediately after SCI, then individual regions change the importance of their network, suggesting that brain networks were reorganized and changed the efficiency of the entire network after SCI.

Title: Serum inflammatory cytokines and biomarkers of injury severity in acute human spinal cord injury

Authors: *K. DONG[1], F. STREIJGER[1], L. BELANGER[3], L. RITCHIE[3], S. PAQUETTE[2], J. STREET[1,2], T. AILON[2], M. BOYD[2], C. G. FISHER[2], M. F. DVORAK[1], N. MANOUCHEHRI[1], K. SO[1], B. K. KWON[1,2];
[1]Intl. Collaboration on Repair Discoveries, [2]Orthopaedics, Univ. of British Columbia, Vancouver, BC, Canada; [3]Vancouver Spine Program, Vancouver Gen. Hosp., Vancouver, BC, Canada

Abstract: Neurologic impairment after spinal cord injury (SCI) is currently measured and classified by functional examination. Biological markers that objectively classify injury severity and predict outcome would greatly facilitate efforts to evaluate acute SCI therapies. We recently reported that concentration levels of inflammatory (IL-6, IL-8, and MCP-1) and structural proteins (TAU, S100B, and GFAP) within the cerebrospinal fluid (CSF) of acute SCI patients are distinct between different injury severities (AIS A, B, and C) and could be utilized to predict AIS conversion and motor score recovery at 6 months post-injury. In an attempt to identify blood protein biomarkers and whether CSF changes are reflected in blood, in this study we conducted similar biochemical analyses in serum samples of SCI patients for whom we have already measured the CSF.

Patients with cervical or thoracic SCI classified as AIS A, B, or C were recruited for insertion of a lumbar intrathecal catheter. Blood and CSF samples were drawn at the same time at the time of catheter insertion and then in the subsequent post-operative period approximately 3 times each day. Blood samples were kept at room temperature for 20 minutes and then centrifuged at 10,000 rcf for 5 minutes to obtain serum. Serum concentrations of IL-6, IL-8, TNF-R1, MCP-1, and IP-10 levels were evaluated using a custom 5-plex kit. Beads were read on the Bio-Plex suspension array system. Serum levels of tau, S100β and GFAP were determined using commercially available enzyme-linked immunosorbent assay (ELISA) kits.

Initial analysis of serum samples from 9 acute SCI patients revealed that the concentrations of proteins such as IL-6, GFAP, and S100β were many orders of magnitude lower in serum when compared to CSF. This is, however, not to say that biomarkers within blood may not correlate with injury severity or predict outcome. Data analysis of serum samples from a small set of AIS A, AIS B, and AIS C patients collected 17-23 hours post-injury showed great promise and revealed an injury severity-dependent change in expression levels of TNF-R1, IL6, MCP-1, IP-10, and GFAP. Notably, increasing the overall sample size of the present study is necessary. This work is currently being done.

By characterizing the acute pathophysiologic responses to traumatic SCI in humans and establishing serum biomarkers for better injury stratification and improved prognostication of neurologic recovery, we hope to provide the field with tools that can be utilized in clinical trials to facilitate the evaluation of novel therapies.

Title: Improved assessment of functional recovery after pyramidotomy injury in mice: Optimized staircase reaching task

Authors: *J. M. MEVES[1,2,3], C. G. GEOFFROY[1], J. J. KIM[1], X. LI[1], B. ZHENG[1,2];
[1]Dept. of Neurosciences, [2]Neurosciences Grad. Program, [3]Med. Scientist Training Program, UC San Diego, La Jolla, CA

Abstract: The unilateral pyramidotomy model is a valuable tool for assessing compensatory growth of uninjured corticospinal tract (CST) axons after damage to the central nervous system. In this model, one side of the CST is lesioned at the level of the medullary pyramids, which induces spontaneous growth of the contralateral intact CST axons in the denervated side of the spinal cord. Previous studies have shown that this form of axon growth can be increased by manipulating a variety of neuron-intrinsic or extrinsic axon growth regulators. While this model allows clear anatomical assessment of axon growth after injury, the use of this model in mice has been hampered by a lack of consistent and robust behavioral assessments. Here we show that a modified staircase reaching task reveals a clear, persistent functional deficit after a unilateral pyramidotomy injury in mice. This behavioral paradigm requires minimal hands-on training of animals or subjective scoring of performance, lending itself as a valuable tool for ongoing studies that assess the functional relevance of molecular manipulations that promote compensatory axon growth.

Title: The role of the RGD binding motif in the survival of a bone marrow-derived mesenchymal stem cell transplant in the injured spinal cord

Authors: *A. E. HAGGERTY, M. OUDEGA;
The Miami Project, Univ. of Miami, Miami, FL

Abstract: Spinal cord injury (SCI) results in nervous tissue loss and so far untreatable functional impairments. Preclinical studies have demonstrated that a transplant of bone marrow-derived mesenchymal stem cells (MSCs) elicit anatomical repair and partial functional recovery, likely through the secretion of paracrine factors. Previously, we have shown that the incomplete repair by an MSC transplant is in part due to their limited survival in damaged spinal cord nervous tissue (Ritfeld et al., 2014). MSCs are anchorage-dependent cells and therefore susceptible to anoikis (i.e., programmed cell death due to lack of adherence to a substrate), which at least in part could be responsible for their poor survival following transplantation into the damaged spinal cord. It is known that MSCs adhere via integrin receptors to the tripeptide, arginine-glycine-aspartic acid (RGD) which is present on components of the extracellular matrix, including fibronectin (FN). Therefore, we have investigated the effect on MSC survival of superfibronectin (sFN), a specific form of fibronectin with increased availability of RGD binding motives, as a cell suspension matrix both in vitro and in vivo using an adult rat model of spinal cord contusion. We have also combined sFN with a synthetic polyurethane-polyethylene glycol co-polymer hydrogel (ESHU), which was found to promote MSC survival in vitro and in vivo, likely due to anti-oxidative properties. We argued that this combination could lead to synergistic effects on MSC survival, with ESHU providing protection against reactive oxygen species-driven apoptosis and sFN providing protection against anoikis-driven apoptosis. This work is supported by the Morton Foundation and the Wings for Life Foundation (contract # WFL-US-015/15).

Title: Impact of sustained sublesional nociception on restoration of spinal excitability following complete spinal transection in mice

Authors: *R. JEFFREY-GAUTHIER[1], M. PICHÉ[2], H. LEBLOND[3];
[1]Trois-Rivieres, QC, Canada; [2]Dept. de Chiropratique, [3]Dept. d'Anatomie, Univ. du Québec à Trois-Rivières, Trois-Rivieres, QC, Canada

Abstract: Pain affects two thirds of patients following spinal cord injury (SCI). While its psychosocial impact is well-understood, we just begin to unravel the interaction between nociception and sensorimotor adaptation responsible for functional improvement. Recent experimental evidence show that nociceptive afferents can hinder locomotor reexpression in mice with complete spinal transection. Besides, locomotor training, partially overcomes nociception-induced locomotor deficits. While part of training's adaptive effects on recovery is due to the recovery of spinal excitability, it is currently unclear how nociception induces its maladaptive impact on locomotor reexpression. The aim of this study is to examine if nociception triggered by chronic inflammation of sublesional paraspinal muscles by injecting complete Freund adjuvant (CFA) alters the recovery of H-reflex excitability following complete spinal transection in mice. H-reflex measurements were collected at day 28 following complete transection in mice and were compared between two groups, including mice receiving a CFA injection (CFA) and controls (CTL) receiving no injection. To avoid anesthesia-induced depression of spinal activity, mice were decerebrated before the recordings, which allowed collecting H-reflex measurements without anesthesia. Preliminary results suggest that H-reflex excitability, measured by the slope of the intensity-response curve, is decreased in CFA compared to CTL mice with complete spinal transection. Since H-reflex excitability is associated with better outcomes after SCI, it is possible that nociception alters the course of locomotor recovery by modulating spinal excitability.

Abstract: Spinal cord injury (SCI) results in loss of voluntary motor control followed by incomplete recovery, which is partly mediated by the descending pathway from the primary motor cortex (M1). Human SCI study with magnetic resonance imaging (MRI) has reported that not only traumatic spinal degeneration but also disability-related atrophy of gray matter in M1 occurred in 2 months after the injury (Freund et al., 2013). However, yet actual cellular degeneration mechanisms behind its atrophic process has not been characterized in details. Therefore in the present study, we longitudinally investigated M1 atrophic process after SCI in common marmosets using voxel-based morphometry (VBM) of MRI gray matter density. After the detection of atrophy, we quantified the feature of shape and somatic volume of the layer 5 pyramidal neurons in M1 using SMI-32P staining, which labels neurofilament specifically expressed in layer 5 pyramidal neurons of cerebral cortex, and considered the relevance between the atrophy and the somatic volume of the pyramidal neurons in M1. Four adult female common marmosets underwent C4/C5 lateral hemisection. We acquired MR images at four time-points; before injury (baseline), and 2 weeks, 6 weeks, and 12 weeks after injury. We assessed atrophy in gray matter across the whole brain by VBM of T1-weighted MR images (N=3). We also performed immunohistochemistry of SMI-32P staining to characterize somatic volume of pyramidal neurons in the layer 5 of M1 at 12 weeks after SCI (N=2). MRI analysis showed a significant gray matter volume decrease in the contralesional M1, from baseline to 6 weeks after the injury [15%, Z score 5.87, $p<0.05$ (corrected for family-wise error)]. SMI-32P staining also revealed significant decrease in the somatic volume in the contralesional M1 compared with that in ipsilesional M1 (32%, two-sample t-test, $p<0.001$). This demonstrated that pyramidal neurons in the contralesional M1 have undergone significant shrinkage at least 12 weeks after SCI. The

current results indicate that gray matter volume decrease in contralesional M1 in hemi-spinalized common marmosets first occurs in 6 weeks after SCI, and at least in part, it results from shrinkage of pyramidal neurons. We showed, for the first time, features of time course of atrophic change of M1 from before the lesion through to the chronic stage. And it is expected that other multiple cortical structures such as microglia and astrocyte drastically made injury-induced reorganization. Therefore it is showed that, in order to clarify the whole picture of clinical condition after SCI, to reveal all those injury-induced drastic cellular reorganizations is important.

Title: Development of a novel technique to investigate the role of autonomic dysfunction in mechanical allodynia following spinal cord injury

Authors: *D. NOBLE, K. K. MARTIN, S. PARVIN, S. M. GARRAWAY;
Physiol., Emory Univ., Atlanta, GA

Abstract: Spinal cord injury (SCI) commonly results in the development of maladaptive pain and autonomic dysfunction. Because we do not fully understand the mechanisms of chronic and maladaptive pain after SCI, there has been limited success in controlling this pernicious facet of injury and developing new therapeutic interventions for its alleviation. Allodynia, defined as a painful response to innocuous stimulation, is indicative of maladaptive pain in studies using animal models. Behavioral tests commonly only assess allodynic responses distal to the dermatomal site of injury at the expense of at-level changes. Here, we present pilot data obtained from a novel setup designed to monitor rodent ventilatory responses - potentially a key autonomic index of at-level allodynia - to clinically relevant mechanical stimulation, with the aim of developing a more complete profile of clinical SCI pain. We focus on a specific fiber population, the C-fiber low-threshold mechanoreceptors (C-LTMRs). C-LTMRs can undergo injury-induced changes to produce allodynia and are of especial interest since it is an active research question whether they are involved in allodynia and chronic pain after SCI. We

stimulated adult mice (SCI with lateral T10 hemisection or sham) mechanically with a small brush at several frequencies within a range previously reported to activate C-LTMRs. At the same time, we used highly sensitive non-contact electric field sensors (EPIC, Plessey Semiconductors) to monitor the ventilatory response to stimulation. Breathing rates were elevated from baseline in SCI mice one day after injury, prior to the development of mechanical allodynia (assessed with the von Frey test), and remained elevated at later time points. Furthermore, mechanical brush stimulation across the animal's side at frequencies ranging from 0.3-30 Hz, corresponding to the tuning properties of C-LTMRs, revealed frequency-dependent changes in breathing rate. Together, these results suggest the possibility that pain is modulated by autonomic dysfunction following SCI and encourage further inquiry into the role of C-LTMRs. Ongoing studies are aimed at investigating breathing rate as a predictive autonomic physiological marker for below- and at-level SCI-induced pain, and selectively recruiting or inhibiting C-LTMRs using optogenetics to more precisely delineate their functional contribution to maladaptive pain following SCI.

Abstract: There are many therapeutic strategies to improve the functional restoration following spinal cord injury (SCI) experimentally, however the effects of treatments are limited and hard to be translated into the clinical setting. DNA methylation is one of the most important epigenetic modulator of gene expression in the mammalian, and recent studies reported that DNA methylation induced by spinal cord injury (SCI) may modulate regeneration-associated genes (RAGs) which control the regeneration capacity and neuronal growth. The aim of this study is to find epigenetic changes within a brain following SCI, and to delineate the supraspinal mechanisms of epigenetic modulation for the neuronal regeneration after SCI. Spinal cord contusion model at thoracic level was made using Sprague-Dawley rats, and performed immunohistochemistry dot blot, and real-time PCR to analyze 5-hydroxymethylcytosine (5hmc), 5-methylcytosine (5mc), Ten-eleven translocation (TET) family, RAGs, and pro-inflammatory genes within the brain from very acute stage (1 hour) to chronic stage (3 months) after SCI. The 5hmc intensity in the motor cortex of brain was significantly increased in SCI group more than in sham operated controls, and this change was prominent in the subacute stage. The mRNA levels of TET family (TET1, TET2, and TET3) were also increased within the brain from 1 hour until 3 months after SCI. Some of pro-inflammatory genes including interleukin-1 beta, interleukin-6 and tumor necrosis factor alpha were increased in the acute stage and many of RAGs were decreased from the subacute stage. We concluded that the activity of DNA methylation can lead to alteration of RAGs and inflammatory cytokines within a brain following spinal cord contusion in rats, and the epigenetic modulation at supraspinal level might be one of the therapeutic strategies for spinal cord regeneration.

Title: Time dependent changes of gene expression following spinal cord contusion in rats

Authors: *J.-W. KIM[1,2], J.-Y. HONG[1,2], J. HYUN[1,2,3];
[1]Dept. of Nanobiomed. Sci. and BK21 PLUS NBM Global Res. Ctr., [2]Inst. of Tissue Regeneration Engin., [3]Dept. of Rehabil. Medicine, Col. of Med., Dankook Univ., Cheonan, Korea, Republic of

Abstract: Numerous clinical trials have been documented to promote the regeneration of damaged neurons after spinal cord injury (SCI), however no effective treatment is developed until now. The pathophysiology of SCI is extremely complex and many in vitro and in vivo studies have continued to report opposite results each other in spite of the same treatments, therefore more fundamental analysis such as an extensive assay of gene expression might be required to find a way for spinal cord regeneration. In this study, we aimed to detect the changes of global gene expression following spinal cord contusion in rats according to the time sequence, and to find a treatment target within the featured changes at each stage. We sequenced spinal cord tissues at contusion site after spinal cord contusion in rats using RNA-sequencing technology. Analyzed genes were classified into three categories according to the mechanisms of SCI; genes associated with inflammatory process, neuronal regeneration, or glial scar formation. For time sequence analysis, five time points was set; 1 hour, 1 day, 1 week, 1 month and 3 months after spinal cord contusion at T9 level using Infinite Horizon impactor, and sham operated rats were used as controls. Quantitative RT-PCR analysis was also performed to validate expression changes of candidate genes in each category. We found that the pattern of global gene expression at acute and subacute stages was quite different from that at chronic stage. Most of gene expression levels of inflammatory cell markers were increased and peak during acute stage (1 hour to 1 week) and maintained until chronic stage. Some of regeneration-associated genes (RAGs) including brain derived neurotrophic factor, glial cell derived neurotrophic factor and ciliary neurotrophic factor were increased at 1 hour or 1 day after SCI. The expression level of myelin associated genes such as APC, MBP, and PLP1 were all decreased from 1 day to 3 months, and most of gene expression levels of M1 macrophage-producing cytokines and chemokines increased from 1 hour after SCI and continue to chronic stage, however M2 macrophage-associated gene level was not changed after SCI. The expression changes of candidate genes using RT-PCR were consistent with RNA-sequencing results.We concluded that the information of gene expression level according to the time sequence after SCI might be useful to determine treatment strategies for spinal cord regeneration especially in chronic stage.

Title: aligned microchannel scaffolds for spianl cord repair

Authors: *D. LEE[1,2], M. KIM[1,2], J.-W. KIM[1,2], J. KNOWLES[1,2,4], J. HYUN[1,2,3];
[1]Dept. of Nanobiomedical Sci. & BK21 PLUS NBM Global Res. Ctr. for, [2]Inst. of Tissue Regeneration Engin., [3]Dept. of Rehabil. Medicine, Col. of Med., Dankook Univ., Cheonan, Korea, Republic of; [4]Div. of Biomaterials and Tissue Engineering, UCL Eastman Dent. Inst., Univ. Col. London, London, United Kingdom

Abstract: Axonal regeneration is hardly achieved spontaneously after spinal cord injury (SCI), and the restoration of somatic and autonomic functions after SCI is also challenging in the clinical field. We developed three dimensional scaffolds which contain numerus microchannels. The microchannels were created by dissolving finely aligned phosphate glass fibers within dried poly(lactic-co-glycolic acid) (PLGA)/tetraglycol or polycaprolactone (PCL)/tetraglycol solution, and the diameter of microchannel was about 20 micrometer. We aimed to delineate the effect of microchannel-containing biopolymer scaffolds to the axonal regeneration after SCI in rats. In vitro study was performed using a three dimensional culture system which enable neuronal cell culture within a scaffold, and we found that the neurite outgrowth of cortical neurons is more effective within PLGA scaffold than PCL scaffold. The PLGA or PCL scaffold were also implanted into transected spinal cord at T9 level in rats. Twelve weeks after implantation, outgrowing axons were visible within the PLGA or PCL scaffolds, and the number of axons crossing the scaffolds was significantly higher in PLGA scaffold than in PCL scaffold. We also applied neurotrophin-3 (NT-3) and brain-derived neurotrophic factor (BDNF) to heparinized PLGA scaffold, and found that NT-3 and BDNF-applied scaffold is more effective to increase the amount of axonal outgrowth crossing the scaffold, and improve locomotor and bladder

functions 12 weeks after implantation. We concluded that PLGA-based mirochannels are effective for spinal cord repair and sustained release of NT-3 and BDNF within the scaffold also facilitate the axonal regeneration after spinal cord transection in rats.

Title: NeuroD1-mediated glia-to-neuron conversion in the injured spinal cord

Authors: H. LI, X. DING, A. CAI, B. PULS, M. KEEFE, K. HE, L. ZHANG, *G. CHEN; Biol., Penn State Univ., University Pk, PA

Abstract: Spinal cord injury (SCI) is a devastating neurological disorder that often impairs the daily function of patients for their entire life. Traumatic injury of the mammalian central nervous system (CNS) often leads to severe neuronal loss along with reactive gliosis, which remain irreversible with existing approaches. Stem cell-based transplantation strategy had great potential to replenish the lost neurons, but it faces ethical issues and the fact that transplanted cells are often eliminated by immune rejection. Recent advance in the field of *in vivo* reprogramming offers new hope to regenerate neurons from the endogenous glial cells. Our recent work showed that over-expressing a single neural transcription factor NeuroD1 in the stab-injured mouse brain converted reactive glial cells directly into functional neurons (Guo Z et al., 2014, Cell Stem Cell). In this study, we evaluate the same *in vivo* reprogramming technology in the adult spinal cord after a stab-injury. We found that NeuroD1 overexpression by a retrovirus was able to convert endogenous glial cells into NeuN+ neurons with high efficiency as early as 1 week after injection. Neurogenin2, a transcription factor upstream of NeuroD1, was also capable of neuronal conversion but with less efficiency than NeuroD1. Further immunostaining analysis showed that new neurons are likely converted from Olig2+ oligodendrocyte precursor cells (OPCs) but not GFAP+ astrocytes. In addition, both NeuroD1 and Neurogenin2 could efficiently reprogram both human and mouse spinal cord glial cells in cultures into functional neurons. Finally, NeuroD1-converted neurons seem to have a higher survival rate than the Neurogenin2-

converted ones. Our study suggests that NeuroD1 is capable of replenishing lost neurons by efficiently converting endogenous glial cells into neurons, providing a novel therapeutic treatment for SCI.

Abstract: Polytrauma consequent to war related injuries, falls or motor vehicle accidents involves injury to at least two body regions, commonly closed head concussive impact injuries (mild traumatic brain injury: mTBI) and limb injuries (bone fracture). mTBI accounts for about 80% of all TBIs, leads to chronic disability and is often accompanied by chronic pain. Chronic pain associated with mTBI is challenging to manage and hinders rehabilitation efforts. Specific treatments for TBI-related pain is lacking partly due to gaps in understanding underlying mechanisms of mTBI related chronic pain development. Many mTBI or chronic pain patients suffer long-lasting neurobehavioral impairments. Mice were assigned to the following experimental groups: Sham/Sham, mTBI/Sham, Sham/Fracture or polytrauma (mTBI/Fracture). Nociceptive sensitization to mechanical stimuli was measured and nociceptive priming effects of mTBI were evaluted using PGE2 challenge. Diffuse Noxious Inhibitory Controls (DNIC) on nociceptive sensitization was measured, immediately after forepaw capsaicin application. Also, Capsaicin evoked spontaneous pain behaviors were measured in all after resolution of

mechanical sensitization. Neurocognitive assessments were done by using the object location/recognition memory (OLM/ORM) tasks, after open field (OF) testing. Lateral closed cortical impact mTBI resulted in hindlimb mechanical allodynia lasting 7-14 days. The mTBI alone resulted in increased hyperalgesic priming and impaired descending pain modulation (DNIC) after local PGE2 application. The polytrauma group displayed more intense and prolonged mechanical allodynia compared to either mTBI or fracture groups. Additionally, impaired descending pain modulation (DNIC) was observed in polytrauma compared with fracture alone. Moreover, the combined injury group had increased sensitivity to local capsaicin when mechanical allodynia had resolved. Deficits in hippocampal dependent (NOL) and hippocampal independent working memory (NOR) were seen in both mTBI and polytrauma groups, though the latter displayed a more affected phenotype. Furthermore, mTBI and polytrauma groups had increased levels of activity (OF) indicative of agitation. Findings presented in our study provide novel observations regarding changes in pain and cognitive function in a mouse model of polytrauma. The model offers clinically relevant features useful for studying interactions between combined neurotrauma-induced pain and neurobehavioral changes with focus towards developing better therapeutic strategies. Further studies characterizing gender differences in the model need to be carried out.

Title: Anoctamin 1 contributes to hypersensitivity associated with burn injury

Authors: *A. R. FURR, K. M. HARGREAVES;
Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Persistent pain associated with burn injury is a major clinical challenge primarily due the lack of efficacious analgesics. Although opioids are a gold standard for pain control, their efficacy in burn injury is insufficient and often associated with adverse side effects such as

tolerance and dependence. Thus, investigating mechanisms that underlie burn injury-related pain is critical for the development of novel, effective pain treatments with limited side effects.
To evaluate peripheral mechanisms of pain associated with burn injury, we have developed a mouse model of burn injury that encompasses the persistent hypersensitivities to thermal and mechanical stimulus modalities that are consistently reported clinically. Furthermore, we have identified a novel calcium-activated chloride channel, anoctamin 1, that contributes to persistent burn pain. We found that pharmacological inhibition of this channel attenuates both thermal and mechanical hypersensitivity on the day of peak burn injury-evoked pain.
To provide a neurophysiological correlate to burn injury-induced hypersensitivity observed behaviorally, we investigated spontaneous and stimulus-evoked response properties of sensory nerve fibers innervating burn-injured glabrous skin at peak nociception. Preliminary data suggest that pain-transducing sensory nerve fibers are activated at lower mechanical stimulation thresholds and display increased spontaneous firing frequency in burn-injured glabrous skin relative to sham controls.
The complementary behavioral and electrophysiological approaches provide a means to identify novel targets contributing to enhanced transmission of nociceptive signals and existence of ongoing burn injury-associated pain. Ongoing experiments will further characterize the stimulus-evoked and spontaneous discharge phenotype of sensory neurons at their peripheral terminals and how anoctamin 1 may contribute to burn injury-evoked alterations. Pharmacological modulation of this channel may serve as an effective treatment strategy for ongoing debilitating burn pain in patients.

Title: Voluntary behaviors as readouts for persistent pain in mice

Authors: ***T. SHEAHAN**, E. R. SIUDA, A. J. SHEPHERD, D. P. MOHAPATRA, R. W. GEREAU, IV, J. P. GOLDEN;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Chronic pain represents an immense clinical problem, with over 100 million Americans afflicted and an annual price tag exceeding half a trillion dollars. One of the major hurdles to effective translation of basic pain research findings is the lack of research that directly translates from animal models into human studies. There is ongoing discussion regarding the validity of using only reflex/withdrawal measures of pain in animal studies, as these endpoints may not adequately model the complexities of human pain. The development of assays that reflect pain-induced changes in voluntary behaviors is therefore important in increasing the broad translatability of preclinical findings. Recently, voluntary wheel running, gait analysis, and social interaction have been used as endpoints to assess non-evoked pain responses in rodents. However, in some cases, it remains unclear if behavioral changes are due to pain or other comorbidities of injury (*i.e.* motor deficits). We tested voluntary wheel running, Catwalk automated gait analysis, and a social approach assay as measures of pain in the context of inflammatory and nerve injury-induced pain in adult C57BL6/J mice. When changes in voluntary behaviors were observed following injury, we tested whether such changes could be reversed by known analgesics. Supported by NINDS grants R01NS042595 and R01NS069898.

Title: Processing temperature stimuli: from receptors to behavior

Authors: *M. GALLIO;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Temperature affects nearly every biological process, hence it is not surprising that animals evolved sophisticated ways to sense and respond to temperature changes. How are hot and cold stimuli detected at the periphery? How are they processed in the brain? How are they integrated to produce behaviors such as temperature preference or avoidance of noxious extremes? We study temperature detection and processing using a variety of systems, from in vitro studies aimed at understanding the molecular mechanisms of heat detection, to whole-brain

imaging in the fruit fly Drosophila, a system ideally suited for the study of simple decision making and innate behavior.

Title: A neuropeptide signaling regulates starvation-dependent reduction of heat nociception in *Drosophila*

Authors: *H. OHASHI, T. SAKAI;
Dept. of Biol. Sciences, Tokyo Metropoli, Hachioji, Tokyo, Japan

Abstract: Nociception is one of the most important sensory functions for animal survival. Many animals typically show escape behavior toward noxious stimuli. Feeding is also essential for animal survival, and hunger can modify various physiological functions. However, it remains unclear whether hunger affects nociception. Here, we report that wild-type *Drosophila melanogaster* shows the reduction of heat nociception after starvation. Immediately after wild-type flies are placed on the hotplate (≧44℃), they show jumping behavior to escape from noxious heat stimuli. To examine whether starvation can modify the responses to noxious heat, we used starved wild-type flies. After 6 and 12h of starvation, the number of flies showing the jumping behavior at 44℃decreased in comparison with that of non-starved flies. Thus, it is possible that 6-12h of starvation inhibits heat nociception.
We further established a novel behavioral assay of heat nociception using decapitated flies. Unlike the normal wild-type flies, the decapitated wild-type flies did not show jumping behavior toward noxious heat stimuli. However, they frequently showed tumbling behavior that gets up after falling on a hotplate. In contrast to the wild-type flies, the frequency of this behavior was significantly inhibited in painless mutant flies with defective heat nociception, indicating that the tumbling behavior can be used as the responses to noxious heat in decapitated flies. Using this behavioral assay, we next examined whether decapitated flies also show the starvation-dependent reduction of heat nociception. After 12h of starvation, decapitated wild-type flies showed normal heat nociception. Thus, it is possible that the reduction of heat nociception results from the starvation-dependent modification of brain functions.

In *Drosophila*, various neuropeptide signals influence feeding behavior because hunger/satiety state can be modified through neuropeptide release from neurosecretory cells in the brain. Thus, we next examined whether neuropeptides and their receptors involved in the regulation of feeding behaviors affect the starvation-dependent reduction of heat nociception. Mutant flies of *leucokinin* (*Lk*) did not show a significant reduction after 12h of starvation, suggesting that the Lk signaling can modify the responses to noxious heat. Since Lk acts as a full signal in *Drosophila*, it is likely that the reduction of Lk release in the brain triggers starvation-dependent reduction of heat nociception.

Title: Relationship between pain and anxiety in a model of facial carcinoma in rats.

Authors: *E. GAMBETA, C. M. KOPRUSZINSKI, R. C. DOS REIS, J. M. ZANOVELI, J. G. CHICHORRO;
Pharmacol., Federal Univ. of Parana, Curitiba, Brazil

Abstract: Orofacial cancer is highly incident in the world population. It is well known that pain and anxiety are common symptoms in this condition, and both significantly impair the quality of life of cancer-suffering patients. Pain control in cancer is considered highly unsatisfactory and associated with frequent and severe side effects. Moreover, clinical studies indicate that anxiety disorders are under diagnosed and undertreated in these patients population. For this reason, studies are warranted to better understand the relationship between cancer pain and anxiety and to provide new strategies that can help to control both symptoms. The aim of this study was to investigate the relationship between facial sensory changes and the anxiety-like behavior in rats with facial carcinoma. In addition, to investigate the influence of the anticonvulsant pregabalin, a drug with potential analgesic and anxiolytic-like effect, in both aspects. Facial carcinoma was induced by tumor Walker-256 cells subcutaneous inoculation in the right vibrissal pad of male Wistar rats. On the third and sixth day after inoculation, facial mechanical hypersensitivity was assessed by the application of a series of Von Frey filaments in the vibrissa pad, followed by animals analysis on the elevated plus maze, light-dark transition and open field tests. In a different set of experiments, the effect of pregabalin treatment (30 mg/kg, p.o.) was evaluated in all tests. All experimental procedures were previously approved by UFPR's Committee on the

Ethical Use of Animals (#938). Our results demonstrated that on day 3 after tumor cells inoculation, tumor-bearing rats showed facial mechanical hypersensitivity, but the anxiety-like behavior was not detected. On the other hand, on day 6 after tumor cells inoculation, tumor-bearing rats displayed facial mechanical hypersensitivity and anxiety-like behaviors.. In addition, systemic treatment with pregabalin was able to reduce facial mechanical hypersensitivity for 2 to 4 hours after its administration, and produced an anxiolytic-like effect when assessed in the EPM. In conclusion, our data indicate that facial tumor-bearing rats develop early mechanical hypersensitivity, which precedes the development of the anxiety-like behavior. Pregabalin may represent a useful drug in the treatment of both conditions. We thank CAPES for the financial support.

Title: Involvement of TRPV-1 receptors on thermal nociception in rats subjected to intraarticular persistent inflammation

Authors: *C. R. LEITE-PANISSI[1], J. K. NEUBERT[2], R. M. CAUDLE[2];
[1]Ribeirao Preto Dent. Sch. - USP, Ribeirao Preto, Brazil; [2]Univ. Of Florida, Gainesville, FL

Abstract: Orofacial pain has a high prevalence associated with debilitating disorders in modern society involving the neck, face, head and all intra-oral structures. In addition, temporomandibular joint (TMJ) -associated inflammation is considered to be one of the reasons for the pain reported by patients with temporomandibular disorders (TMD). Nevertheless, our previous study has shown that TMJ persistent inflammation promoted an anxiogenic-like effect in rats. To study orofacial pain mechanisms, a model using the operant behavior was developed and correlates orofacial pain with psychological processes. So, the aim of this study was to characterize thermal orofacial sensitivity (cold, neutral and hot stimuli) during development of TMJ using the operant behavior. In addition, we evaluated the role of transient receptor potential vanilloid 1 (TRPV1) on nociceptive responses of rats with TMJ persistent inflammation. The experiments were performed with hairless Sprague-Dawley rats (male and female, 250-300g)

with or without TMJ inflammation induced by carrageenan (CARR). The orofacial pain was evaluated on the operant orofacial pain assessment device (OPAD) in the presence of a range of cold, neutral and hot stimuli. Resiniferatoxin (RTX) was administered into TMJs prior CARR to lesion TRPV1-expressing neurons. Our results show that the number of facial contacts was significantly altered by the temperature of the thermodes in males and females with persistent TMJ inflammation. Particularly, we observed an increased number of facial contacts and alterations in the aversive index on neutral and cold temperature. However, the hot temperature (42°C) did not modify the parameters analyzed on the OPAD test (male or female rats). Additionally, the present results revealed that prior administration of RTX in the TMJ prevented the thermal hyperalgesia induced by CARR. In conclusion, the results show that the TMJ persistent inflammation altered the orofacial sensibility evaluated by OPAD. In particular, CARR administered into TMJ increased the number of face contacts and reduced the lick/face contact ratio (L/F) at cold (21°C) and neutral (37°C) temperatures in female and male rats. Additionally, our results show that at neutral temperature the hyperalgesia is longer in females compared to males. And, it was possible that TRPV1 is involved in this inflammatory hyperalgesia because the pre-administration of RTX into TMJ, that promote a pharmacological lesioning of TRPV1-expressing neurons, reduced these effects on male and female rats.

Title: Postoperative pain in aged mice

Authors: M. PATIL[1], J. MECKLENBURG[1], *A. N. AKOPIAN[2];
[1]UTHSCSA, San Antonio, TX; [2]UT Hlth. Sci. Ctr., San Antonio, TX

Abstract: Introduction: There is consensus that wound healing dynamics, biochemistry, physiology, and anatomy in the elderly is negatively altered by age (Benyamin et al., 2008; Portenoy et al., 2004). In addition, old age could affect plasticity in the nociceptive pathway. Very little basic research has been conducted on aged animals and some data contradict one

another (Yezierski, 2012; Weyer et al., 2016). Thus, it is unknown how old age affects postoperative pain. Accordingly, we have investigated whether postoperative thermal and mechanical hypersensitivity time-course and magnitude are altered in aged mice compared to adults. Given that hyperalgesic priming is an indicator of nociceptive pathway plasticity, we also evaluated whether age alters surgery-induced hyperalgesic priming. **Methods:** We used plantar incision model to model postoperative pain conditions in mice (Pogatzki and Raja, 2003). Thermal and mechanical nociception was measured using Hargreaves apparatus and Dynamic Plantar Aesthesiometer, respectively. Surgery-induced hyperalgesic priming was evaluated by PGE2 administration 10 and 24 days post-surgery for adults and aged mice, respectively. **Results:** Despite the fact that both 18-month-old and 24-month-old mice are considered "aged" their postoperative thermal and mechanical hypersensitivity was dramatically different magnitude and time-course-wise. Thus, adult (2-6 month-old) and 18 month-old mice have similar postoperative thermal and mechanical hypersensitivity levels and time-course (last 7-10 days). In contrast, postoperative thermal and mechanical hypersensitivity was more pronounced and lasted as long as 21 days for 24-month-old mice. Surgery-induced hyperalgesic priming was also statistically different in aged compare to adult mice. **Conclusion:** Postoperative hypersensitivity characteristics including hyperalgesic priming is dramatically altered by aging, especially in 24 month-old mice. This may indicate that neuronal plasticity is altered in the pain pathways in aged mice compared to adults. Therefore, pain management techniques will need to be adjusted in aged individuals.

Title: Inflammatory abdominal pain disrupts performance in a visual attention task in rats.

Authors: *T. J. MARTIN, T. J. STRASSBURG, S. A. KIM, D. G. RIRIE, J. C. EISENACH; Anesthesiol., Wake Forest Univ. Sch., Winston Salem, NC

Abstract: Pain is a multisensory experience that produces behavioral effects across sensory/discriminative, affective/motivational, and cognitive domains. In laboratory animals, much work has focused on the sensory aspects of pain, with the affective/motivational and cognitive domains having received greater attention of late. Pain is known to interfere with tasks requiring sustained attention in humans, however similar effects of pain in laboratory rodents have not been well documented. We recently developed a variant of the 5 choice serial reaction time task in which task difficulty is systematically adjusted in real time to match the performance capabilities of the subject. This is achieved by altering the visual cue duration, such that cue duration decreases following correct responses and increases following incorrect responses or omissions. The sensitivity of this behavior in rats to inflammatory abdominal pain was examined using intraperitoneal injections of dilute lactic acid. The primary endpoint of visual attention performance was the median cue duration (MCD), which was increased in a linear manner (r^2=0.95) by injection of lactic acid concentrations ranging from 0.9% - 5.4% (v/v, 1 ml/kg i.p.). The MCD increased from 0.6±0.1 s at baseline to a maximum of 30±2.5 s after injection of 5.4% lactic acid. Pretreatment with either morphine (0.3-3.0 mg/kg, s.c.) or ketoprofen (0.03-0.3 mg/kg, s.c.) dose-dependently blocked the effects of 1.8% lactic acid injection on visual attention performance. Injection of scopolamine (0.03-0.3 mg/kg) also increased MCD in a dose-dependent manner, however pretreatment with either morphine (3.0 mg/kg) or ketoprofen (0.1 mg/kg) failed to alter the effects of scopolamine. The cue duration titration variant of the 5 choice serial reaction time task is sensitive to disruption by inflammatory abdominal pain in rats, and is reversed by analgesic doses of morphine and ketoprofen. This assay may prove valuable in understanding the basic mechanisms by which pain alters attention processing in rodents, as well as provide a means for assessing the efficacy of novel analgesics for attenuating attention deficits in the presence of pain. Title: Assessing age differences in multiple pain behavior assessments

Authors: *C. A. SALCIDO, M. K. GELTMEIER, N. L. MOORE, P. N. FUCHS;
Univ. of Texas At Arlington, Arlington, TX

Abstract: The elderly population is currently the fastest growing demographic of the world. As the prevalence of persistent pain increases with age, the elderly are estimated to comprise a large percent of the 126.1 million American adults that suffer from pain. Yet despite this high prevalence and increasing population, there remains much ambiguity about age-related patterns of pain. This is in part due to equivocal or lack of data from clinical research, driven by patients' reluctance to discuss pain, the misconception that pain is a natural part of the aging process, or age-related cognitive impairment. In pre-clinical models, the overwhelming majority of studies utilize young adult rodents (3-6 month) and there are surprisingly few studies with older animals. Therefore, the purpose of this study was to provide data on a number of preclinical behavioral nociceptive assessments. In this comprehensive assay, one hundred and thirty-seven Sprague Dawley rats ranging from 3-6, 11-15, and 18-24 months were assessed using mechanical paw withdrawal threshold testing (MPWT), thermal threshold testing, formalin, place-escape avoidance paradigm (PEAP), and open-field testing. The results revealed a significant decrease in MPWT assessments for 18-24 month animals compared to 3-6 months. Unexpectedly, there were no significant differences across age for thermal threshold testing. For formalin testing, there were significant increases in mean pain score for 11-15 and 18-24 month animals compared to 3-6 month animals. For PEAP assessments, data revealed significant decrease in avoidance behavior for 18-24 months carrageenan treated animals compared to 3-6 month animals. Lastly, there were significant reductions in the total distance travelled and mean velocity for 11-15 and 18-24 month animals compared to 3-6 month animals. Thus, the results of this study suggest specific patterns of age-related differences, with older animals showing enhanced nociceptive responses involving mechanical reflexive testing and acute inflammatory models, but less responding in a measure of pain affect. Future studies should seek to further assess the relationship between pain and age in order to obtain a comprehensive understanding of pain behaviors with a goal of investigating the underlying biological mechanisms that that influence age related pain-behaviors. Ultimately, such an approach can provide critical information that can translate to clinical populations and lead to improvements in the quality of life of the elderly population.

Title: Effects of Phα1β on the analgesic and adverse effects of repeated morphine treatment in a mouse model of postoperative pain

Authors: *R. TONELLO[1,2], G. TREVISAN[3], M. V. GOMEZ[4], J. FERREIRA[1];
[1]Pharmacol., Federal Univ. of Santa Catarina, Florianópolis, Brazil; [2]Dept. of Anesthesiol., Univ. of Cincinnati Med. Ctr., Cincinnati, OH; [3]Univ. do Extremo Sul Catarinense, Criciúma, Brazil; [4]Inst. de Ensino e Pesquisa da Santa Casa de Belo Horizonte, Belo Horizonte, Brazil

Abstract: Background: Opioids are the "gold standard" treatment for postoperative pain, but these drugs also have limiting adverse effects. Thus, adjuvant drugs might be useful in opioid therapy for postoperative pain. An important target for opioid-induced analgesia is the blockade of voltage-gated calcium channels (VGCCs). Phα1β, a peptide purified from the venom of the Brazilian armed spider *Phoneutria nigriventer,* is a VGCC blocker. The aim of the present study was to evaluate effects of Phα1β, on the antinociceptive and adverse effects of morphine in a mouse model of postoperative pain. **Methods:** In this randomized and blinded study, we evaluated the effect of intrathecal (i.t.) injection Phα1β on the antinociceptive (reduction of mechanical hyperalgesia and guarding behavior) and adverse effects (tolerance, constipation, hyperalgesia and withdrawal syndrome) induced through single or repeated (increasing doses, 3 times a day for 3 consecutive days) subcutaneous (s.c.) injections of morphine in C57/BL6 mice subjected to right hind plantar incision. This study was approved by the Committee on the Use and Care of Laboratory Animals of our university (Process No. 117/CEUA/PROPESQ/2013. Procedure PP00872). **Results:** Single injections of Phα1β (100-300 pmol/site, i.t.) or morphine (3-10 mg/kg, s.c.) reversed post-operative nociception in mice. Moreover, in doses that did not produce antinociception when administered separately, Phα1β (30 pmol/site, i.t.) and morphine (1 mg/kg, s.c.) produced an expressive analgesic effect when concomitantly administered. Repeated treatment with morphine in operated mice caused not only tolerance to its antinociceptive effect but also induced paradoxical heat and mechanical hyperalgesia, withdrawal syndrome and constipation. Except constipation, Phα1β (30 pmol/site, i.t.) was able to reverse these adverse effects. **Conclusions:** Taken together, these findings demonstrated that Phα1β not only presented analgesic effects but also potentiated the analgesia and reversed some adverse effects of morphine on operated mice, indicating the potential use of this agent as an adjuvant drug in opioid therapy for postoperative pain.

Title: Characterization of pain associated behaviors in a rat model of temporomandibular joint osteoarthritis.

Authors: *S. SANNAJUST[1], I. IMBERT[2], T. KING[2];
[1]Biomed. Sci., [2]Univ. of New England, Biddeford, ME

Abstract: Temporomandibular disorder (TMD) is a musculoskeletal orofacial disorder characterized by pain in the temporomandibular joint (TMJ). Although TMD is a heterogeneous disorder, osteoarthritis (OA) has been found to be present in approximately 15% of the patients. Pain is the primary complaint associated with loss of function in these patients and is a primary motivation for these patients to seek medical care. We characterized a rat model of TMJ OA in which monosodium iodoacetate (MIA) is injected into the TMJ at a dose previously established to produce cartilage loss. We tested the hypothesis that MIA injection into the TMJ produces tactile hypersensitivity, alters meal patterns, and produces ongoing pain using conditioned place preference (CPP). MIA altered meal patterns 7 days post-MIA, with reduced time spent eating and increased the number of meals eaten overnight. Combined, these meal patterns resulted in no changes in overnight time spent eating compared to saline control rats. In addition, no weight loss was observed in MIA treated rats compared to saline controls. These changes in meal eating patterns were not observed D14 post-MIA, with no change in meal duration or number of meals eaten overnight compared to saline treated controls. These data indicate that MIA injection into the TMJ produced a transient change in meal eating behaviors that resolved by 14 days post-MIA. MIA into the TMJ produced tactile hypersensitivity at the joint and infraorbital test sites within 7 days that continued through 14 days post-injection. Administration of lidocaine systemic lidocaine (10 mg/kg, s.c.) D14 post-MIA reversed the MIA-induced tactile hypersensitivity within 60 min post-injection. In addition, MIA treated rats demonstrated CPP to systemic lidocaine (10 mg/kg, s.c.) indicating that this dose of lidocaine alleviates ongoing pain. These observations indicate that MIA-induced OA of the TMJ produces tactile hypersensitivity and ongoing pain that can be reversed with lidocaine 14 days post-MIA. Notably, these pain behaviors were observed at a time when meal eating behaviors had normalized, indicating that the rats adapted to the ongoing joint pain. These results indicate that we have developed a model of osteoarthritis of the TMJ. This model may lead to improved mechanistic understanding of the mechanisms driving TMJ pain that is necessary for development of improved therapeutic

strategies for this subpopulation of TMD patients. This work was funded in part by COBRE grant P20GM103643.

Title: Effect of pregabalin on spinal wide dynamic range neuronal activity, burrowing behavior of reserpine-induced fibromyalgia in rats

Authors: V. GOURA, A. VUYYURU, R. KALLEPALLI, P. JAYARAJAN, R. NIROGI, *S. M. IRAPPANAVAR;
SUVEN LIFE SCIENCES LTD, HYDERABAD, India

Abstract: Chronic pain is an abnormal and non-protective response which represents a major health problem. Chronic widespread pain is a core symptom in fibromyalgia patients. We investigated the effect of pregabalin in central sensitivity syndrome (like fibromyalgia). Fibromyalgia was induced in rats using reserpine (1 mg/kg s.c., once daily for three consecutive days), basal reading was obtained on day 4 after final dose of reserpine using Von Frey filaments / analgesymeter. Selected rats were used for experimentation. Central sensitization was investigated using in-vivo electrophysiology in dorsal horn neurons of fibromyalgia in rats. Central sensitization clinically and physiologically represents allodynia and hyperalgesia conditions, we investigated for the same using Von Frey monofilaments (allodynia) and analgesymeter (hyperalgesia). Further we investigated to translate “bedside-to-bench” outcomes from the human pain phenotype to rodents for the first time in reserpine induced fibromyalgia in rats through burrowing behavior (which evaluates non-evoked and unbiased pain response). Results indicate pregabalin significantly reversed electrically evoked response of the dorsal horn neurons, attenuated mechanically evoked pain response using Von Frey monofilaments and analgesymeter. Analgesic activity of pregabalin significantly reversed burrowing defects due to pain in rodents. Results suggest that pregabalin may be effective against multiple aspects of fibromyalgia.

Title: The effect of aging on peripheral kappa opioid receptor-mediated antinociceptive signaling

Authors: *E. JENNINGS, H. R. SMITH, P. LOCOCO, J. ZAMORA, T. CHAVERA, K. BERG, W. CLARKE;
Pharmacol., Univ. Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Pain management in the growing elderly population is a major medical challenge. Targeting peripheral opioid receptors could provide effective and safer medications for the elderly, bypassing centrally mediated adverse effects. However, little is known regarding the effects of aging on nociceptor (pain-sensing neuron) responsiveness or the functionality of opioid receptors expressed on nociceptors. Here, we determined the effects of the kappa opioid receptor (KOR) agonist, Salvinorin A (Sal A), on nociceptors in young (4-months-old) and aged (26-months-old) Fisher x Brown Norway rats. Behavioral responses to noxious heat were measured following intraplantar injections of opioid agonists. Intraplantar (i.pl.) administration of Sal A produced significant antinociceptive responses in aged rats. By contrast, antinociceptive responses were not observed in young rats at this dose. Similarly, KOR-mediated inhibition of adenylyl cyclase activity was greater in nociceptors derived from aged versus young rats. Intraplantar injection of young rats with Sal A produced significant antinociceptive responses following exogenous administration (i.pl.) of arachidonic acid (AA). Administration of AA had no additive effect on antinociceptive responses in aged rats. Our results indicate that aging alters kappa opioid receptor sensitivity to agonists, such that in non-inflamed tissue Sal A produces an

antinociceptive effect in aged rats only. We propose that peripherally-restricted kappa agonists may be a valuable analgesic strategy for treating pain in the elderly.

Title: Confirmation of pain-related behavior changes of newly developed persistent post-operative pain model by using MyD88 and TRIF knock out mice

Authors: *A. NAKAE[1], K. NAKAI[2], Y. KUMAGAI[1], K. HOSOKAWA[3], Y. YOSHIOKA[1]; [1]Osaka Univ. Immunol. Frontier Res. Cent, Suita, Japan; [2]Univ. of Fukui hospital, Eiheiji, Japan; [3]Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Background: Persistent post-operative pain has recently been recognized as adversely affecting the patients' quality of life. The International Association of the Study of Pain defines persistent postoperative pain (PPP) as pain that persists for more than 3 months after surgery. However, general animal models of postoperative pain show that their pain lasts a maximum of two weeks. Whereas, based on a chronic constriction injury model, the nerve injury impedes sensory functions of the affected area for about two weeks. Thus, there is a need to develop a new animal model of PPP. This model can be used to evaluate their condition continuously from just after surgery to chronic pain periods. Inflammatory response is crucial when the symptoms of pain appears after surgery. It is well known that the MyD88 and TRIF pathway is important for innate immune reaction. A few studies revealed that these genes' knock out mice showed less pain-related behavior by modulating the cytokine dependent pain pathway. The aim of this study is to confirm the significant changes of pain-related behavior of the newly developed PPP model by using MyD88-/- and TRIF-/- mice. Methods: All experiment protocols in this study were approved by the Animal Care and Use Committee of Osaka University. C57Bl/6J mice, MyD88-/- mice and TRIF-/- mice were anesthetized and laid in the prone position. The new PPP model was developed accordingly as follows; the incision is made around plantar skin and the flap is raised with preserving posterior tibial vessels and nerves. Afterwards, the flap is sutured into the original position. Behavioral tests were carried out before the surgery and after the surgery-1 to 3

days post-surgery and 1, 2 and 4 weeks post-surgery. Von Frey Filaments were delivered to the injured hind paw. For behavioral experiments, data were evaluated by two-way analysis of variances followed by a Tukey-Kramer multiple comparison test. Results below 0.05 is considered significant. Results & Discussion: The PPP surgery to the hindpaw induced mechanical hyperalgesia that startedThank 1 day after surgery and lasted 4 weeks after surgery. Compared to the wild type mice, MyD88$^{-/-}$ and TRIF$^{-/-}$ mice showed significantly higher withdrawal threshold at 1 and 2 days after surgery, whereas, 2 and 4 weeks after surgery, MyD88$^{-/-}$ showed higher withdrawal threshold than wild type mice. These results showed that the new PPP model could be used for the study of PPP in mice and MyD88$^{-/-}$ and TRIF$^{-/-}$ may be important factors for maintaining persistent pain states.

Title: Activation of spinal membrane estrogen receptors rapidly attenuates opioid receptor-like 1 (ORL1) receptor-mediated modulation of nerve injury-induced tactile hypersensitivity in the rat

Authors: *D. M. HECKARD[1], S. NAG[2], S. S. MOKHA[2];
[2]Neurosci. and Pharmacol., [1]Meharry Med. Col., Nashville, TN

Abstract: Numerous studies have reported that women have a higher prevalence of chronic pain disorders such as temporomandibular joint disorder, fibromyalgia etc. We have previously shown that estrogen attenuates opioid receptor like -1 (ORL1) receptor mediated antinociception in females [Claiborne et al. J Neurosci. 26:13048-53, 2006]; and down regulates the ORL1 gene expression [Flores et al. Neurosci. 118:769-78, 2003]. Recently, we have shown that activation of selected membrane estrogen receptors (mERs: GPR30, Gq-MER, ERα, but not ERβ) abolishes ORL1-mediated acute thermal antinociception via an ERK2-dependent non-genomic mechanism [Small et al. Neurosci. 255:177-190, 2013]. However, whether the activation of mERs attenuates ORL1-mediated modulation of nerve injury-induced tactile hypersensitivity is unknown. Thus,

the present study was designed to investigate whether activation of spinal mERs attenuates ORL1-mediated modulation of nerve injury-induced mechanical hypersensitivity. We employed the spared nerve injury (SNI) model as previously described by Decosterd and Woolf [Pain. 87:149-58, 2000] to induce mechanical hypersensitivity in male and ovariectomized (OVX) female Sprague Dawley rats. Stretched PE10 cannulae were also implanted intrathecally at the same time. After a 7-day recovery period, E2BSA, a membrane impermeable analog of estradiol, or a selective mER agonist and OFQ, the endogenous ligand for the ORL1, were co-administered intrathecally. Paw withdrawal thresholds (PWTs) were recorded using an automated dynamic plantar aesthesiometer. SNI significantly reduced PWTs in both males and OVX females. Intrathecal administration of OFQ significantly increased PWTs in both groups with or without SNI. E2BSA as well as selective mER activation abolished OFQ-induced increase in PWTs. Thus, we conclude that activation of mERs rapidly attenuates ORL1-mediated modulation of nerve injury-induced mechanical hypersensitivity. This may constitute a biological mechanism that increases female vulnerability to the development of chronic pain disorders.

Title: The role of spinal adrenoceptor subtypes in trigeminal nerve injury-induced mechanical hypersensitivity of rats

Authors: *K. NAKAI[1], A. NAKAE[2], T. KUBO[3], Y. MINEGISHI[1], Y. FUJINO[4], K. HOSOKAWA[3];
[1]Univ. of Fukui Hosp., Eiheiji-Cho, Fukui, Japan; [2]WPI Immunol. Frontier Res. Center, Osaka Univ., suita, Japan; [3]Plastic Surgery, [4]Anesthesiol. & Intensive Care Med., Osaka Univ. Grad. Sch. of Med., suita, Japan

Abstract: (Background) Substantial evidences revealed that descending spinal adrenergic transmission had an important role in the process of pain modulation. Spinal administration of the alpha 1 and alpha 2 adrenergic receptor agonists has been shown to produce antinociception. The contribution of spinal alpha 1and alpha 2 adrenergic receptor subtypes in inhibiting the

trigeminal neuropathic pain remained unclear. Chronic constriction injury to the infraorbital nerve (ION-CCI) has been proven a useful model for trigeminal neuropathic pain. The present study evaluated the possible role of spinal alpha1A, alpha2A, and alpha2C adrenergic receptors in ION-CCI rat model.
(Material and Methods) Male Sprague Dawley rats underwent unilateral CCI to the right ION. Two nylon (5-0) ligatures were tied around the ION. Series of von Frey filaments were used to determine pain hypersensitivity to mechanical stimulation on day 14 after surgery. A polyethylene (PE-10) catheter was implanted for upper cervical spinal injection of drugs. The rats were allowed to recover for 7 days. The time course of the antiallodynic effects and the dose-response effects of intrathecally administered an alpha 1A adrenergic receptor agonist A 61603, an alpha 1A adrenergic receptor antagonist WB 4101, an alpha 2A adrenergic receptor agonist guanfacine, an alpha 2A adrenergic receptor antagonist BRL 44408, an alpha 2C adrenergic receptor agonist nitrobiphenyline, and an alpha 2C adrenergic receptor antagonist JP 1302 were examined. The time course data for the dose-response effects were analyzed by two-way analysis of variance and Tukey-Kramer multiple-comparison test. (Results) Intrathecal administration of A 61603, guanfacine, and nitrobiphenyline increased mechanical thresholds in a dose dependent manner (P <0.05). Intrathecal administration of WB 4101, BRL 44408, and JP 1302 did not alter mechanical thresholds. (Conclusions) The results indicated that descending pain inhibitory system in the spinal cord may be activated via spinal alpha1A, alpha2A, and alpha2C adrenergic receptors in a rat model of trigeminal neuropathic pain.

Title: Oxytocin-induced analgesia is facilitated by the vasopressin 1b receptor in mice

Authors: *J. C. MORALES-MEDINA[1], H. K. CALDWELL, 44240[2];
[1]Ctr. for Res. and Advanced Studies, Tlaxcala, Mexico; [2]Biol. Sci., Kent State Univ., kent, OH

Abstract: The neuropeptides arginine vasopressin (Avp) and oxytocin (Oxt) act as strong antinociceptive agents. However, the receptors that mediate the antinociceptive effects of Avp

and Oxt remain unknown. While the physiological effects of Avp are mediated by three receptors Avp 1a receptor (Avpr1a), Avp 1b receptor (Avpr1b), Avp 2 receptor (V2); the effects of Oxt are modulated a single receptor subtype, the Oxt receptor (Oxtr). However, all four receptors are sensitive to both nonapeptides. In the present study, we aimed to investigate whether genetic deletion of the *Avpr1b* (Avpr1b KO), in mice, had antinociceptive effects on their response to Avp, Oxt and osmotic stress (OS) challenge in the absence of injury and after peripheral inflammation with the complete Freund's adjuvant (CFA). Avpr1b KO mice had increased mechanical thresholds after Oxt administration in control and CFA-treated mice. Most notably, Avpr1b KO mice had reduced mechanical hypersensitivity after CFA administration, with no changes in paw edema. Thus, these results suggest Avpr1b is involved in nociception and facilitates the antinociceptive effects of Oxt.

Title: Effects of monoamine uptake inhibitors on pain-depressed behavior in mice.

Authors: K. ALEXANDER, T. RODRIGUEZ, A. SARFO, T. B. PATTON, *L. L. MILLER; Psychological Sci., Augusta Univ., Augusta, GA

Abstract: Pain-related decreases in behavior are among the primary diagnostic and treatment concerns for physicians, but preclinical laboratory research on pain often does not address this important endpoint. For instance, intraperitoneal injection of dilute lactic acid is a nociceptive pain stimulus that stimulates a stretching response in rodents, and drug-induced decreases in acid-stimulated stretching is interpreted as a pain-relieving effect. Such pain-related stimulation of behavior bears little resemblance to clinically-relevant pain-related depression of behavior. Studies that address the motivational consequences of pain may improve understanding of pain

mechanisms, and contribute to the development of new pain treatments. In the present study, we modeled pain-related depression of behavior by examining nesting behavior in male ICR mice. Nest building is an innate mouse behavior that occurs at a high rate under control conditions. Nesting is depressed by intraperitoneal injection of dilute lactic acid (0.56%), and the clinically effective nonsteroidal anti-inflammatory drug (NSAID) ketoprofen blocks acid-induced depression of nesting. Monoamine uptake inhibitors have a history of use as antidepressants, but have more recently been used in the treatment of pain. This project examines effects of monoamine uptake inhibitors with varying selectivity for serotonin (5HT), norepinephrine (NE) and dopamine (DA) transporters on pain-related depression of nesting. Citalopram (5HT-selective), nisoxetine (NE-selective), milnacipran (mixed action, 5HT/NE-selective), and bupropion (DA-selective) were evaluated for their ability to block lactic acid-induced depression of nesting and lactic acid-stimulated stretching behavior. Consistent with previous findings in other assays of acute pain-related depression of behavior, monoamine uptake inhibitors lacking significant activity at dopamine transporters do not block acid-depressed nesting, but do block acid-stimulated stretching. These findings suggest that serotonergic and noradrenergic monoamine uptake inhibitors have limited efficacy in the treatment of acute pain-related depression of behavior. Unlike findings from studies using other models of acute pain-related depression of behavior, the DA-selective uptake inhibitor bupropion also did not block acid-depressed nesting. Together these findings support the use of assays of pain-depressed behavior to study motivational aspects of pain, but point to the need for more work to identify determinants of the expression, mechanisms, and treatment of pain-related depression of behavior.

Title: Sound stress activates corticotropin-releasing factor receptor-2 (CRFR2) in the lumbar spinal cord of rats with thermal injury

Authors: *N. SOSANYA, A. TREVINO, R. CHAVEZ, R. CHRISTY, B. CHEPPUDIRA; Battlefield Pain Mgmt., Inst. Of Surgical Res., JBSA Ft Sam Houston, TX

Abstract: Introduction: Studies have shown that exposure to stressful stimuli alters basal pain processing and also exacerbates injury induced pain. However, the underlying mechanism associating stress and pain remains unclear. Corticotropin-releasing factor (CRF) signaling pathways play an important role in stress-induced disorders including pain. The present study examined the involvement of CRFR2 in sound stress-induced changes in hyperalgesic behaviors of rats with thermal injury.
Methods: Sound stress in male Sprague Dawley rats was induced by exposing them to 105 dB tone over several different frequencies ranging from 11 to 19 kHz, each lasting for 5- 10 s within a 30 min period, over 3 consecutive days. One day after induction of sound stress, rats were deeply anesthetized and subjected to unilateral partial-thickness thermal injury by placing a pre-heated (100° C) soldering tip on the mid-plantar surface of the right hind paw for 30 sec. The development of hyperalgesic behavior was assessed at 1, 4, 7, and 14 days using the Hargreaves' thermal test. Following behavioral experiments, the animals were euthanized and the lumbar spinal cord section was harvested and analyzed for CRF2 receptors using qRT-PCR and gel electrophoresis validation of PCR products.
Results: Consistent with earlier reports, the thermal injury alone led to persistent thermal hyperalgesia on the injured paw (ipsilateral), but not on the contralateral paw. However, thermal injured rats that had prior exposure to sound stress exhibited greater magnitude of hypersensitivity compared to control rats (non-stressed + burn injured rats). Additionally, the mRNA expression level of CRFR2 was significantly upregulated in the lumbar spinal cord of thermal injured rats that had prior exposure to sound stress, but not in rats that just received thermal injury.
Conclusion: These novel results indicate that sound stress alters CRF2 receptors expression in the lumbar spinal cord. This data suggests that sound stress following thermal injury activates and releases CRF which in turn binds CRF2 receptors resulting in exacerbated pain behaviors.

Title: Conditioned place preference/aversion facilitates prolongation of migraine pain-related affective behavior after single meningeal CFA administration

Authors: *S. KOKANE[1], C. NAIG[2], A. NGO[2], F. TAO[3], Q. LIN[1];
[1]Psychology, [2]Univ. of Texas At Arlington, Arlington, TX; [3]Biomed. Sci., Texas A&M Hlth. Sci. Ctr. Baylor Col. of Dent., Dallas, TX

Abstract: Current animal models of chronic headache (migraine) involve activating nociceptors of the trigeminal afferents present on the meninges by repeatedly administering a mixture of inflammatory mediators in to the cisterna magna or via direct topical application on the dura. Single administration of inflammatory mediators has been shown to induce acute migraine-like headache that lasts for up to 24-48 hours.In our study, we injected 5 µl of Complete Freund's adjuvant (CFA) directly on to the dura of adult C57BL/6 male mice. Von Frey filaments were used to determine cutaneous allodynia in the craniofacial region. We also used the conditioned place preference/aversion (CPP/A) paradigm to determine the persistence of negative affective component associated with migraine-like headache.We observed that cutaneous allodynia persisted for 72 hours after single CFA application. After 72 hours, mechanical thresholds in the craniofacial regions reverted back to baseline. Interestingly however, after conditioning the animals using the CPP/A paradigm, we observed that the animals demonstrated a prolonged preference to the chamber that was paired with "no pain" condition for up to 8 days after single CFA application to the dura.These results indicate that although physiological effects of single CFA application persisted for acute stages, the negative affective component associated with migraine pain persisted for much longer which was potentially facilitated by CPP/A paradigm. Thus, our pilot study demonstrates a potential use of CCP/A paradigm in the possible development of a chronic migraine headache model.

Title: Calcitonin gene-related peptide mediated development of headache-related behaviors in a clinically relevant rat model of post-traumatic headache

Authors: *D. BREE[1], D. LEVY[2];
[1]Headache Res. Lab., Boston, MA; [2]Anesthesia, Beth Israel Deaconess Med. Center, Harvard Med. Sch., Boston, MA

Abstract: One of the most common, debilitating and difficult symptoms to manage after a concussion, or mild traumatic brain injury (mTBI) is chronic posttraumatic headache (PTH) with migraineous features. The mechanisms that mediate the onset and maintenance of PTH remain elusive in part due to the lack of an animal model that mimics the most common type of head trauma and exhibits pain behaviours similar to those seen in individuals with PTH. The present study aimed to characterize for the first time headache-related behaviours in a clinically relevant rat model of mTBI, which is the major type of trauma associated with PTH. Under isoflurane anaesthesia, mTBI was induced in adult male Sprague-Dawley rats by a closed head injury using a modified Marmotou weight-drop device. Post-concussion behavioural characterisation involved assessment of cephalic mechanical pain hypersensitivity, using calibrated von Frey monofilaments and ongoing pain, using the conditioned place preference paradigm. Injured rats displayed increased cephalic mechanical hypersensitivity up to 7 days post-injury. Acute administration of the anti-migraine drug Sumatriptan (1mg/kg i.p.) attenuated the mechanical hypersensitivity and produced conditioned place preference at discrete time points (Day 7) following head injury. Following resolution of the cephalic hypersensitivity by Day 14 post-injury, administration of the common migraine trigger glycerol trinitrate (GTN) (100µg/kg i.p.) resulted in a renewed pain-related behavioural phenotype in mTBI but not in sham animals, which was aborted by acute treatment with sumatriptan. Targeting CGRP, using weekly administration of a blocking mAb (10mg/kg i.p.), starting immediately after the head injury, inhibited the acute development of cephalic mechanical hypersensitivity as well as that triggered by GTN later on. The current data suggest that mTBI in rats is associated with the emergence of a headache-related behavioural phenotype, which is amenable to treatment with common and novel putative migraine therapies and may serve as viable model for the study of the pathophysiology of post-traumatic headache.

Title: Electroacupuncture attenuates inflammatory pain in the rat model of CFA-induced arthritis: involvement of peripheral resolvin

Authors: Y. KIM[1], B. JI[1], C. LI[1], J. LEE[1], *S. KOO[1,2];
[1]Dept. of Korean Med. Sci., Pusan Natl. Univ., Yangsan, Korea, Republic of; [2]Div. of Meridian and Structural Med., Pusan Natl. University, Sch. of Korean Med., Yangsan, Korea, Republic of

Abstract: Resolution of acute inflammation is known to be biochemical processes that enable inflamed tissues to return to homeostasis. Resolvin, a mediator of resolving inflammation, is known to reduce inflammation and also attenuate inflammatory pain. Acupuncture is widely used for various painful conditions include knee arthritis. In the present study, we investigated the involvement of peripheral resolvin in the analgesic effects of electroacupuncture (EA) in the rat model of inflammatory pain.
Arthritis was induced by injecting 125μl CFA into the knee joint cavity of the right hind limb. To evaluate the level of pain, the stepping pressure of the hind limb (weight bearing force; WBF) was measured before and after arthritis induction. The rats were divided into 3 groups (anesthesia control and two EA treated groups). For the EA treatment, a pair of needles was inserted in ST36 or SP6 point in a depth of 5 mm. EA treatment was delivered under gaseous anesthesia for 30 min via parameter of 10 Hz of frequency and 1 mA of intensity. The animals in the control group were given anesthesia only for same period of EA treatment. After measuring the daily baseline, EA was given from the post injection day (PID) 2 once a day for 12 times. For the resolvin analysis, we collected synovial fluid of the right knee on the PID 2, 3, and 7 and measured the amount of resolvins and inflammatory cytokines using multiplex ELISA.
The WBF of affected limb was rapidly decreased from the PID 1 presumably due to the inflammatory pain. The pain behavior was maximized on PID 2 and significantly lowered for all period of experiment in control group. However, the WBF of ST36 group was increased significantly compare to those of the SP6 or control group. Furthermore, the WBF of ST36 group at PID 7 was reached at those of control group at PID 14 meaning repeated EA treatment of ST36 made early recovery of inflammatory pain. In the ELISA analysis, RvD1 was increased significantly in the synovial fluid of ST36 treated animals compare to amount of SP6 or control group at PID 2.

Data suggest that EA applied to ST36 point shows analgesic and pro-resolving effects in the rat model of arthritis in a point specific manner. Peripheral RvD1 is probably involved in the underlying mechanism of EA effects in the inflammatory pain. Therefore, it cloud be concluded that EA can not only reduce inflammatory pain but also resolve the inflammation.

Title: Investigation of neuronal circuits underlying light-aversive behavior

Authors: ***L. P. SOWERS**[1,2], B. J. REA[1,2], R. TAUGHER[1,2], Y. KIM[1], A. KUBURAS[1], L. TERAN[1], S. MA[1], J. WEMMIE[1,2], A. RUSSO[1,2];
[1]Univ. of Iowa, Iowa City, IA; [2]VA, Iowa City, IA

Abstract: Veterans returning from active duty are at an increased risk for post-traumatic headache (PTH) and migraine. Migraine alone affects 10% of men and 25% of women, with the lifetime risk increasing to 18% and 43% respectively. Sensory abnormalities are present in individuals with PTH and migraine including extreme light and sound sensitivity. Light sensitivity in patients with PTH or migraine can be debilitating and treatments are lacking. One reason interventions and treatments continue to fall short is that there is a poor understanding of the relevant neuroanatomical correlates that underlie sensory changes in headache. Calcitonin gene-related peptide (CGRP) is a critical neuropeptide involved in pain signaling and has recently come to the forefront of migraine research where it contributes to headache and associated sensory abnormalities. In this study we attempt to identify anatomical regions where CGRP could act to induce light-aversive behavior in migraine and PTH. The posterior thalamus (Po) has been suggested to be a brain region that could integrate light and pain. In addition to the Po, the periaqueductal grey (PAG) has been suggested to play a role in migraine headaches. We hypothesized that CGRP acts as a neuromodulator in the Po and/or the PAG to induce light aversive behavior. To test this hypothesis, we used two targeted approaches to probe areas of the brain thought to be important in the development of photophobia. The first was direct calcitonin gene related peptide (CGRP) injection into the Po. The second was optogenetic stimulation using channelrhodopsin driven by the CaMKII promoter to stimulate either the Po or the PAG. We

found that CGRP injection in the Po as well as optical stimulation of the Po induces significant light aversive behavior, without increased anxiety in light-independent assays. However, in contrast to the Po, PAG stimulation led to both light aversion and light-independent anxiogenic behavior. These data suggest that the Po can induce light aversion associated with CGRP actions, while the PAG may trigger not only the Po, but also other brain regions involved in anxiogenic behaviors. These results may begin to shed light on the complex circuitry of light-aversive behaviors in mice.

Title: A crosstalk between neuropathic pain and depression establishing a novel drug development platform

Authors: *S. EDUT[1], G. RICHTER-LEVIN[2];
[1]Haifa Univ., Raanana, Israel; [2]Haifa Univ., Haifa, Israel

Abstract: Pain, especially chronic pain, is an emotional condition as well as a physical sensation. It is a complex experience that affects thought, mood, and behavior. Clinical reports estimate that over half of chronic pain patients also possess a robust stress-like component, reflecting a significant affective cognitive aspect. The physiologic basis for the comorbidity of chronic pain and depressive illnesses is not well understood, impeding appropriate therapeutic approaches from being adopted. Studies focusing on mood disorders have indicated that stress affects different forms of synaptic plasticity and memory processes in the hippocampus. Experience of continued stress can impair high-frequency stimulation (HFS) to induced long-term potentiation (LTP). Stress-induced modifications in synaptic plasticity could therefore represent a useful model to examine whether physical chronic pain state affects subsequent responsiveness to psychogenic stressors. We have recently described a relatively unique role for the dentate gyrus (DG) of the hippocampus. Under stressful conditions, the DG response is variable and complex, much like the behavioral outcomes of such circumstances. In this study, we investigated the impact of chronic pain on activity and plasticity in the DG. We have employed the Sciatic nerve ligation (SNL) model of neuropathic pain, a most common form of chronic pain and have examined synaptic transmission/plasticity in the DG of anaesthetized rat.

Behavioural tests such as novel place exploration and elevated plus maze were also conducted. We display that activity and plasticity in the DG are affected by exposure to stress, but in a complex way. Local circuit activity is sensitive to the different kind of stress and can be a measure to differentiate between effects of acute and chronic pain. Freezing in a novel place was also found to be a group depended behaviour. Till now we learned that both chronic stress (NP) and acute stress (SHAM) affect the LTP in the DG

Title: Validation of a translational pain questionnaire assessing behavioral quality of life measures in a naturalistic canine model of osteoarthritic pain and urate-induced pain

Authors: *J. A. ARAUJO[1], S. KELLY[2], J. BAULK[2], D. ARAUJO[2], C. DE RIVERA[2], D. BARONOWSKI[3], J. GABRIELE[3];
[1]InterVivo Solutions, Toronto, ON, Canada; [2]Vivocore Inc., Toronto, ON, Canada; [3]Delivra Inc, Burlington, ON, Canada

Abstract: Evaluation of pain in animal models typically relies on responsive measures, such as withdrawal reflexes from noxious stimuli. Because affective pain measures relevant to quality of life often are not included or not available, the translational value of animal models of pain is limited. In the current study, a questionnaire assessing pain during performance of standard daily functions was validated using approved NSAID pain therapeutics in both naturalistic and induced canine models of pain. Specifically, the naturalistic canine model employed aged dogs with radiographic evidence of osteoarthritis scored by a veterinary radiologist and the induced model employed injection of sodium urate into the stifle of normal dogs. Both models were used to evaluate the utility of the pain questionnaire under control conditions compared to treatment with meloxicam, which is approved for human and veterinary use. For both models, the questionnaire evaluated functional ability and observable pain of dogs performing standard behaviors such as walking, trotting, galloping, stepping over obstacles, climbing and descending

stairs, rearing for food and jumping down from a perch. In aged dogs with naturally occurring osteoarthritis, treatment with meloxicam (0.1 mg/kg PO and 0.4 mg/kg SC) reduced measures of pain compared to negative control and also when compared to the first day of treatment. Moreover, injection of sodium urate into the stifle joint produced a significant increase in pain evident 4, 8 and 24 hours after injection. Treatment with meloxicam (0.2 mg/kg PO) significantly decreased pain measures at all the same time-points. This demonstrates that meloxicam, administered according to the veterinary approved labeling reduces pain measured by the quality of life based questionnaire used in the current study. Therefore, the improvement in pain observed under meloxicam validates the pain questionnaire used in the current study. Given meloxicam improves measures of pain in both dogs and humans, the pain questionnaire may provide a translational assessment of affective pain that is clinically translational. Additional studies are required to extend the utility of the current model beyond effects of NSAIDS.

Title: Involvement of anandamide in differential sympatho-sensory control

Authors: *C. DEAN-BERNHOFT[1], C. J. ROBERTS[2], F. A. HOPP[2], Q. H. HOGAN[2]; [1]Anesthesiol., Med. Col. of Wisconsin, Zablocki VA Med. Ct, Milwaukee, WI; [2]Med. Col. of Wisconsin and Zablocki VA Med. Ctr., Milwaukee, WI

Abstract: Sympatho-sensory integration in the dorsal periaqueductal gray (dPAG) is fundamental to the response to acute stress. A differential increase in sympathetic nerve activity and blood pressure accompany decreased sensitivity to pain (antinociception) to allow escape from a stressor. This study was undertaken to address disassociation of the two components, which could provide therapeutic potential to decrease the response to pain without the unwanted side effects of increased sympathetic outflow and blood pressure. Blood pressure, whole renal sympathetic nerve activity (RSNA) and unit discharges of dorsal horn neurons (DHN) responding to high intensity mechanical stimulation of the hindpaw were recorded from anesthetized rats. The synaptic excitant D,L-homocysteic acid (30 nl, 4 mM) or the endocannabinoid anandamide (AEA) (30 nl, 50 μM) were microinjected into the dPAG, targeting coordinates from which a stress response can be evoked. Microinjections were made at 0.5 mm depth intervals and blue dye microinjected at the deepest microinjection site for subsequent histological mapping. Electrophysiological data was analyzed using Spike2 software and Sigma Plot 11. DLH and AEA could evoke (i) a differential pattern of neural response consisting of increased RSNA with decreased DHN or (ii) a decrease in DHN without change in RSNA. dPAG sites were also found from which no sympathy-sensory responses were elicited. These data demonstrate that there is a role for cannabinoids in the integration of sympathoexcitation and sensory inhibition in the dPAG. Further, selective inhibition of DHN activity by dPAG neurons could provide a cannabinergic target with therapeutic potential for analgesia. Supported by Veterans Affairs A NURA-009-13S

Title: Female specific regulation of postoperative pain by sensory neuronal prolactin receptor and extrapituitary prolactin

Authors: *M. J. PATIL[1], V. GOFFIN[2], M. A. HENRY[3], A. N. AKOPIAN[1];
[1]Endodontics, UT Hlth. Sci. Ctr., San Antonio, TX; [2]Inserm and Univ. Paris Descartes, Paris, France; [3]Univ. of Colorado, Denver, CO

Abstract: Aim of Investigation: Sex-dependent regulation of the nociceptive processing is estrogen and/or testosterone dependent, but detailed mechanisms are largely unknown. We have previously shown that prolactin (PRL) levels in serum and extra-pituitary tissues are dually regulated by estrogen and tissue injury. Such properties of the prolactin system (PRL and PRL receptor - Prlr) imply that it could play a critical role in sex-dependent regulation of pain. Accordingly, we investigated whether the prolactin system is involved in sex-dependent regulation of pain and the cellular mechanisms that are responsible for such regulation. **Methods:** Classical hindpaw incision on mice and rats was used as an acute postoperative pain model. Hypophysectomised male and female rats were used to evaluate the contribution of extra-pituitary PRL in mediating postoperative hypersensitivity. We immunohistochemically (IHC) characterized the expression of PRL in various cell types at surgical site and spinal cord. Nav1.8-cre/Prlr-lox conditional knockout (CKO) was used to evaluate the role of sensory neuronal Prlr in postoperative pain. **Results:** Ablation of Prlr in sensory neurons caused significant reduction in postoperative thermal and mechanical hypersensitivity exclusively in females. Hypophysectomy in male and female rats did not cause significant change in both postoperative thermal and mechanical hypersensitivity in females. PRL is expressed in sensory neuronal peripheral and central terminals as well as astrocytes. The role of PRL in astrocytes in female-specific postoperative pain was examined. **Conclusions:** Sensory neuronal Prlr controls sex-dependent regulation of postoperative hypersensitivity only in females. Extra-pituitary PRL released locally at the site of incision and/or spinal cord, but not the PRL originated from the pituitary, mediates sex-dependent regulation of postoperative hypersensitivity via autocrine and paracrine mechanisms.

Title: Fear of pain influences the extent to which autonomic arousal mediates the effects of stimulus intensity on pain

Authors: D. MISCHKOWSKI[1], E. PALACIOS-BARRIOS[1], L. A. BANKER[1], T. C. DILDINE[1], *L. Y. ATLAS[2,1];
[1]Natl. Ctr. for Complementary and Integrative Hlth., NIH, Bethesda, MD; [2]NIH (NCCIH, NIDA), Bethesda, MD

Abstract: Skin conductance represents a cardinal measure of autonomic arousal and, as such, consistently correlates with self-reports of physical pain in response to noxious stimulation (e.g., Geuter, Gamer, Onat, & Büchel, 2014; Loggia, Juneau, & Bushnell, 2011). However, it remains unclear whether increased autonomic arousal during pain reflects objective stimulus proprieties (i.e., stimulus intensity) or stimulus-independent psychological factors, such as negative affect in anticipation of noxious stimulation. If pain-related affective processes beyond objective stimulus intensity influence autonomic arousal, (1) a stronger disposition for fear in response to pain should influence skin conductance responses (SCR) following noxious input, and (2) SCR should predict trial-by-trial pain reports, controlling for noxious input. In addition, these relationships may be influenced by individual differences known to modulate pain. We tested whether SCR mediates the effects of stimulus intensity (i.e. temperature) on pain and whether dispositional fear of pain (McNeil, Rainwater, & Aljazireh, 1986) moderated the effect of stimulus intensity on SCR. Participants (N=59) received 24 trials of low, medium, and high painful thermal stimulation and provided pain ratings on every trial following heat offset. We measured SCRs evoked during noxious stimulation. Using multilevel mediated moderation to account for hierarchical data structure, we found that a) SCR increased as a function of temperature, consistent with previous work (z=6.71, p<.001), b) dispositional fear of pain increased the association between temperature and SCR (z=2.06, p<.05), c) SCR predicted pain ratings independent of temperature (z=4.57, p<.001), and d) SCR mediated the effect of temperature on reported pain (z=3.90, p<.001). These findings suggest that a) stimulus-independent fluctuations in affective processes influence pain; b) these processes can be measured with SCR; and c) stimulus intensity effects on SCR are influenced by fear of pain. More research is needed to isolate the effects of specific underlying psychological factors (e.g. attention, emotion, and expectation) that give rise to fluctuations in SCRs during pain and to investigate the utility of autonomic measures as biomarkers for pain.

Title: Biological activity of alanine, lysine and aspartic acid-substituted analogues of α-conotoxin Vc1.1 on high voltage-activated calcium channels in mice DRG neurons

Authors: *M. SADEGHI[1], B. CALLAGHAN[2], R. J. CLARK[3], D. J. ADAMS[1];
[1]Illawarra Hlth. and Med. Res. Institute,, University Of Wollongong, Australia; [2]Anat. and Neurosci., The Univ. of Melbourne, Melbourne VIC 3010, Australia; [3]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane QLD 4072, Australia

Abstract: α-Conotoxins are peptides obtained from cone snail venoms and are characterized by their affinity for nicotinic acetylcholine receptors (nAChR). They are distinguished by two disulfide bonds that have Cys^{I}-Cys^{III} and Cys^{II}-Cys^{IV} connectivity with a varying number of residues within these two loops. Several α-conotoxins with distinct selectivity for nAChR subtypes have been identified as potent analgesics in animal models of neuropathic and chronic pain. Analgesic α-conotoxins, Vc1.1 and Rg1A, are selective α9α10 nAChR antagonists, however, some Vc1.1 analogues which potently antagonized α9α10 nAChR, had no analgesic effect in rat models of neuropathic pain (Nevin et al., 2007, Mol pharmacol 72, 1406-1410). We showed that α-conotoxin Vc1.1 and Rg1A inhibited N-type Ca^{2+} channel currents in rat dissociated dorsal root ganglion (DRG) neurons via activation of G protein-coupled $GABA_B$ receptors ($GABA_BR$) (Callaghan et al., 2008, J Neurosci 28, 10943-10951; Callaghan et al., 2010, Channels 4, 51-54). Scanning mutagenesis revealed the key residues crucial for biological activity of α-conotoxins Vc1.1 and RgIA on α9α10 nAChRs (Halai et al., 2009, J Biol Chem 284, 20275-20284). Therefore, in the present study we investigated the structure–activity relationships between α-conotoxin Vc1.1 and $GABA_BR$. The residues except the conserved cysteines contained in the amino acid sequence of Vc1.1, were subsequently replaced by alanine (A), lysine (K) and aspartic acid (D). We examined the activity of Vc1.1 analogues on high voltage-activated (HVA) Ca^{2+} channel currents in mice DRG neurons using the whole-cell patch clamp recording technique. Alanine substituted analogues of Vc1.1 exhibited reduced potency and efficacy at $GABA_BR$-mediated inhibition of HVA Ca^{2+} channels except where alanine substituted amino acids in second loop at positions Asp^{11}, Glu^{14} and Ile^{15} of Vc1.1. These analogues retain activity at $GABA_BR$ and potently inhibited Ca^{2+} current but lost their activity at α9α10 nAChR. In contrast, [N9A]Vc1.1 was inactive at $GABA_BR$ but retained activity at α9α10 nAChR whereas [N9K]Vc1.1 was active at $GABA_BR$. These results suggest that the small

hydrophobic residues at position 9 increase the potency at nAChR whereas the positive charged residues at this position increase the selectivity for $GABA_BR$ over nAChR. Therefore, the residues in the second loop of Vc1.1 play an important role in the selectivity for $GABA_BR$ activation whereas those in the first loop are important for binding to the receptors. These findings enhance our understanding of the key residues important for binding of Vc1.1 at $GABA_BR$ and the selectivity for $GABA_BR$ over α9α10 nAChRs.

Title: The posterior hypothalamus modulates pain behaviors in the formalin model of acute inflammatory pain

Authors: ***Z. WANG**, M. ARIFFIN, T. SOONG, S. KHANNA;
Natl. Univ. of Singapore, Singapore, Singapore

Abstract: In the present study we have explored the role of posterior hypothalamic (PH) regions in nociception. The region is interconnected with limbic and brainstem areas that are associated with affect-motivation, at least in part. Indeed, the lateral supramammillary nucleus (lSuM) and the ventral mammillary bodies (MB) of the PH are associated with the septo-hippocampal network which is implicated in facilitation of nociception. Inactivation of the lateral SuM (lSuM) blocked hippocampal nociceptive responses induced on hind paw injection of formalin, an algogen, in anaesthetized animal. We, thus, hypothesized that the PH is involved in nociception. So as to test the hypothesis, the effects of attenuation of neural activity along the dorso-ventral axis of the PH was tested on acute behaviors evoked on hind limb injection of formalin. The neural activity was attenuated by microinjection of muscimol (2ug/ul, 0.1ul), a GABA mimetic, or NBQX (10ug/ul, 0.1ul), a receptor antagonist at the glutamatergic AMPA receptors, into the lSuM or the MB.
Microinjection of the drugs evoked a site-dependent effect on nociception. A weak effect was observed with microinjection into the lSuM, whereas microinjection into the MB evoked a strong effect. In this regard, microinjections of muscimol or NBQX into lSuM attenuated flinching behavior in the second phase (11-60mins after hind paw formalin injection) of the formalin test,

without affecting licking responses. Neither did muscimol-microinjection affect the power of the hippocampal theta observed during the formalin test, theta being 3-12 Hz rhythmic sinusoidal extracellular waveform that reflects neural processing of information. However, the dose administered was sufficient to attenuate reticular stimulation-evoked hippocampal neural responses in anesthetized rat. The reticular stimulation-evoked hippocampal responses are known to be mediated via the lSuM.
On the other hand, microinjections of both muscimol and NBQX into MB resulted in suppression of flinching and licking behaviors, the effect of NBQX being quite marked. The behavioral effect of muscimol-microinjection into MB was accompanied by reduction in the amplitude of theta wave activity recorded from the hippocampus.
Collectively, the foregoing data point towards functional differences along the dorso-ventral axis of the PH such that the ventral MB play a much greater role in acute nociception in the formalin test. Indeed, the findings suggest a role of glutamatergic transmission in MB in mediation of nociception.

Title: Characterization and validation of photosensitivity as a biomarker of post-traumatic headache in mice.

Authors: ***A.-S. WATTIEZ**, L. P. SOWERS, B. J. REA, T. C. YIN, A. KUBURAS, A. F. RUSSO;
Mol. Physiol. & Biophysics, Univ. of Iowa, Iowa City, IA

Abstract: The prevalence of post-traumatic headaches (PTH) in military personnel who have been diagnosed with traumatic brain injury (TBI) reaches 59%, leading to a severe disruption of the daily activities, ability to work and quality of life of thousands of Veterans. Although extremely prevalent and debilitating, the pathophysiological mechanisms underlying PTH remain unknown, and the efficacy of existing treatments is poor. PTH presents symptom similarities

with chronic migraine, including a high prevalence of photosensitivity in patients both during and in between headaches, which makes it a practical biomarker of both conditions. The goal of the present study is to characterize and validate photosensitivity as an objective biomarker of PTH in a mouse model, which would enable us to test future treatment strategies pre-clinically. In order to model TBI, the heads of the mice are exposed to an over-pressure chamber while under anesthesia. In order to mimic the multiple head injuries that some soldiers can receive, we compared the effect of sham-injured mice with mice receiving 1 injury, or 3 injuries over 90 minutes or 1 week. In those animals, photophobia was measured within two assays. In the light aversion assay, the animals can freely choose between a light and a dark zone. This test was run in parallel with two tests in order to control for activity and anxiety: the open-field assay and the elevated plus-maze assay. In the eyelid closure assay, the squinting of mice in the different groups was scored and compared in the dark and in response to exposure to bright light.
Our preliminary data show that expositions to an over-pressured chamber are able to produce photophobia in mice, as compared with their sham littermates. Those animals do not show anxiety or decrease of activity at 5 weeks after the injury. Present results need to be repeated and extended to later time-points. If confirmed, those findings will support the validity of photosensitivity as an objective biomarker of post-traumatic headache, and will allow us to study the mechanisms behind the injury, as well as screen for future PTH treatments.

Title: cAMP and cGMP attenuate nociceptive sensitization *In vivo* in a novel model organism, M. sexta

Authors: *F. E. ARREOLA[1], C. MOFFATT[2], M. FUSE[2];
[1]Biol., [2]San Francisco State Univ., San Francisco, CA

Abstract: Nociception describes the process of encoding the response to potential or damaging stimuli by the central nervous system, which is noted as pain in higher organisms. Nociceptive sensitization is a form a non-associative learning that can persist for days or months in animals,

where the noxious stimulus elicits a stronger response or where an otherwise innocuous stimulus now generates a response. Genetic analysis of different species suggests a conservation of nociceptors and signaling molecules such as soluble guanylyl cyclase, and protein kinases typically involved in sensitization. However how these cellular factors mediate and modify nociceptive cells in different animals remains unclear. Research suggests that cAMP and cGMP, both second messengers, have roles in nociceptive sensitization, but results differ between and within organisms (e.g. central vs peripheral effects). cGMP is often the product of soluble guanylyl cyclase, typically activated by NO. Using a novel organism to study nociception - *Manduca sexta,* commonly known as the Tobacco hornworm - we tested the actions of cGMP and cAMP in modulating nociceptive sensitivity. We used the modified Simplified Up Down (SUDO) method to assess the threshold of a defensive strike behavior that occurs after a noxious insult. We then assessed nociceptive sensitivity after injection of the membrane permeable cGMP and cAMP analogs, 8-Bromo-cGMP and 8-Bromo-cAMP, respectively, as well as the soluble guanylyl cyclase inhibitor Methylene Blue. Injections of 8-Bromo-cGMP and 8-Bromo-cAMP each had an analgesic effect on animals that had a noxious stimulus applied, in that sensitivity was reduced in the presence of the exogenous compound. Animals treated with Methylene Blue demonstrated increased sensitivity with or without receiving a noxious stimulus. Our data suggests that cGMP and cAMP may mediate analgesic effects in *M. sexta*. *M. sexta* appears to be a suitable new model to study nociceptive sensitization that may offer unique advantages over other model organisms.

Title: Analgesic effect of Oxytocin was attributed to AVP1a receptor-mediated hyperpolarization of dorsal root ganglion cells

Authors: *T. HAN[1], H. NA[1], H. KIM[1], S. BACK[2,3], H. KIM[3], S. OH[3];
[1]Korea Univ. Col. Med., Seoul, Korea, Republic of; [2]Dept. of Pharmaceutics & Biotech., Col. of Med. Engineering, Konyang Univ., Chungnam, Korea, Republic of; [3]Dent. Res. Inst. and Dept. of Neurobio. and Physiol., Sch. of Dentistry, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Recent studies have provided several lines of evidence that peripheral administrations of OT-induced analgesia in human and rodents. However, the exact underlying mechanism of the analgesia still remains elusive. In the present study, we investigated 1) to identify which receptor mediated analgesic effect of OT, 2) to see whether OT affected capsaicin-induced intracellular calcium transients, the membrane excitability and capsaicin-induced current of TRPV1 channel. If so, we examined 3) which receptor mediated these changes. Lastly we interrogated 4) to verify the expression patterns of mRNA of these receptors.
For these aims, we examined whether the intraperitoneal (IP) injection of specific antagonist for OT and AVP1a receptors reversed the OT-induced analgesia during the pain behavioral tests such as Hargreaves' and capsaicin injection tests in rats. We explored the effect of OT and its antagonists on capsaicin-induced intracellular calcium transient using fluorescent microscopy in the dissociated dorsal root ganglion (DRG) cells. In addition, we investigated the effect of OT and its antagonists on the membrane excitability and the capsaicin-induced current of TRPV1 channel using patch clamp in the dissociated DRG cells. Further, we determined mRNA expression patterns of TRPV1 and the oxytocin related receptors in the individual cells by single cell RT-PCR.
The behavioral results showed that the antagonist for AVP1a receptor reversed the OT-induced analgesia. The fluorescent imaging experiments demonstrated that OT partially inhibited capsaicin-induced intracellular calcium transient through AVP1a receptor in the DRG cells. The electrophysiological study also demonstrated that OT hyperpolarized the membrane potential and reduced the current of TRPV1 channel through AVP1a receptor in the DRG cells. Furthermore, single cell RT-PCR discovered co-expression of mRNA of TRPV1 and AVP1a receptor in the DRG cells. Also, the number of cell expressing mRNA of AVP1 receptor was much more than that of OT, AVP1b, and AVP2 receptors.
Taken together, our findings possibly suggested that OT-induced membrane hyperpolarization of the DRG cells contributed to the analgesic effects of peripheral administration of OT through AVP1a receptor.

Title: Is it possible for pro-inflammatory cytokine in intervertebral disc to induce discogenic low back pain ?

Authors: *E. PARK, S. MOON, H. SUH, H. HAN;
Col. of Medicine, Korea Univ., Seoul, Korea, Republic of

Abstract: Intervertebral disc (IVD) can be a major source of low back pain (LBP). Some studies reported that in degenerated IVDs the upregulation of pro-inflammatory cytokines such as interleukin-1 beta (IL-1β) or tumor necrosis factor-alpha (TNF-α) can promote nerve fiber to grow into the deep layer of annulus fibrosus and give rise to painful IVD. However, it is not clear whether pro-inflammatory cytokines in IVDs can participate in nociceptive processing. The purpose of this study was to characterize the responses of mechanosensitive afferent (MSA) in IVD after the intradiscal injection of IL-1β or TNF-α. We previously identified that the paravertebral sympathetic trunks (PST) of male SD rats innervated lumbar IVD through DiI labeling (2μl; a lipophilic and fluorescent dye). Using male SD rats (300-350g; Korea), PST was teased into small strands and placed on a unipolar platinum electrode in warm mineral oil pool, and *in vivo* single nerve recording of the IVD afferent was done before and 30 min after intradiscal injection of IL-1β (1 or 10ng/ml) or TNF-α (1ng/ml). Drugs (3μl) were delivered through 25G needle and tubing connected to a Hamilton syringe, and MSA activities (maximum spikes per second) stimulated by von Frey filament (0.4 to 10g) were counted. Compared to saline-injection group, MSA activities in IL-1β or TNF-α-injected group significantly increased 30 min post-drugs injection time. The present study implicate that the nociceptive information from IVDs can be transmitted to spinal cord through paravertebral sympathetic pathways, and the upregulation of pro-inflammatory cytokines in degenerated IVD can induce discogenic pain.

Title: Phenotypic characterization of a mouse model of Hereditary Sensory and Autonomic Neuropathy type V: new central aspects of feeling pain

Authors: G. TESTA[1], L. PANCRAZI[1], M. CECI[1,2], C. MORELLI[3], M. FABBRI[1], M. COSTA[4], P. HEPPENSTALL[3], A. CATTANEO[1,2], *S. CAPSONI[1];

Abstract: The Hereditary Sensory and Autonomic Neuropathy type V (HSAN V) is linked to defects in Nerve Growth Factor (NGF) signaling. HSAN V is clinically characterized by absence of pain sensation leading to painless fractures, bone necrosis, osteochondritis, and neuropathic joint destructions (Capsoni, 2014). The genetic mutation responsible for the disease is the R100W point mutation (661C>T) in the NGF gene (Einarsdottir et al., 2004). HNGF R100W is a preferential TrkA biased agonist (Covaceuszach et al 2010; Capsoni et al 2011). We confirmed the finding by Larsson et al. (2009) that the R100W mutation inhibits processing of proNGF to mature NGF, with an accumulation of proNGF in cultured cells. To understand the mechanisms at the basis of this disease, we have generated two knock-in mouse lines in which the murine NGF coding sequence is replaced by the coding sequence of human NGF, either in its wild type or R100W forms. Haploinsufficiency of mature NGF could be the cause of death of homozygous HSAN V mice occurring during the first month of life. To continue the characterization of the effects of HSAN V mutation during adulthood, we performed a combination of molecular, neuroanatomical and behavioral analyses in heterozygous mice. Due to the known effects of NGF on learning and memory, we analyzed heterozygous mice for the presence of deficits in object recognition and spatial memory tests and found no impairment in both tasks. At two months, heterozygopus mice show no deficits in thermal perception, anxiety and “cage behavior”, which, however, are impaired in 6 month-old heterozigous HSAN V mice. At all ages, the R100W mutation causes less sensitivity to pain induced by capsaicin injection, in dosage and sex-dependent manner. The insensitivity to pain might interfere with learning and memory of painful events or with their interpretation as painful. Thus, in the fear conditioning test, we increased the potency of the aversive stimulus with respect to wild type mice and found

that, despite the perception of the aversive stimulus, HSAN V mice do not show a fear response. Interestingly, the late onset of the phenotype and the inability to mount aversive responses to pain accurately model the clinical phenotype of heterozygous patients (Minde et al., 2009). In conclusion we were able to reproduce in mice the main clinical HSAN V phenotype. Further study of this model will allow to expand our knowledge on the pro-nociceptive actions of NGF, from peripheral sensory system to central mechanisms of pain perception and is providing new insights into the central consequences of growing without feeling pain.

Title: Induction of photophobic behavior in mice by peripheral CGRP: Implications for migraine therapy

Authors: ***B. N. MASON**[1], A. KUBURAS[1], L. GARCIA-MARTINEZ[2], J. A. LATHAM[2], A. F. RUSSO[1];
[1]Univ. of Iowa, Iowa City, IA; [2]ALDER BIOPHARMACEUTICALS, BOTHELL, WA

Abstract: The neuropeptide calcitonin gene-related peptide (CGRP) has been firmly established as a key player in the pathophysiology of migraine. However, there is controversy brought to the forefront by the recently reported efficacy of CGRP-blocking antibodies in clinical trials as to the relative contributions of CGRP in the periphery versus the central nervous system. We have previously documented that light aversion in mice can be used as a surrogate for photophobia in response to central ICV administration of CGRP. In this study, we confirm these central mechanisms and report that two strains of wildtype mice (C57Bl/6J, CD1) show light aversive behavior in bright light (27,000 lux) following peripheral I.P. administration of CGRP. As with central administration, the phenotype was not solely due to increased anxiety based on a light-independent anxiety assay. In addition, motility was decreased in the dark zone, but not in the light. Importantly, both sumatriptan, a 5-$HT_{1B/D}$ migraine drug, and a CGRP monoclonal antibody attenuated CGRP-induced light aversion. To address the site(s) of CGRP action, we used a genetic strategy with a transgenic strain of CGRP-sensitized mice that have elevated

hRAMP1 CGRP receptor subunit in nervous tissue (nestin/hRAMP1). These mice failed to exhibit light aversion with low levels of light (55 lux) after peripheral injection of CGRP; this in contrast to the ability of a central injection of CGRP to elicit light aversion in these mice. These results suggest that CGRP can act both in the periphery and the brain to induce light aversive behavior in mice but through different mechanisms.

Title: Peripheral injection of PACAP38 induces photophobia in mice

Authors: A. KUBURAS[1], B. N. MASON[1], L. P. SOWERS[1], M.-C. MOLDOVAN LOOMIS[2], L. F. GARCIA-MARTINEZ[2], J. A. LATHAM[2], *A. F. RUSSO[1];

Abstract: Migraine is a disabling neurological disorder and a significant public health problem. The pathophysiology of migraine is not well understood, but studies have shown that calcitonin gene-related peptide (CGRP) plays a strong role. In recent years there has been a significant interest for role of pituitary adenylate cyclase-activating polypeptide-38 (PACAP38) in migraine. The objective of this study is to determine if administration of PACAP38 will induce photophobia, a migraine-like symptom, in wild-type CD1 mice. As a surrogate to photophobia, we measured light aversion behavior. Our results show that intraperitoneal injection of PACAP38 induced a significant light-aversive response in CD1 mice compared to mice treated with vehicle. In addition, PACAP38 also caused an increase in resting time in the dark reflecting a possible aggravation of pain by movement as experienced during migraine. Future work will attempt to understand more about PACAP38 and possible connections with CGRP in migraine and to explore PACAP as a potential novel target in migraine therapy.

Title: A flexible model for characterizing sub acute and chronic back pain trajectories and etiology

Authors: *B. PETRE, A. APKARIAN;
Physiol., Northwestern Univ. Dept. of Physiol., Chicago, IL

Abstract: Distinct brain physiology in subacute back pain (SBP; pain 4-16 weeks) is associated with different pain outcomes one year later, and suggests high motivational load underlies pain persistence. Our aim is to develop a formal definition of these outcomes by modeling pain trajectories. We pursue this using a previously published group of 59 SBP patients, encountered up to 8 times over the course of a year, who received T1 and diffusion imaging scans at study entry. We apply our model to sparse subsets of this data to demonstrate its flexibility. Parsimonious subdivisions of pain trajectories are identified by fitting a Gaussian mixture model to visual analog scale pain ratings. Four roughly equal subdivisions are obtained, matching previously identified subacute and chronic back pain trajectories. Normalizing by percent change in pain suggests a more parsimonious model preserving one of the preliminary recovery-like subgroups (N=14) and aggregating the rest (42) who show persistent pain (3 outliers remain). Using hierarchical nonlinear Bayesian regression we construct a probabilistic latent model of these trajectories which we use to parameterize Naive Bayesian classifiers of novel pain trajectories measured at arbitrary timepoints. We evaluate the classifier based on within-subject subsamples of pain reports and obtain high classification accuracies (AUC=0.8-0.9) using either randomly or systematically selected singular follow-up pain reports, although subject level

confidence increases with additional data.
Two exemplary biomarkers of pain persistence previously identified in this dataset, hippocampal volume and fractional anisotropy (FA), were investigated for correspondence to specific pain trajectories. As expected, biomarkers differ significantly between pain trajectory clusters (FA: t-test, $p = 0.015$, volume: t-test, $p = 0.021$). More notably, pain report data at a randomly selected follow up can achieve classifications with similar differences in brain etiology (FA $p = 0.013$, volume not significant) while explaining 74% of the variance in posterior probabilities obtained with the full pain trajectory dataset.
These findings show persistence and recovery from SBP can be formally assessed using a simple classifier on pain rating data collected at arbitrary timepoints, which can be flexibly applied to novel experimental or clinical settings.

Title: Cortical mechanisms of pain processing in non-human primates

Authors: *B. J. HANSEN, J. D. VARDIGAN, S. J. TYE, S. V. FOX, J. M. USLANER;
In Vivo Pharmacol., Merck Res. Labs., West Point, PA

Abstract: Traditional ways of measuring analgesia clinically rely on subjective reports of pain, which cannot be measured preclinically in animals. Over the past decade, the importance of developing objective, quantifiable experimental pain models has been acknowledged in the clinical setting; however, there has been little preclinical work towards this effort. For example, clinical research has established a model in which electrical activity in the brain is measured during application of painful heat stimulation to the forearm. To this end, we have developed a novel and highly translatable experimental paradigm to record electroencephalography (EEG) activity from multiple cortical locations and measure event-related potentials (ERPs) in awake-behaving primates during heat stimulation. Briefly, four female rhesus macaques (*Macaca mulatta*) were implanted with a PhysioTel D70 (Data Sciences International) capable of wirelessly transmitting EEG activity from three distinct cortical regions corresponding to F3, C3 and P3. Heat stimulation was controlled using a contact heat-evoked potential stimulator (CHEPs; Medoc Ltd.) with a round thermode that contacts a cutaneous area of 572.5 mm^2. This device reliably delivered temperatures with a heating rate of 70°C/s. On a given trial, heat

stimulation at either 44 or 50°C was applied to the animal's right volar forearm for 0.5 s followed by a 30 s ITI. Each temperature was randomly presented 50 times in a given session. The data were pre-processed using custom software coded and complied in Matlab according to the following steps: (1) artifact rejection (e.g. high amplitude trials); (2) baseline subtraction of the average activity 200 ms prior to trigger onset; (3) Savitzy-Golay filter with polynomial order of three. For each channel and temperature we measured the negative (N_2; 200-400 ms) and positive (P_2; 300-500 ms) potentials from baseline to peak and calculated the peak-to-peak (N_2-P_2) amplitude. Temperature specific changes were observed in N_2-P_2 amplitude (44: mean +/- SEM, 11.61 +/- 1.42μV; 50: mean +/- SEM, 17.17 +/- 2.58μV). Interestingly, this effect was strongest on P3, the EEG channel located over the Inferior Parietal Lobe, an area involved in the interpretation of sensory information. Now there is an unprecedented opportunity to study the cortical mechanisms of pain processing in non-human primates, which is directly translatable to the clinic. This will allow us to assess the role of analgesic compounds and their influence on cortical activity in a large animal species in a preclinical setting.

Abstract: Cholinergic inputs to the cerebral cortex and limbic system, originating primarily from the cholinergic basal forebrain (CBF), play an important role in cortical sensory processing, largely through modulation of inhibitory interneurons. Cholinergic agonists given spinally, intracerebroventricularly (ICV) or systemically depress reflex nocifensive responses, but systemic cholinergic **antagonists** also depress some affective responses to pain and impair

attention to aversive stimuli and stress reactions. In the present study, we determined the effects of selective cerebral cholinergic denervation, using ICV microinjection of 4 ug of 192-saporin in 10 µl (Advanced Targeting Systems, San Diego, CA) on operant thermal escape responses to aversive thermal stimuli (10° C, 44.5° C) and hyperalgesic effect of sound stress (ten X 30 sec bursts of 100 dB white noise over a 15 min period, 20 mins prior to thermal escape testing) in normal and CBF-lesioned rats compared to effects of systemic cholinergic antagonism (0.1 mg/kg, i.p., scopolamine, 20 minutes prior to thermal escape testing) in intact, normal rats. All rats were on the thermal escape task prior to either scopolamine, or sound stress testing and prior to ICV 192-saporin. At the conclusion of behavioral testing, choline acetyltransferase immunohistochemistry confirmed that 192-sap produced 62-81% loss of CBF cholinergic neurons. CBF-lesioned rats showed **decreased** thermal escape responses to both temperatures (10°C and 44.5°C) for >19 weeks. There also was no increase in escape responding (hyperalgesia) after sound stress as seen in normal rats. Scopolamine in normal rats produced decreased thermal escape responses to cold (2° C, 6°C and 10° C) and to heat (44.5° C). These results suggest that systemic scopolamine mimics the effects of CBF destruction on pain and together the overall results are interpreted to indicate an important role for the CBF in cerebral pain processing. These findings may be relevant to clinical pain care in patients with cerebral cholinergic dysfunction, such as Alzheimer's disease.

Title: Detection of CGRP-induced pain by a facial response assay in a mouse migraine model

Authors: *B. J. REA[1], J. L. BITTLE[1], L. TERAN[1], P. POOLMAN[2], W. A. JOHNSON[1], L. P. SOWERS[1], R. H. KARDON[2], A. F. RUSSO[1];

Abstract: Migraine is a complex neurological disorder that afflicts over 6% of men and 18% of men in the United States. Having a myriad of symptoms, migraine is denoted by debilitating,

unilateral pain, lasting up to 72 hours, and at least one of two symptoms: nausea and/or vomiting, or photophobia and phonophobia. Photophobia is a condition where low to normal levels of light cause discomfort and light aversion in the perceiver. This photosensitivity is a subjective experience for each migraineur and is a common trigger.
Calcitonin gene-related peptide (CGRP) is a neuropeptide that is elevated during migraine. Clinical evidence suggests that CGRP plays a key role in migraine etiology. In particular, intravenous injection of CGRP has been shown to induce migraine-like headache in migraineurs but only fullness-of-head in non-migraineurs. Currently we have an established mouse model for CGRP-induced photophobic behavior. However, we have yet to quantify pain expression post CGRP administration. We hypothesized that our mice would exhibit increased expression of pain after CGRP administration and that this expression may be increased in the presence of light. Mice were acclimated to a customized restraint and recorded using multiple cameras during dark and light conditions. Mice were then given an intraperitoneal injection of CGRP (0.1-0.5 mg/kg) or saline and underwent the same conditions. Using the Mouse Grimace Scale and point-to-point measurement software, mice were independently scored by blinded observers for pain expression.
CGRP caused a significant increase in pain expression compared to saline control in both dark and light conditions. A difference between dark and light was not observed. Thus, CGRP causes a facial pain response in mice that is consistent with the causal role of CGRP in migraine.

Title: Reduced PFC activity may underlie reduced attentional performance from incisional pain

Authors: *D. RIRIE, D. BOADA, T. MARTIN;
Wake Forest Univ., Winston Salem, NC

Abstract: Introduction. Cognitive capacity may be reduced from exposure to inflammation, surgery, anesthesia, and pain (1-2). Attentional performance can be measured serially in the rat using the 5 Choice Serial Reaction Titration Variant (5CTV) and surgical incision impairs attentional performance (3,4). In this study, we hypothesized that a reduction in local field potentials (LFP) in the medial prefrontal cortex (mPFC) occurs in response to incision and

correlates with reduced attentional performance.
Methods. After Institutional Animal Care and Use Committee Approval, 8 Male Fisher 344 Rats were trained in the 5CTV (4). After a stable titration of cue duration (a measure of attention is the median cue duration (MCD)) to < 1 second, animals underwent anesthesia for placement of electrodes into the mPFC. After return of the MCD to <1 s, LFP and MCD were measured in all animals before and on postop day (POD) 1 and 3 after paw incision (5). Change in LFP power spectral density (PSD) was measured. Data were analyzed using repeated measures ANOVA to test significance with corrections for multiple comparisons. Results. The MCD is increased on POD 1 and 3 compared to baseline prior to incision consistent with worse performance ($p<0.05$). Average PSD from 0-50 Hz in the mPFC was reduced on POD1 and POD3 ($p<0.05$) (Figure 1: Power Spectral Density Change after Incision). The reduced LFP power in the mPFC parallels the decrease in attentional performance measured by the increase in MCD that occurs from surgery. Discussion. The reduction in mPFC synaptic activity as measured by a local decrease in LFP power may underlie the inability to maintain attention and to perform maximally. Furthermore, the effects of anesthesia and pain on mPFC cortical activity extend beyond the day of anesthesia and surgery and may reduce attentional performance for days after a small procedure. Pain may alter attentional performance by increasing attentional load and disrupting information processing and altering input (6). Although the MCI related attentional dysfunction resolves, the ramifications for persisting beyond the immediate recovery from anesthesia are large. MCI may impair recovery time from the standpoint of return to optimal functioning in daily activities, particularly activities with higher risks requiring maximal attention and optimum performance for the greatest safety for the patient and those affected by their performance.

Title: Nile rats as novel model of protracted type-2 diabetes-induced peripheral sensory neuropathy

Authors: *J. SINGH[1], A. RUANGKITTISAKUL[1], P. SHELEMEY[2], T. JOY[3], J. SCHNEIDER[1], Y. SAUVE[1], K. BALLANYI[1], C. WEBBER[3];
[1]Dept. of Physiol., [3]Div. of Anat., [2]Univ. of Alberta, Edmonton, AB, Canada

Abstract: A devastating complication of type-2 diabetic (T2D) is the development of peripheral sensory neuropathy (PSN) typified by mechanical allodynia, hyperalgesia, spontaneous burning pain, thermal hypersensitivity and numbness in lower extremities. Current animal models have provided insights on the contribution of nociceptor (A-delta and C-fibers) sensitization to T2D neuropathic pain; however, genetic complexity, alteration of the biological system, and rapid T2D progression makes these animals models difficult to select for and mimic human T2D pathogenesis at preclinical stages. Recently, Nile rats fed standard laboratory rodent chow (Prolab 2000) were shown to develop hyperinsulinemia at 2 months of age followed by hyperglycemia at 6 months with ultimate decompensation (islet beta cell loss and inability for systemic glucose retention) by 18 months. We relied on these animals to study whether they also demonstrate evidence of neuropathic pain by comparing them to age-matched controls obtained by feeding an independent group of Nile rats a higher fibre low calorie diet (Mazuri). This group of animals (controls) did not develop hyperglycemia up to 18 months of age. Here, we show using a saphenous skin-nerve preparation (Zimmermann et al [2009] Nature Prot. 4:174-196) that 18 month T2D-NGR A-delta and C fibers have decreased electrical and mechanical (Von-Frey test) excitation thresholds. Similar to human patients, Nile rats have a reduced number of intra-epidermal pain-sensing nerve fibers (immunolabeled for pan-axonal marker protein gene product 9.5) in the footpad, when compared to controls. Furthermore, anatomical changes take place in both A-delta and C fiber as documented by immunolabeling at their cell bodies in the dorsal root ganglion neurons (with anti-calcitonin gene-related peptide and anti-Isolectin B4 antibodies, respectively). Our findings indicate that Nile rats fed standard rodent chow develop pathological features of T2D-induced peripheral sensory neuropathy that have analogies with the human pathogenesis. This novel model opens long waited and needed opportunities to undertake preclinical studies for diabetic neuropathy.

Title: Investigating primary cilia in nociceptive dorsal root ganglion neurons and their potential links to acute and chronic pain.

Authors: *K. L. LINDROS, E. J. BILSKY, K. L. TUCKER;
Univ. of New England, Biddeford, ME

Abstract: After being considered a "vestigial organelle" for many years, recent research has provided convincing evidence of the crucial importance of primary cilia in the development and function of multiple components of the central nervous system. Notably, robust numbers of cilia appear in embryonic development shortly after elaboration of axons in sensory DRG neurons and persist throughout postnatal stages of maturation. Primary cilia can be eliminated through inactivation of genes that encode proteins essential for the maintenance of primary cilia, such as *Ift88*. Loss of *Ift88* should result in a working model for a lack of cilia in sensory areas that largely control pain processing, without affecting other biological processes in the animal. Mice expressing a CRE recombinase integrated into the TrpV1 locus are used as a tool to specifically eliminate ciliary genes in nociceptive neurons. We have crossed the TrpV1:CRE driver to an inducible mutant that we have successfully used to eliminate primary cilia in neurons of an *Ift88* flox mutant. The mouse model is tested for a variety of standard behavioral phenotyping and nociceptive-testing assays for indications of initial deficits in sensory/pain processing. More advanced testing assesses the role that nociceptor cilia play in response to tissue injury, including models of nerve injury. These assays offer insight on whether primary cilia expressed by postnatal nociceptive neurons of the DRG modulate nociceptive signals arriving from the periphery and thereby modulate nociceptive signaling under normal physiological conditions and/or during pathophysiological states.

Title: Glucocorticoid receptor expression is decreased in the dorsal root ganglia in a rat model of inflammatory low back pain

Authors: S. I. A. IBRAHIM, W. XIE, *J. A. STRONG, J.-M. ZHANG;
Dept Anesthesiol, Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: Low back pain can be caused by disorders of lumbar intervertebral discs and compression of nerve roots. Because these conditions include inflammation, local injection of anti-inflammatory corticosteroids is a common treatment. However, current medications fail to work in many patients. Therefore, there is a need to optimize the treatments. Clinically used steroids for back pain injections target the glucocorticoid receptor (GR). In addition, they can activate the mineralocorticoid receptor (MR) with significant potency, which has a pro-inflammatory role in the dorsal root ganglia (DRG) that may offset the anti-inflammatory effects of GR activation. Local inflammation of the L5 DRG with the immune activator zymosan was used as a model for inflammatory low back pain. Local DRG inflammation induces mechanical hypersensitivity, mechanical allodynia and cold allodynia in the hindpaw. In the current study, we first characterized the expression pattern of the GR receptor in normal and inflamed DRG. Then, we examined the effectiveness of a GR agonist with and without the MR antagonist in alleviating local DRG inflammation-induced mechanical hypersensitivity. Using immunohistochemistry, we found that GR expression is widely expressed in the majority of neuronal and non-neuronal cells in the DRG. Local inflammation, however, significantly decreased GR expression on postoperative day 1. Eplerenone, a selective MR antagonist, was locally administered to the inflamed L5 DRG alone or in combination with dexamethasone. Although dexamethasone alone reduced pain behaviors, the effectiveness was improved when combined with eplerenone. The ineffectiveness of the epidural steroid injections may be attributed to the reduced expression/activation of GR in the inflamed sensory ganglia as well as to concurrent activation of the MR.

Title: A novel method to study tumor-nerve interaction for oral cancer pain

Authors: *S. RUPAREL[1], M. BENDELE[2], L. CHODROFF[2], A. WALLACE[2], V. VALENZUELA[2];
[1]Endodontics, Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Pain is often the presenting and the top ranked symptom in oral cancer patients, leading to significant reduction in quality of life. Unlike other cancers, pain in these patients is produced at the primary site of the tumor even when the tumor is still quite small in size suggesting that tumor cells control the activity of surrounding nociceptors. It is therefore crucial to understand the interaction of oral tumor cells with surrounding sensory nerves to delineate mechanisms by which oral cancer produces pain. The current study developed and validated a novel orthotopic in vivo tongue cancer model that mimics patient symptoms. Moreover, using this model, we have established a novel electrophysiology method that allows us to study tumor-nerve interactions at the site of primary tumor growth.
Injection of human oral squamous cell carcinoma cells (HSC2) into the tongue of athymic mice produces a well-differentiated tumor by day 6 post-inoculation. Control groups received normal human oral keratinocyte cells in the tongue. By day 9, tumor-bearing animals demonstrated patient reported symptoms such as pain during eating, ongoing pain and facial pain as measured by feeding behavior, conditioned placed preference test and Von Frey testing in the vibrissae respectively. We then, used this in vivo model to dissect out the tumor growing tongue or normal tongue and its associated lingual nerve to determine and characterize lingual nerve fibers and their firing responses in response to the tumor. We were able to successfully record increased nerve discharges upon mechanical stimulations and compare with normal tongues.
Our in vivo orthotopic tumor model is the first oral cancer pain model that reflects patient symptoms. We have now used this model to develop a tumor-tongue electrophysiology method that allows studying interactions of tumor and peripheral nerve fibers. Currently we are characterizing the different types of fibers with different stimulus modalities to determine the effect of oral tumor on sensory firing.

Title: Serotonin induces distinct types of responses in primary cultures from rat dorsal root ganglia

Authors: D. DOMOCOS[1], T. SELESCU[1], *E. E. CARSTENS[2,1], M. IODI CARSTENS[2], A. BABES[1];
[1]Anatomy, Physiol. and Biophysics, Univ. of Bucharest, Bucharest, Romania; [2]Neurobiology, Physiol. & Behavior, Univ. of California Davis, Davis, CA

Abstract: Serotonin (5-HT) is an important inflammatory mediator of both pain and itch. The mechanisms through which 5-HT activates primary sensory neurons are not completely established. We used calcium microfluorimetry and pharmacological tools to investigate the action of 5-HT in primary cultures of rat sensory neurons. Dorsal root ganglia (DRG) were dissected out from adult Wistar rats and dissociated neurons were cultured on glass coverslips. After 24 h, the cells were loaded with Calcium Green-1 AM and imaged while being chemically stimulated using a fast-exchange superfusion system. Based on their kinetics we classified the responses to 5-HT (50 μM) as transient, spiky and sustained. Most of the 5-HT-sensitive neurons had only transient responses and were positive for Isolectin-B4 binding. The transient responses were also elicited by the 5-HT3 agonist SR 57227 (1-10 μM) and were completely inhibited by the 5-HT3 antagonist granisetron (1 μM). The 5-HT4 agonists cisapride and tegaserod maleate activated a sub-population of neurons different from the one responding to 5-HT. On the other hand, the non-selective agonist 5-carboxamidotryptamine (5-CT, 50 μM) induced only spiky responses, solely in the neurons responding in the same manner to 5-HT. Recently reported activators or inhibitors of 5-HT receptors from mouse DRG neurons, LY344864 (a 5-HT1F agonist), LP44 (a 5-HT7 agonist) and SB269970 (a 5-HT7 antagonist) had no effects on rat DRG neurons. Nominally calcium-free solutions abolished the transient and spiky components as did the co-application of 5-HT with lanthanum, a non-selective calcium channel (Ca_v) blocker. The

L-, N- and T-type Ca_v antagonists nifedipine, cilnidipine and mibefradil respectively, had no inhibitory action on the 5-HT-elicited responses. Ruthenium red, a broad range blocker of transient receptor potential (TRP) ion channels had either no effect, or enhanced the spiky responses. All the responses to 5-HT were abolished when sodium ions were replaced with N-methyl-D-glucamine. Activation of spiky responding neurons by 5-HT was simultaneously recorded using calcium imaging and patch clamp. In voltage clamp mode, at a holding potential of -80 mV, 5-HT activated only transient currents (inhibited by granisetron), while in current clamp mode it triggered bursts of action potentials accompanied by intracellular calcium increase. Taken together, our results show that 5-HT3 receptors mediate the transient responses to 5-HT, while the more sustained calcium entry accompanies action potentials following activation of not yet identified 5-HT receptors, also sensitive to 5-CT.

Title: Mechanisms underlying the excitation of rat sensory neurons via metabotropic 5-HT receptors

Authors: *E. GANTUMUR, I. SALZER, A. YOUSUF, S. BOEHM;
Med. Univ. of Vienna, Wien, Austria

Abstract: Serotonin (5-HT) is an inflammatory mediator and involved in pain sensation. Ionotropic 5-HT_3 receptors of dorsal root ganglion (DRG) neurons are thought to mediate this effect. However, the role of metabotropic 5-HT receptors remained controversial. Here, the contribution of metabotropic 5-HT receptors and their functional interactions with Kv7, TTX-resistant Na^+ channels, TRPV1 and Ca^{2+}-activated Cl^- channels (CaCCs) were investigated. Using the perforated and whole-cell patch clamp technique in voltage and current clamp mode on primary cultures of rat DRG neurons, effects of 5-HT receptor ligands on membrane potential and currents through Kv7, TTX-resistant Na^+ channels, TRPV1 and Ca^{2+}-activated Cl^- channels were investigated. 5-HT depolarized DRG neurons and increased their excitability. This effect was not altered by the 5-HT_3 receptor antagonist tropisetron, but reduced by the 5-HT_2 receptor antagonist ritanserin. Moreover, this increased excitation of DRG neurons by 5-HT was inhibited by TRPV1 antagonist capsazepine and CaCC blocker CaCC-Inh A01. Furthermore, this 5-HT-

induced excitation was inhibited by the 5-HT_{2C} receptor-specific antagonist RS102221 hydrochloride, but not by the 5-HT_{2A} receptor-specific antagonist 4F4PP oxalate or the 5-HT_{2B} receptor-specific antagonist SB204741. Currents through Kv7 channels and TTX-resistant Na^+ channels of DRG neurons were not affected by 5-HT. In contrast, 5-HT enhanced currents through TRPV1 channels in DRG neurons. This increase of TRPV1 current was inhibited by the non-selective 5-HT_2 receptor antagonist ritanserin as well as the specific antagonists of 5-HT_{2A} (4F4PP oxalate), 5-HT_{2B} (SB204741), and 5-HT_{2C} (RS102221 hydrochloride) receptors. Additionally, 5-HT also induced currents through CaCCs which were inhibited by the CaCC blocker CaCC-Inh A01 and the 5-HT_{2C} receptor-specific antagonist RS102221 hydrochloride, but not by the 5-HT_{2A} (4F4PP oxalate) or the 5-HT_{2B} (SB204741) receptor-specific antagonists. These results show that 5-HT enhances the excitability of DRG neurons via 5-HT_2 receptors with a major contribution of 5-HT_{2C} which simultaneously mediates a potentiation of TRPV1 channels and an activation of CaCCs.

Title: Identification of metabolite-sensing muscle afferents *In vivo* using GCaMP6s.

Authors: *K. M. SMITH-EDWARDS[1], A. R. LIGHT[2], C. J. WOODBURY[1];
[1]Zoology & Physiol., Univ. of Wyoming, Laramie, WY; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Although many chronic pain conditions are musculoskeletal in nature, the sensory inflow from muscles under different metabolic states is poorly understood. Recently, two populations of muscle afferents were shown to respond to different concentrations of muscle metabolites in reduced preparations (Light et al., J Neurophys 100: 1184, 2008; Jankowski et al., J Neurophys 109 : 2374, 2013); metaboreceptors responded best to lower levels found in muscle following moderate exercise and may contribute to the sense of fatigue, whereas metabonociceptors responded best to higher levels found after strenuous and/or ischemic

contractions and may contribute to pain (Pollak et al., Exp Physiol 99:368, 2014). To better understand the properties of metabolite-sensing muscle afferents in vivo we imaged population responses of these cells in GCaMP mice. Briefly, mice with GCaMP6s expression in all cells were anesthetized, L3-4 DRGs exposed, and DRG cells imaged while infusing the gastrocnemius with different metabolite solutions [control: 300nM ATP, 1mM lactate, pH 7.4; low: 1μM ATP, 15mM lactate, pH 7.0; high: 5μM ATP, 50mM lactate, pH 6.6; N=6). To date, 40 DRG cells that responded to infusions have been characterized. A few (n=6) responded equally well to control and metabolite infusions and were presumably chemically-insensitive mechanoreceptors. However, most in our sample (n=34) responded robustly to elevated metabolite levels and could be divided into two subpopulations. Half responded best to high metabolite levels (17.03 ± 3.35 $\Delta F/F$, n=17, $p<0.01$, ANOVA w/ Tukey's) and were presumably metabonociceptors, whereas the rest responded best to low metabolite levels (16.61 ± 2.68 $\Delta F/F$, n=17, $p<0.05$) and thus identified as metaboreceptors. Interestingly, the cell bodies of most metaboreceptors were small (76% ≤ 27 μm) whereas the majority of metabonociceptors had medium-to-large diameter somata (60% between 28-43 μm), further suggesting these are distinct populations. While some metaboreceptors also displayed sensitivity to mechanical (3/17) and/or heat stimuli (5/17), most were found to respond only to metabolites (10/17). Overall, these findings confirm two populations of metabolite-sensing muscle afferents in vivo under normal conditions and suggest that the majority of metaboreceptors exhibit fine-diameter afferent fibers that are selective for metabolites. Further studies using GCaMP to examine plasticity of these afferents in vivo may provide valuable insight into the development of chronic musculoskeletal pain.

Title: Operant tests assessing rat orofacial mechanical pain induced by systemic administration of oxaliplatin and local injection of Complete Freund's Aadjuvant into temporomandibular joints

Authors: *V. VIATCHENKO-KARPINSKI, F. EROL, J. LING, J. GU;
Anesthesiol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Chronic orofacial pain conditions are important clinical problems that are poorly treated. Two main causes of chronic orofacial pain states are cranial nerve neuropathy and orofacial tissue inflammation. Common symptoms associated with these pathological conditions are mechanical allodynia and hyperalgesia. In the present study, the chemotherapy drug oxaliplatin, which is known to be able to induce peripheral neuropathy, was systemically administered to rats to induce neuropathic pain. Complete Freund's Adjuvant (CFA) was locally injected into temporomandibular joints (TMJ) to induce inflammatory pain of TMJ. We assessed orofacial mechanical pain in these two animal models using the orofacial operant test. In both pathological pain models, the operant test showed significant changes in operant behaviors in the presence of mechanical stimulation, which indicated orofacial mechanical allodynia/hyperalgesia in these animals. We determined whether the hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels may be involved in the orofacial mechanical allodynia/hyperalgesia by testing ZD 7288, a blocker of HCN channels, on orofacial operant behaviors. Administration of ZD 7288 at the dose of 25 μg/kg (*i.p.* injection) showed no significant improvement of orofacial operant behaviors in oxaliplatin-induced orofacial pain model. We determined whether mechanical allodynia/hyperalgesia induced by oxaliplatin could be alleviated by retigabine, a KCNQ2/3 channel potentiator. We found that retigabine at the dose of 2 mg/kg (*i.p.* injection) significantly improved orofacial operant behaviors. KCNQ2/3 channels may provide an effective therapeutic target for the treatment of chronic orofacial pain manifested with mechanical allodynia/hyperalgesia.

Title: EPAC is responsive for the exacerbation of the injury-induced pain hypersensitivity after the second surgery

Authors: *M. MATSUDA, F. AMAYA;
KPUM, Kyoto, Japan

Abstract: Background
Activation of cAMP sensor protein EPAC in the DRG is associated with the development of chronic pain. Injury-induced pain hypersensitivity after the second surgery is greater than initial one, even the baseline sensitivity prior to the succeeding injury has been restored. In the present

study, we investigated the role of EPAC signaling in the DRG for the exacerbation of the injury-induced pain hypersensitivity after the second surgery.
Methods
Male SD rats (200-250g) were used for the experiments. All experimental procedures were approved by the animal ethics committee of the Kyoto Prefectural University of Medicine. Plantar incision model was used for a model of surgical injury. Initial and succeeding incisions were performed on left plantar with 14days intervals. Withdrawal threshold against mechanical stimulation by von Frey hair was analyzed up to 10days after each incision. To see the effect of EPAC inhibitor ESI-09 on pain hypersensitivity after the incision, animals were divided into two groups. ESI1 group received intraplantar injection of ESI-09 (25μg) 2hours prior to the first surgery. ESI2 group received intraplantar injection of ESI-09 (25μg) 2hours prior to the second surgery. Control group received same amount of vehicle.
Results
Plantar incision induced reduction of mechanical threshold against von Frey stimulation, indicating injury-induced pain hypersensitivity. Pain hypersensitivity was detected up to 5days after the first surgery. Succeeding injury induced longer pain hypersensitivity continuing for 10days. Mechanical threshold at 7days after the second surgery was significantly lower compared to the first surgery. ESI-09 inhibited prolonged pain hypersensitivity observed after the second surgery, but had no effect on the pain hypersensitivity after the first surgery.
Conclusion
Second surgery induces prolongation of the injury-induced pain hypersensitivity compared to the first surgery. EPAC signaling involves in the pain exacerbation after the second surgery.

Title: Prevention of muscle IL1β upregulation blocks ischemia/reperfusion injury-induced muscle afferent sensitization and pain-related behaviors

Authors: *J. L. ROSS, J. E. LAMB, L. F. QUEME, B. KATRAGADDA, Z. K. FORD, M. P. JANKOWSKI;
Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Musculoskeletal pain is a widely experienced, yet relatively understudied, clinical issue. Complications with peripheral circulation have been increasingly suggested as an underlying cause of muscle pain in multiple disease states, including sickle cell anemia and peripheral vascular disease. In our model of transient ischemia with reperfusion injury (I/R) in male Swiss Webster mice, we previously showed altered chemosensitivity and mechanical thresholds in single group III and IV muscle afferents as assessed with an *ex vivo* muscle-nerve-dorsal root ganglion (DRG)-spinal cord recording preparation. Primary afferent sensitization correlated with increased spontaneous (guarding) and evoked (von Frey mechanical stimulation) pain-related behaviors as well as decreased muscle strength and voluntary activity *in vivo*. These alterations in pain-like behaviors and sensory neuron responsiveness appeared to be due to increased interleukin 1β (IL1β) in the injured muscles acting at the upregulated interleukin 1 receptor (IL1r1) within the DRGs, as an afferent-specific knockdown of IL1r1 inhibited I/R-induced changes in afferent response properties and animal behaviors. In this study, we have used two additional strategies to effectively block the I/R-induced increase in muscle IL1β. Here we show that voluntary wheel running for two days prior to I/R not only prevented this IL1β enhancement, but also ablated the subsequent development of ischemic myalgia-like behaviors (increased paw guarding and reduced mechanical threshold, grip strength, and voluntary activity). In addition, systemic injection of the IL1 receptor antagonist (IL1RA), which would also block the effects of IL1β during I/R, was similarly found to prevent injury-induced upregulation of IL1r1 within the DRGs, and recapitulated most of the preventative effects of exercise or nerve-specific IL1r1 knockdown on I/R-related behaviors. IL1RA-treated animals, however, still experienced an I/R-induced grip strength deficit, suggesting that systemic inhibition of IL1β may potentially have other effects on muscle repair and/or function. Nevertheless, IL1RA was still found to block I/R-induced changes in afferent mechanical thresholds, chemosensitive muscle afferent prevalence, and gene expression in the affected DRGs. Altogether, these data strengthen the evidence that transient ischemia and reperfusion injury sensitizes group III and IV muscle afferents via increased IL1β in the muscles, which leads to the development of ischemic myalgia. This work may also provide insight into potential therapies for the prevention of persistent muscle pain initiated by an ischemic insult.

Title: Inward current and spontaneous excitatory transmission enhancement produced by orexin B in adult rat spinal substantia gelatinosa neurons

Authors: C. WANG, T. FUJITA, T. YU, R. HIRAO, N. MAGORI, R. SUZUKI, *E. KUMAMOTO;
Saga Med. Sch., Saga, Japan

Abstract: There is much evidence showing that oxytocin or orexin (hypocretin) originating from the hypothalamus inhibits nociceptive transmission from the periphery in the spinal dorsal horn. We have previously reported that oxytocin (0.5 μM) produces an inward current at a holding potential of -70 mV in 67 % of the spinal dorsal horn lamina II (substantia gelatinosa; SG) neurons examined without a change in glutamatergic spontaneous excitatory transmission. The SG neurons play a pivotal role in regulating nociceptive transmission from the periphery. An action of orexin on synaptic transmission in adult rat SG neurons has not yet been examined fully. In order to know cellular mechanisms for antinociception produced by orexin B (hypocretin 2), we examined its effect on holding current and spontaneous excitatory transmission at -70 mV by applying the blind whole-cell patch-clamp technique to SG neurons of adult rat spinal cord slices. In 17 % of the SG neurons examined (n = 129), orexin B (0.05 μM) superfused for 2 min produced an inward current which was not accompanied by a change in spontaneous excitatory transmission. On the other hand, 19 % of the SG neurons did not alter holding currents while exhibiting an increase in the frequency of spontaneous excitatory postsynaptic current (sEPSC). Both of the inward current and sEPSC frequency increase were produced in 27 % of the SG neurons. The sEPSC frequency increase subsided within 10 min after washout of orexin B. The inward current had the averaged peak amplitude of 6.8 ± 0.3 pA (n = 57) and sEPSC frequency around 2 min after the onset of orexin B superfusion averaged to be 188 ± 8 % (n = 59) of that before its superfusion with no change in its amplitude. Remaining neurons (n = 48; 37 % of the neurons) did not respond to orexin B. The inward current and sEPSC frequency increase were repeated at a time interval of 20 min. The orexin B activities were concentration-dependent; half-maximal effective concentration values for the inward current and sEPSC frequency increase were 0.020 and 0.066 μM, respectively. These results indicate that orexin B produces a membrane depolarization in SG neurons and increases the spontaneous release of L-glutamate to SG neurons from nerve terminals; the former action is

similar to that of oxytocin. Such orexin B actions could contribute to its antinociceptive action in the spinal dorsal horn.

Title: Dissecting protein kinase C-sensitive adenylyl cyclase signaling complexes in mouse sensory neurons with affinity purification mass spectrometry

Authors: C. ESANCY, B. K. DRAGOO, R. GEGUCHADZE, *D. C. MOLLIVER;
Biomed. Sci., Univ. of New England, Biddeford, ME

Abstract: Gs-coupled metabotropic receptors play a significant role in the sensitization of nociceptors in response to inflammatory insult or injury, by activating the adenylyl cyclase (AC)-cAMP-protein kinase A (PKA) pathway. Conversely, ACs are inhibited by Gi/o-coupled receptors, which is one mechanism underlying analgesia provided by opiates. Type II AC isoforms are uniquely regulated in that they can be activated by protein kinase C (PKC) as well as Gs, making them potential integrators of signaling through multiple second messenger pathways usually considered to be distinct. Coincident activation of Gq/11-coupled receptors (leading to activation of PKC) and Gs-coupled receptors is likely to occur in response to peripheral injury or insult. Furthermore, Type II ACs are insensitive to inhibition by Gi/o-coupled receptors, suggesting the possibility that these AC isoforms, if expressed in primary afferent nociceptors, could contribute to persistent pain recalcitrant to descending inhibition or exogenous opiates. Therefore, we examined the distribution of Type II ACs ADCY2, ADCY4 and ADCY7 in sensory neurons of the dorsal root ganglion (DRG) from adult male mice. Real-time PCR revealed mRNA for all 3 isoforms in whole DRG (ADCY2 > ADCY7 > ADCY4). RNA levels did not change significantly 3 days after inflammation induced by hindpaw injection of complete Freund's adjuvant or 7 days after sciatic nerve crush. Analysis of mRNA levels in neuronally-enriched and glial-enriched DRG fractions by endpoint RT-PCR indicated expression

of ADCY2 and 7 mRNA in DRG neurons. Immunohistochemistry revealed intense staining of small-diameter neurons for AC2, the majority of which were also positive for TRPV1. We next used affinity purification mass spectrometry to identify binding partners of AC2, using antibodies to the endogenous protein. Two dimensional difference gel electrophoresis (2D DiGE) was analyzed with DeCyder 7 software to identify any changes in binding partners in response to nerve injury. Spots of interest on 2D gels were picked, fragmented with trypsin and analyzed by MALDI ToF peptide mass fingerprinting to characterize protein complexes associated with AC2 in DRG from healthy and nerve-injured mice.

Title: A rapid method for selective enrichment of Nav1.8-containing sensory neuron synaptosomes from the rat spinal cord

Authors: *J. A. MCROBERTS, H. S. ENNES, J. C. MARVIZON;
Dept Med., UCLA, Los Angeles, CA

Abstract: Much of what is known about the presynaptic terminals of sensory neurons in the spinal cord has been inferred from studies of dorsal root ganglia cell bodies, measurement of neurotransmitter release, or co-localization of antibodies in spinal cord sections. The objective of this study was to selectively enrich synaptosomes prepared from the spinal cord of rats for those arising from synaptic terminals of small diameter sensory neurons involved in pain transmission. An antibody recognizing an extracellular epitope of the voltage gated sodium channel, Nav1.8 (Alomone) was covalently crosslinked to amine-derivatized MagnaBind beads (Thermo Sci) using BS^3 as a crosslinker. After quenching the reaction with Tris, the beads were washed with PBS and blocked with a protein-free blocking buffer. Non-derivatized beads were prepared identically except that the antibody was left out of the reaction. For rapid isolation of synaptosomes, spinal cord tissue was homogenized with a Dounce tissue grinder in Syn-PER reagent (Thermo Sci). The homogenate was centrifuged at 1200 *g* for 10 min and the supernatant (crude extract) centrifuged at 15,000 *g* for 20 min. A sample of the supernatant (cytosol) was

collected for analysis and the pellet (crude synaptosomes) resuspended and preabsorbed with the non-derivatized beads for 1 hr. The beads were removed and the synaptosomes added to the Nav1.8-derivatized beads for 2 hr. After washing, the affinity enriched synaptosomes were eluted from the MagnaBind beads with buffer containing 1% SDS. All fractions were subjected to SDS gel electrophoresis and western blots were probed with antibodies to synapsin-1, Nav1.8, TrpV1, and Cav2.2. The density of each band was measured and normalized to that of the crude extract. As shown in the table, the crude synaptsome preparation was enriched in all 4 proteins, however the Nav1.8 affinity purified synaptosomes were selectively enriched in the heat and acid sensing channel, TrpV1, and N-type calcium channel α1 subunit, Cav2.2, as well as Nav1.8. This preparation may be useful in identifying changes in the phosphorylation and protein composition of sensory neuron terminals in the spinal cord.

	Synapsin-1	Nav1.8	TrpV1	Cav2.2
crude extract	1.00	1.00	1.00	1.00
cytosol	0.68	0.52	0.23	0.06
crude synaptosomes	1.57	2.26	6.73	1.68
Nav1.8 enriched synaptosomes	2.22	4.94	14.14	4.22

Abstract: A first draft digital reconstruction and simulation of the somatosensory cortical microcircuit of a two-week-old rat was recently published. Using this resource, we explored whether methods from algebraic topology can provide a novel and useful perspective on the structural and functional organization of the microcircuit. Structural topological analysis revealed that directed graphs representing the connectivity between neurons are significantly different from random graphs even when distance dependence of connectivity is taken into account. Further, there exist an enormous number of simplicial complexes of different dimensions representing all-to-all connections within different sets of neurons, the most extreme motif of neuronal clustering reported so far in the brain. Functional topological analysis based on data from simulations confirmed the interest of the new approach to studying the relationship between the structure of the connectome and its emergent functions.

Title: Systematic integration of literature-derived knowledge into data-driven large-scale neuronal modeling workflows

Authors: *C. O'REILLY, E. IAVARONE, S. HILL;
Blue Brain Project, École Polytechnique Fédérale De Lausanne, Geneva, Switzerland

Abstract: Building large-scale realistic models of neuronal circuits such as those being designed in the context of the Blue Brain Project requires setting values to a large number of parameters. Previously reported values must therefore be systematically extracted from the literature, in some cases to be directly included in the model (e.g., when no experimental data are available) or for validation purposes. This process requires an extensive and time consuming review of the literature. Further, without appropriate curation methodology, the outcome of this work is generally poorly reusable between projects. Moreover, without a systematic way to include these values into models, the traceability of their origin can be easily lost. To address these issues, we have developed a series of open-source tools to systematically and collaboratively curate the relevant literature (NeuroCurator[1,2]), share this information in annotation corpora, and systematically query corpora (thanks to links with ontological terms) to feed appropriate values to models (MetaModeler[3]). Inserted values are associated with unique IDs, which allow to find the exact source of populated values (i.e., not only an unambiguous reference to the original publication but also the precise place where this value is reported in the original document). This software pipeline has been designed in Python with user-friendly Qt-based graphical user interfaces, as well as back-end APIs allowing manipulating corpora programmatically, e.g., through Jupyter (IPython) notebooks. We demonstrate the usefulness of this approach by showing its application in modeling the thalamocortical loop in the context of the Blue Brain Project. In future work, we want to better integrate these software with other existing tools, both annotation producers (e.g., annotation interfaces such as Hypothes.is[4] or B2Note[5] as well as text-mining applications such as Sherlok[6]) and consumers (e.g., web interfaces such as Knowledge-Space[7]).

Abstract: Uncovering hidden regularities and topological structures of cortical microcircuitry is vital for understanding neural computation. Recent experimentally-constrained dense in silico reconstructions of ~0.3mm^3 of rat somatosensory neocortex, consisting of ~31,000 neurons and ~40 million synapses, have provided an unprecedented opportunity to analyze microcircuitry at the synaptic-level. We identified multiple wiring specificities, distinct for excitatory (E) and inhibitory (I) populations. The number of E and I synapses/cell varied across neurons, yet excitatory neurons maintained relatively constant E/I ratio. The microcircuit contained highly connected hub-neurons, belonging to a small subset of cell types; these hubs are strongly interconnected among themselves, forming cell-type-specific rich-clubs. Certain three-neuron motifs were overrepresented, matching recent experimental results. Global small-world topology was observed, with an average of 2.5 synapses separating any two neurons. By unraveling the topological backbone of a dense neocortical microcircuit, this study provides several experimentally testable predictions and a systematic approach to interpret micro-connectomics "big data".

Abstract: At many scales in neuroscience, appropriate mathematical models often take the form of complex dynamical systems. Constraining such models to the multitude of available experimental data is a global nonlinear optimisation problem with a complex fitness landscape, generally requiring heuristic techniques to find suitable approximate solutions. Stochastic optimisation approaches, such as evolutionary algorithms, have been shown to be effective, but often the setting up of such optimisations is non-trivial, requiring domain-specific expertise. Here we describe BluePyOpt, an extensible open-source Python-based framework targeted at the broad neuroscience community to simplify the development of data-driven model parameter optimisations. The versatility of the BluePyOpt framework is demonstrated by working through three representative neuroscience specific use cases: point-neuron and morphologically detailed neuron models, and a calcium-based model of synaptic plasticity. Further, BluePyOpt provides methods for setting up both small- and large-scale optimisations on a variety of platforms, ranging from laptops to Linux clusters and cloud-based compute infrastructures. BluePyOpt is intended as a resource for the community, and as been deployed on public resources such as the

Human Brain Project Brain Simulation Platform (https://collab.humanbrainproject.eu), and the Neuroscience Gateway (http://www.nsgportal.org).

Abstract: Humans' advanced cognitive capabilities are often attributed to our recently evolved neocortex. However, we do not know whether neurons composing the human neocortex themselves possess unique biophysical or computational capabilities. Combining rare physiological and anatomical data with modeling approach, we find that layer 2/3 pyramidal cells in human temporal cortex (HL2/3 PCs) are exceptional in three major ways. First, the cell membranes have a surprisingly low specific capacitance (C_m = ~0.5 μF/cm^2), which promotes excitability. Second, they have disproportionally elongated distal basal dendrites, which receive powerful (AMPA + NMDA) synaptic input, providing the cells with a large number of semi-independent nonlinear functional subunits. Third, the cells generate axonal Na^+ spikes upon activation of 80-120 excitatory synapses (out of 15,000-30,000), endowing them with a huge combinatorial input/output repertoire. Our study provides the first-ever comprehensive model of

any human neuron and demonstrates the biophysical and computational uniqueness of human cortical neurons.

Title: Extracellular calcium influences on long-term plasticity

Authors: ***R. PERIN**[1], G. CHINDEMI[2], E. MUELLER[2], H. MARKRAM[2];
[1]Brain Mind Institute, EPFL, Lausanne, Switzerland; [2]EPFL, Lausanne, Switzerland

Abstract: Calcium is an essential ion involved in determining how neuronal activity impacts long-term synaptic plasticity. Here we studied the effects of varying extracellular calcium concentration on long-term potentiation and depression in thick-tufted layer 5 pyramidal neurons of the somatosensory cortex of young rats (postnatal days 14 to 18). Patch-clamped neurons in acute brain slices *in vitro* maintained in extracellular calcium concentrations ranging from 1 mM to 2 mM were stimulated with either long-term depression or facilitation protocols. We observed that in certain cases the same protocol applied under different calcium concentrations produced very different effects. These results suggest that synaptic plasticity *in vivo* would be influenced by calcium concentration changes found between sleep and wakefulness and may also be affected by network states, which may cause short-term changes in the levels of calcium.

Abstract: The Blue Brain Project has developed a data-driven process for the digital reconstruction of juvenile rat somatosensory cortex by integrating biological data on its cellular and synaptic anatomy and physiology. The resulting microcircuit reconstruction was released in October, 2015 and was found to be broadly consistent with the state of knowledge on the structure and function of neocortical microcircuitry. For the October, 2016 (2016.10) release of the microcircuit, a series of updates and refinements have been made, including morphological classification of pyramidal neurons based on newly developed topological methods, axonal morphologies based on in vivo axonal reconstructions and synthesis approaches, models of synaptic transmission accounting for multi-vesicular release and long-tailed synaptic physiology distributions, neuron model parameterizations for each electrical type were optimized for each morphological type, structural representation of glia, addition of gap junctions between inhibitory neurons, and addition of synthesized thalamo-cortical axonal projections. We assessed quantitative differences compared to the previous version of the reconstruction across a suite of anatomical and physiological validations at the synaptic, cellular and network levels, and relate these differences to the underlying refinements. As with previous releases, the 2016.10 microcircuit release is available as a resource to the community through the NMC portal (https://bbp.epfl.ch/nmc-portal), and the Human Brain Project Brain Simulation Platform (https://collab.humanbrainproject.eu).

Title: A somatotopic distribution of physiological, morphological, and connectivity properties in the ventral posterolateral nucleus

Authors: *J. YI[1], E. IAVARONE[2], C. O'REILLY[2], R. PERIN[1], H. MARKRAM[2];
[2]Blue Brain Project, [1]EPFL, Lausanne, Switzerland

Abstract: The ventral posterolateral (VPL) nucleus of the thalamus serves as a relay center for the somatosensory system, receiving various forms of tactile and proprioception information from the periphery. These sensory signals are known to be mapped onto the somatosensory cortical surface in a topographic point-for-point correspondence. The VPL, a subcortical input to the somatosensory cortex, has also been observed to exhibit a similar somatotopy, and thus, we hypothesized a corresponding distribution of the physiology, morphology, and connectivity of the neurons. Here, we systematically investigated the electrophysiological and morphological characteristics of the VPL in rats of age postnatal 14-18 days. We obtained whole cell multi-patch clamp recordings of VPL relay cells in acute slices and stained and morphologically reconstructed the neurons. In addition, we used retrograde tracing to map the parallel connectivity between the VPL relay cells and associated primary cortical regions. The VPL relay cell data is being integrated into the *in silico* model of the rat somatosensory cortex (Markram et al. 2015) to reconstruct and simulate this thalamocortical pathway. We explored how the heterogeneity of functional and morphological properties of the VPL and their connectivity properties may impact sensory perception.

Title: A data-driven computational model of relay cells of the ventral posterolateral nucleus of the thalamus

Authors: *E. IAVARONE[1,2], C. O'REILLY[1,2], J. YI[2,3], H. MARKRAM[1,2,3], S. HILL[1,2]; [1]Blue Brain Project, Geneva, Switzerland; [2]École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [3]Brain Mind Inst., Lausanne, Switzerland

Abstract: Thalamic sensory nuclei are important relay stations along the lemniscal and paralemniscal pathways, which transfer somatosensory information from the periphery to the neocortex. However, the sensory thalamus is also part of the thalamocortical loop, a circuit that sustains sleep rhythms, wakefulness, alertness, and consciousness, in cooperation with the thalamic reticular nucleus and brainstem modulatory nuclei. Our long-term goal is to investigate these brain functions in a detailed computational model of the thalamocortical loop. We first focused on thalamocortical (TC) cells of the ventral posterolateral nucleus (VPL), the direct counterpart of the neocortical microcircuit model of the hindlimb somatosensory cortex proposed by Markram *et al*. (2015).
We used the NEURON simulator to build data-driven biophysical models of TC cells. Model construction and validation were achieved using open-source software and well-established pipelines, in reproducible steps organized in Jupyter (IPython) notebooks. Features characterizing the two main firing regimes of TC cells (*i.e*. tonic firing and bursting) were extracted from electrophysiological recordings. The free parameters describing ion channels densities and distributions were constrained using a multi-objective optimization strategy already applied by our group (Van Geit *et al*., 2016). We validated our model by observing that values describing cell properties, not fitted during the model construction phase, fell within expected physiological ranges. The final set of parameters was applied in combination with different 3D

morphologies and the resulting models were considered acceptable if the firing responses fell in the range of experimental variability.
Our methodological approach makes the process of building data-driven *in silico* neurons reproducible and easily adaptable. The results of the simulations replicated many experimental findings, including the firing behavior reported in the literature and observed in our multi-patch recordings.

Title: A data-driven unifying model of synaptic variability and multi-vesicular in neocortical microcircuitry

Authors: ***J. RAHMON**, G. CHINDEMI, R. PERIN, M. REIMANN, M. NOLTE, H. MARKRAM, E. MULLER, S. RAMASWAMY;
EPFL Blue Brain Project, Geneve, Switzerland

Abstract: Synaptic connections between neurons are characterized by a diversity of efficacy and reliability. Here, we focused on connections between layer 5 thick-tufted pyramidal cells (L5TTPCs), where the synaptic anatomy and physiology are well characterized experimentally.

We used an extension of the classical quantal model of synaptic transmission to examine how synaptic variability and muti-vesicular release (MVR) contribute to the efficacy and reliability of L5TTPC connections. We implemented a model of synaptic variability and MVR into morphologically-detailed *in silico* reconstructions of L5TTPC connections, and systematically calibrated the synaptic parameters by iteratively comparing the behavior of *in silico* connections against *in vitro* biological data. Next, we applied a novel technique to predict additional features of synaptic variability, such as intra-synapse correlations between the size of the readily-releasable pool and the postsynaptic response to the release of a single vesicle, for which biological data is either sparse or lacking. Finally, we implemented the validated model of synaptic variability and MVR into a digital reconstruction of neocortical microcircuitry. This work provides detailed insights into the impact of synaptic variability and MVR on properties of neocortical network activity, including spiking probability, and spike timing reliability of neurons.

Abstract: We present an overview of the core functionalities of the Human Brain Project (HBP) Brain Simulation Platform (BSP), on behalf of all contributors. The BSP was developed as one of six internet-accessible ICT platforms for collaborative brain research being developed by the European HBP, with the goal of providing scientists with new user-friendly tools to reconstruct and simulate scaffold models of various neuron types and whole brain tissue in a data-driven fashion. Its development is done in a tight co-design loop between science and engineering within the HBP consortium, to stimulate the required substantial technical and scientific innovations. One important co-design driver has been the reconstruction and simulation of the neocortical microcircuitry of the Blue Brain Project (Markram et al., Cell, 2015), and the recent application of these techniques and workflows to other brain regions, notably the cerebellum, hippocampus and basal ganglia. The BSP was released to the public in April, 2016, (https://www.humanbrainproject.eu/pl/sp6-brain-simulation-platform) providing intricate pipelines for reconstruction and simulation packaged into web-accessible workflows, or showcased as use cases. Many of the fundamental software packages that the BSP relies on and develops are freely available as open source. Using these tools and workflows, the BSP hosts team-science Collabs for collaborative building of scaffold models of different neurons, synapses and brain regions. The unique functionality of the BSP accelerates collaborative brain research worldwide and allows novel questions to be addressed, which were previously inaccessible.

Title: Quantitative topological analysis of neuronal trees

Authors: *L. KANARI[1], P. DLOTKO[2], M. SCOLAMIERO[3], R. LEVI[4], J. SHILLCOCK[1], K. HESS[3], H. MARKRAM[1];
[1]Blue Brain Project, EPFL, Geneve, Switzerland; [2]DataShape, INRIA Saclay, Ile-de-France, Paris, France; [3]Lab. for Topology and Neurosci. at the Brain Mind Institute, EPFL, Lausanne, Switzerland; [4]Inst. of Mathematics, Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Simulations of the mammalian neocortex, such as those performed by the Blue Brain Project, rely fundamentally on accurate neuronal morphologies. The shape of neuronal arborizations is a key feature for the classification of neurons, and defines amongst other aspects their physical connectivity and functionality. Yet an efficient method for quantitatively analyzing the spatial structure of such trees has been difficult to establish.
The wide diversity of neuronal morphologies in the brain, even for cells identified by experts as of the same type, renders an objective classification scheme a challenging task. We propose a new topological method for quantitatively capturing the branching shapes of neurons, the Topological Morphology Descriptor (TMD), that overcomes the limitations of existing techniques such as feature extraction. The TMD of neuronal trees allows different neuronal populations to be clearly distinguished, including those whose visual appearance is only subtly different, and therefore provides an objective classification of cells into discrete morphological classes.
This method is applicable to any tree-like structure, and we demonstrate this by applying it to groups of mathematical random trees as well as neuronal trees. Our results show that the TMD of tree shapes is highly effective for reliably and efficiently distinguishing different groups of trees. We also propose an extension to the method that can be used to track the morphological evolution of trees.

Title: Data-driven reconstruction of mesoscale connectivity in a whole mouse-brain model

Authors: *M.-O. GEWALTIG, C. EROE, D. KELLER, H. MARKRAM;
Blue Brain Project, Ecole Polytechnique Federale De Lausanne, Geneve, Switzerland

Abstract: Retrograde Recombinant Adeno-Associated Virus (rAAV) is a virus used to trace neural pathways by expressing fluorescent proteins in the cell bodies, dendrites, and axons of injected neurons. Recently, the Allen Institute for Brain Science (Oh et al. 2014) published an extensive dataset of multiple rAAV injections along with the estimated connection probabilities between 213 areas from the Allen Brain Atlas (ABA) and their statistical significance in terms of P-values.In this contribution, we present an alternative analysis of the same data with the aim to estimate the long-range connectivity of a point neuron network of whole mouse brain (Eroe et al. 2015). Our workflow consisted of two steps: In the first step, we generated an approximate model of the positions of all excitatory and inhibitory neurons in the mouse brain, based on the Allen Brain Atlas. In the second step, we used the raw rAAV voxel data to create synaptic connections between pairs of neurons using an acceptance-rejection method. To compare our mesoscale connectivity model with the previously published connectome from the ABI, we determined the connection probabilities between the same 213 brain regions as analyzed by Oh et al. Assuming that the strength of an inter-areal connection proportional to the number of mutual synaptic contacts, we counted the number of mutual synaptic contacts for each pair of brain regions. Finally, we compared our synapse-based connectome to the ABI mesoscale connectome, focusing on the strongest 50% of the connections. This allowed us to to identify connections that are common in both connectomes, connections that are exclusively predicted by Oh et al. and connections that are exclusively predicted by our approach. Both connectomes showed similar patterns of connectivity, which was expected as both used the same rAAV injection datasets. We also observed a similar near log-normal distribution of the connections strengths (in number of synapses). Current work focusses on integrating other data-sets (Markram et al. 2015) to also obtain microscale connectivity between cortical neurons.

Title: Network state-dependence of synaptic transmission in neocortical microcircuitry

Authors: *S. RAMASWAMY, J. G. KING, M. W. REIMANN, H. MARKRAM, E. MULLER; EPFL - Blue Brain Project, Geneva, Switzerland

Abstract: The neocortex contains a rich diversity of excitatory and inhibitory neurons. Decades of studies have enriched our understanding of the principles of neuronal and synaptic organization in neocortical networks. However, detailed knowledge on how network activity states regulate neuronal physiology and synaptic transmission is still lacking. The Blue Brain Project has developed a process to pragmatically integrate neuronal and synaptic organizing principles to digitally reconstruct the detailed anatomy and physiology of neocortical microcircuitry from sparse biological data. The *in silico* reconstruction of neocortical microcircuitry comprises a volume of 0.29 mm^3, ~31,000 neurons distributed across 6 layers, 55 layer-specific morphological and 207 morpho-electrical neuron subtypes, and ~8 million synaptic connections with ~37 million synapses. Simulations of spontaneous activity in the reconstruction revealed a spectrum of network states spanning synchronous neuronal activity on one end, and asynchronous activity on the other. The *in silico* reconstruction predicts the physiology of 31,000 neurons, and their synaptic connections in a spectrum of network activity states mediated by tonic depolarization and extracellular Ca^{2+} ranging from *in vitro* (~2 mM) to *in vivo* (~1.2 mM) levels. Experimentally testable predictions provide further insights into network state-dependence of the efficacy and short-term dynamics of excitatory and inhibitory synaptic transmission in neocortical microcircuitry across a range of neuronal depolarization and extracellular Ca^{2+} levels. We propose the reconstruction as a powerful complementary approach to existing experimental techniques to foster a systematic characterization of the structure and function of neocortical microcircuitry.

Title: In silico voltage sensitive dye imaging in a digital model of somatosensory cortex.

Authors: ***T. H. NEWTON**[1], M. ABDELLAH[2], E. MULLER[2], F. SCHUERMANN[2], H. MARKRAM[2];
[1]EPFL BBP, Geneva, Switzerland; [2]BBP, EPFL, Lausanne, Switzerland

Abstract: We report on an in silico implementation of voltage sensitive dye imaging (VSDI) for exploring and validating mesoscopic neural activity in a biologically detailed digital reconstruction of rat somatosensory cortex. The cortical model comprised a network of ~775,000 neurons arranged in a five by five hexagonal grid of connected functional microcircuit units, spanning a patch of simulated tissue 1990 μm x 1840 μm in area and 2000 μm deep. Two methods of acquiring in silico fluorescence signals were compared for computational performance, namely Monte Carlo simulation and a Beer-Lambert law-based approximation of light scattering and absorption in tissue. We evaluated the behavior of our in silico VSDI model against several findings reported in the literature, including sublinear summation of paired stimulation, activity spread velocity, and state-dependent stimulus response. Furthermore, leveraging the flexibility of our digital model, we addressed two unresolved questions concerning the origins of the VSD signal: 1) the relative importance of spiking activity vs. subthreshold fluctuations in membrane potential, and 2) the respective contributions of excitatory and inhibitory cells.

Abstract: A first detailed draft of digitally reconstructed and numerically simulated interactions in ~1/3 of a cubic millimeter of the rat neocortex has recently been reported (Markram et al. 2015). This work integrated the current state of experimental knowledge about the detailed 3D anatomy and physiology of the various neuron types and their synaptic properties and connectivity. On the other hand, for large-scale network simulations, point-neuron models are typically used for describing and analyzing network dynamics and functions. The properties and connectivity structure of point neuron models, for the most part, have not been constrained by biological data and thus were using ad hoc assumptions. This makes some of the mathematically tractable models somewhat disconnected from experimental neuroscience. To bridge the gap between these two extremes (the detailed and the oversimplified), we aimed to derive point-neuron network models from data-driven detailed network models in an automated, repeatable

and quantitatively verifiable manner. The simplification occurs in a modular workflow, in an *in vivo*-like state. First, synapses are moved from dendrites to the soma while correcting for dendritic filtering using low-pass filters for the synaptic current with parameters computed numerically in a morphology-type specific manner. Next, point-neuron models for each neuron in the microcircuit are fitted to their respective morphologically detailed counterparts. Here, generalized integrate-and-fire point neuron models are used, leveraging on a recently published fitting toolbox (Pozzorini et al. 2015). The fits are constrained by currents and voltages computed in the morphologically detailed reference neurons with soma-located synapses. Benchmarking the simplified network model to the detailed microcircuit model for a range of simulated *in vivo* and *in vitro* protocols, we found good agreement for both quantitative and qualitative aspects. Our approach not only makes it possible to continuously update the simplified circuit as the detailed network integrates new data but the modularity of the simplification process also makes it applicable to other point-neuron and synapse models and network simulators. In addition to providing strong validation for carefully-reduced point neuron network models, our approach is fundamentally important and informative, in particular in cases when network functionalities are lost during the simplification pipeline. Missing functionalities can illustrate the contributions of specific synaptic and cellular (anatomical and physiological) properties to the overall computations implemented by the network.

Title: The connectome is also a mathematical problem

Authors: ***M. W. REIMANN**, H. MARKRAM;
Blue Brain Project, Geneve, Switzerland

Abstract: Obtaining the synaptic connectivity between neurons is one of the biggest challenges of modern neuroscience. Various approaches involving a considerable amount of effort and resources have been devoted to experimentally map the connectivity between neurons. Yet, each of these approaches only sample a minuscule and potentially biased fraction of any given brain region, and conversely, a map of connectivity between neurons large enough to understand brain function still cannot be fully established. Here, we argue that full experimental mapping of all connections may not be necessary since known principles of biological organization already constrain which connections can and cannot exist. To know the state of a system, exhaustive sampling is only required if it is completely random, however, the brain like any other biological system is characterized by structure. We show mathematically, how the application of known rules of biological structure and simple physical limitations - such as limited axon lengths and bouton densities, multi-synaptic connections and the requirement of axo-dendritic overlap - constrain the neocortical connectome. We measure the remaining entropy of the connectome before and after the application of constraints and further show which strategic measurements are expected to most reduce it in the future.

Title: Multi-level brain region reconstruction and simulation on supercomputers: Enhancements for performance, scalability, and usability.

Authors: ***J. G. KING**[1], P. KUMBHAR[1], M. HINES[2], A. DEVRESSE[1], T. SCHUMANN[1], A. OVCHARENKO[1], S. YATES[1], F. DELALONDRE[1], F. SCHUERMAN[1], H. MARKRAM[1]; [1]Blue Brain Project, Brain Mind Institute, EPFL, 1202 Geneva, Switzerland; [2]Dept. of Neurobio., Yale Univ., New Haven, CT

Abstract: The Blue Brain Project has developed a data driven process to digitally reconstruct and simulate a piece of neocortical tissue, which faithfully reproduces an array of laboratory experiments. Efforts continue to extend the capabilities of tools to support greater variety and biological accuracy of these reconstructions. The first part of the workflow consists of implementing applications for large-scale neuronal network reconstructions including millions of neurons. New additions to the building capabilities have first been focused on increasing the level of biological details and thus the faithfulness of model. As such support for more complex rotations implemented as quaternions has been added to better capture the anatomy of curved tissue rather than flat tissue slices prior. This was done with an initial use case involving regions of the Hippocampus. Parallel to these scientific developments the usability of the building pipeline has been increased by adding the capability to output model deltas at each stage of the building pipeline and make all microcircuit reconstruction features accessible through the Human Brain Project "Software as a Service (SaaS)" Collaboratory for ease of use by the community. To leverage the recent improvements of the model-building pipeline, new simulation capabilities have been added to brain simulators at three different scales. At the coarsest scale, a parallel implementation of the NEST import module has been implemented and tested on up to 28 racks of the Juqueen supercomputer to allow the faithful model building of the mouse brain size with both short and long range biological data connections. At the intermediate scale, CoreNeuron has been open sourced on github to support development of more efficient and scalable simulation of large neuronal networks (up to 550 million neurons) on 48 racks of the MIRA supercomputer. Finally, the STEPS simulator has been extended to support the distributed execution of coupled stochastic reaction-diffusion and eField model on up to 1,000 cores.

Title: Neural mechanisms underlying odor preference choice in *Drosophila* larva

Authors: *Y. DAIRYO, K. EMOTO;
The Univ. of Tokyo, Tokyo, Japan

Abstract: The sensory-evoked behavior of animals is flexible and can be changed dramatically during development, yet the underlying mechanisms remain obscure. We focused on the odor preference behaviors in *Drosophila* larvae as a model system and established a quantitative assay system for the larval odor preference behavior. Using this assay system, we found that the third instar larvae dramatically change their odor preference during the late larval stages. For example, foraging larvae (72-96 hours after egg laying) are strongly attracted to propionic acid, whereas wandering larvae (96-120 hours after egg laying) show less interest to the same odor. This suggests that neural circuits that determine the odor preference might be modified during 24 hours prior to metamorphosis. To elucidate neural circuits underlying the preference change, we attempted to identify neurons involved in the odor preference choice by genetically manipulating neuronal functions. We recently identified two pairs of candidate neurons involved in the preference change. The wandering larvae failed to change the odor preference if the candidate neurons were functionally silenced. Moreover, the candidate neurons projected to the mushroom body neurons, the neurons involved in various innate behaviors and associative olfactory learning in *Drosophila*, suggesting that the MB neurons serve as a modification site for the odor preference change. We would like to discuss how the brain makes decision and also changes the decision against the same sensory information.

Title: Interaction between cell-type specific excitation and inhibition in the *Drosophila* mushroom body circuit

Authors: *K. INADA[1,2], H. KAZAMA[1,2];
[1]RIKEN BSI, Wako Saitama, Japan; [2]Grad. school of arts and sciences, Univ. of Tokyo, Bunkyo-ku, Japan

Abstract: Information about external stimuli is encoded as spatiotemporal patterns of neural activity in the periphery. These neural representations are transformed progressively in multiple brain regions. Different types of neurons in a region play different roles in computation, but the underlying biophysical mechanisms remain unclear. To understand the mechanism, it is essential to place individual neurons in the context of a circuit and examine how synaptic transmissions interact in these cells. In practice, this involves manipulating specific types of inputs to a target cell, which can be difficult to achieve.

Here we use the mushroom body (MB) circuit of *Drosophila melanogaster*, which is suitable to achieve this goal. The MB encodes odors sparsely and plays an essential role in olfactory association. The principal neurons of the MB, the Kenyon cells (KCs), are morphologically divided into three subtypes: α/β, α'/β' and γ. They receive excitatory input from a subset of projection neurons (PNs) in the antennal lobe and inhibitory input from a giant GABAergic anterior paired lateral (APL) neuron in the MB.

We started by examining how excitatory inputs are integrated in KCs. We expressed an optogenetic probe in PNs to manipulate their activity while performing whole-cell patch-clamp recording from postsynaptic KCs. Because each PN sends dendrites exclusively to a single glomerulus in the antennal lobe, the activity of a specific type of PNs can be manipulated by targeting a specific glomerulus with light. Glomeruli were stimulated either with a pulsed laser or wide-field blue light. We found three major rules of signal processing. First, synaptic transmission between PNs and KCs is faithful: KCs respond in proportion to the PN firing rate. Second, KCs integrate inputs from multiple PNs linearly. Third, responses of KCs are largely determined by directly-connected PNs with little influence from indirectly-connected (lateral) PNs.

As we increased the strength of PN input to the MB, APL neuron started to provide feed-back inhibition to KCs. We found that although APL neuron morphologically innervates the entire MB, it can inhibit KCs locally: only a subset of KCs was inhibited depending on the level of PN activity. Notably, this inhibition was recruited mainly by α'/β' KCs. Because optogenetic stimulation of APL neuron inhibited all KC subtypes similarly, our data together suggest that input from KCs to APL neuron is the origin of specificity.

Our results reveal cell-type specific circuit mechanisms that shape the activity of KC subtypes, each contributing to different aspects of olfactory memory.

Title: Postmetamorphic plasticity of the mushroom bodies

Authors: *B. TREBELS[1], S. DIPPEL[2], E. A. WIMMER[2], J. SCHACHTNER[1];
[1]Deptartment for Biology, Animal Physiol., Philipps-University Marburg, Marburg, Germany;
[2]Dept. of Developmental Biol., Georg-August-University Göttingen, Göttingen, Germany

Abstract: With its fully sequenced genome and the susceptibility for reverse genetics based upon RNA interference (RNAi), *Tribolium castaneum* is best suited to study the development and plasticity of the nervous system. While plasticity can be provided by various mechanisms, we focus on ongoing cell proliferation in the adult brain. It is well established that neurogenesis persists in the mushroom bodies (MB) of adult insects, including beetle *T. castaneum* where neuroblasts giving birth to MB Kenyon-cells remain active for more than one month after adult eclosion. To label cell proliferation in the adult beetle we successfully adapted the 5-ethyl-2'-deoxyuridine (EdU) technique to living beetles. Combined with immunohistochemistry against the glia-cell marker reversed-polarity and the use of transgenetic lines expressing neuron- and/or glia-specific markers, we labeled the progenies of adult persisting neuroblasts, determined their identity and counted the newborn Kenyon cells in within the first week after adult eclosion to determine the proliferation rate.
In several studies it was proposed that newborn neurons of MBs may play a role during olfactory processing and learning. We combined the EdU-staining with olfactory stimulation using the leaf alcohol cis-3-hexen-1-ol and again determined the proliferation rate. Our data suggest at least two phases. Direct after adult eclosion, proliferation is independent from stimulation with the leaf alcohol, while after about three days, proliferation is influenced by olfactory stimulation.
To further investigate MB plasticity, we plan to use other odors, including the beetle's aggregation pheromone 4,8-dimeythydecanal (DMD), odor deprivation and knockdown of the general olfactory receptor (Orco) via systemic RNAi.

Title: Illuminating the function of inhibitory microcircuits in the zebrafish homolog of olfactory cortex

Authors: ***T. FRANK**, R. W. FRIEDRICH;
Friedrich Miescher Inst., Basel, Switzerland

Abstract: The brain creates dynamic representations of the sensory environment by extracting stimulus features at early processing stages and synthesizing more abstract object representations in higher brain areas. We dissect the function of neuronal microcircuits in higher olfactory brain areas in order to identify elementary computations of basic cortical circuits and to analyze the underlying cellular mechanisms. To this end, we use a combination of genetic, electrophysiological and optical approaches to visualize, record, and manipulate different types of interneurons (INs) in different subdivisions of the posterior zone of the dorsal telencephalon (Dp) of adult zebrafish. This brain area is homologous to olfactory cortex in mammals and assumed to be involved in olfactory object representations and associative memory. We identified two types of INs with similar electrophysiological properties that are differently connected to other neurons in Dp and also impact excitatory responses differently. These results shed light on cell-type specific computations in a higher-order olfactory area and provide insights into canonical computations performed by basic cortical circuits.

Title: Odor and stress-induced pERK expression reveal distinct neural activity patterns in the forebrain of adult zebrafish

Authors: *B. A. PORTER, G. STEVENS, T. MUELLER;
Div. of Biol., Kansas State Univ., Manhattan, KS

Abstract: Altered smell sensation is a hallmark of human affective disorders. Schizophrenia and bipolar disorder, for example, are characterized by deficits in odor discrimination. Likewise, increased sensitivity to smell accompanies fear and anxiety disorders. Despite their medical relevance, the neural circuits mediating olfaction and emotion in higher forebrain regions such as the telencephalon, hypothalamus, and habenula, are barely understood. Zebrafish, due to its small size and amenability to genetic manipulations, has become an important model to dissect neural circuits of sensory processing and behavior. To this date, however, the functional organization of the olfactory pallial (cortical) nuclei in zebrafish and their relationships to the mammalian situation remains unresolved. To shed light on the functional organization of these and other odor-processing nuclei in the zebrafish forebrain, we began to investigate neural activity patterns with an antibody against **p**hosphorylated **e**xtracellular signal-**r**egulated **k**inase (pERK) as a postmortem readout of neural activity in odor-driven experimental paradigms. Specifically, we compare pERK expression patterns after stress induced by netting with those resulting from the application of qualitative different odors. When compared with each other, the three different paradigms (stress, food extract, and alarm substance) reveal distinct expression patterns supporting an overall conserved functional forebrain organization. In this future, we will use this method to further functionally characterize the zebrafish forebrain in regard to odor-processing nuclei. The results of this study will provide a solid foundation to dissect neural circuits of odor-induced emotion and socio-sexual (reproductive) behavior in this important model organism.

Title: Connectome of mouse olfactory system

Authors: ***M. ZHU**, B. ZINGG, L. GOU, M. BIENKOWSKI, H. HINTIRYAN, H. DONG; USC, Los Angeles, CA

Abstract: Olfaction is important for survival and quality of life in both animals and humans. How odor information is encoded in the olfactory bulb (OB) has been extensively studied in the last three decades. Yet, it remains largely unclear how olfactory information is processed sequentially in other brain structures within the olfactory network that includes the anterior olfactory nucleus (AON), piriform cortex (PIR), cortical amygdalar areas (COA), and olfactory tubercle (OT). Here, we report our effort to construct the mouse olfactory connectome. Coinjections of anterograde and retrograde tracers were placed into all brain regions that receive direct input from the main olfactory bulb (MOB). Our preliminary data, together with those in the literature (Haberly and Price, 1978; Luskin and Price, 1983), suggest that all olfactory cortical areas are heavily interconnected and share direct connections with the lateral entorhinal cortex (ENTl, which is classically considered a part of the olfactory cortical area), the hippocampus (especially with the ventral and intermediate CA1 and subiculum), and the agranular insular cortex (AI). To systematically and accurately map and quantify these connectivity pathways, we developed informatics algorithms to register all microscopic images to a standard mouse brain atlas, to extract and quantify tracer signal, to perform network analysis, and to construct a connectivity matrix. This comprehensive olfactory connectome will facilitate hypotheses regarding the functional relevance of the entire olfactory system.

Title: Structure of the human central olfactory system

Authors: J. LI[1], A. WEIBMAN[1], T. BOZZA[4], E. BIGIO[2], M.-M. MESULAM[3], *J. A. GOTTFRIED[1], C. GEULA[3];
[1]Neurol., [2]Pathology, [3]Cognitive Neurol. & Alzheimer Dis. Ctr., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [4]Neurobio., Northwestern Univ. Weinberg Col. of Arts and Sci., Evanston, IL

Abstract: There are profound interspecies variation in olfaction, with corresponding differences in the central olfactory apparatus. While numerous components of the central olfactory system are preserved when rodent species are compared to the primate, the layout of these components differs greatly. Most of our understanding of the anatomy of the central olfactory system in the primate is derived from the macaque brain. The purpose of this study was to investigate the detailed structure of this system in the human brain. Full hemispheric sections from three normal brains were processed to visualize cell bodies using the Cresyl violet Nissl stain. One brain was embedded in celloidin, and alternate thick sections were stained for Nissl, or for myelin using the Loyez method. Throughout most of its course, the olfactory tract (OTr) displays a triangular shape in cross section, with myelinated axons concentrated in the periphery. Once the tract reaches the most posterior aspects of the olfactory sulcus in the medial orbitofrontal cortex (OFC), the apex of the triangle elongates with two streams of axons directed dorsally toward OFC. More posteriorly, the bases of the triangle merge into a primary bundle of axons directed laterally, and a minor bundle directed medially, the latter contributing axons to medially streaming white matter. The lateral bundle further differentiates into two streams, with a minor component directed laterally toward the insula, and a major component directed ventrally toward the temporal pole (TP), where it enters layer I of cortex. Another distinct target of the OTr is the anterior olfactory nucleus (AON), appearing first as a small collection of neurons within the posterior aspects of OTr, just before OTr enters cortex. More posteriorly, the AON is located at the base of the olfactory sulcus as several relatively large collections of neurons surrounded by OTr axons. Just dorsal and posterior to AON lies the OFC component of piriform olfactory cortex (PCx). As in the macaque, the PCx trifurcates from a “root” near the limen insula (i.e., the junction where the orbitofrontal, temporal and insular cortices first join), contributing

components to the OFC, the insula (Ins), and the TP. These three components occupy a large region, and the PCx protrudes in small but distinct gyri in the three cortical areas. In summary, the components of the central olfactory system described in the primate can be identified in the human brain. However, the extent of the area occupied by these components in the human is considerably expanded, underscoring the widespread anatomical diversity of afferent projections from the OTr that define the human olfactory system.

Title: Odor processing by a feedforward inhibitory circuit in the piriform cortex

Authors: N. SUZUKI, M. L. S. TANTIRIGAMA, H. H.-Y. HUANG, *J. M. BEKKERS; John Curtin Sch. Med. Res., Acton, Australia

Abstract: The piriform cortex (PC) is a trilaminar paleocortex that is important for constructing and remembering odor percepts. We use the PC as an anatomically simple model system for studying canonical cortical circuits that have persisted through evolution. In this project we focused on feedforward inhibitory synaptic circuits which, in the PC, are largely confined to the upper part of layer 1 (layer 1a), where they are readily accessible ‘in vivo’ using two-photon-targeted patch clamping and calcium imaging. We describe the properties of a prominent feedforward circuit in layer 1a of the anterior PC, including the response of this circuit to odors. METHODS. The anterior PC of GAD67-GFP mice aged 35-75 days was surgically exposed under urethane or fentanyl anesthesia, in accordance with institutional guidelines. Targeted whole-cell recordings were obtained from identified layer 1a neurogliaform (NG) and horizontal (HZ) cells using a two-photon microscope. Some experiments used ‘in vivo’ two-photon calcium imaging with the indicator Cal-590 AM. An olfactometer was used to apply up to 15 monomolecular odorants. Some experiments were done using acute brain slices (300 microns thick). RESULTS. NG and HZ cells were identified ‘in vivo’ by their soma location, GFP

fluorescence intensity and intrinsic electrical properties. Both NG cells and HZ cells were broadly excited by odors and exhibited oscillations in subthreshold membrane potential that were phase-locked to respiration. However, they differed strongly in the dynamics of their odor response: NG cells fired early after odor onset (<0.5 s), whereas HZ cells fired late (>1 s). This finding was also confirmed using calcium imaging. Whole-cell recordings 'in vivo' and in slices indicated that the delayed firing of HZ cells could be explained by their early inhibition by NG cells. By recording from layer 2 principal cells, we also found that NG and HZ cells provide phasic inhibition with characteristic dynamics. CONCLUSIONS. We have identified a cascading feedforward inhibitory circuit in the PC that likely refines the afferent excitatory input received by the PC from the olfactory bulb. Future work will need to explore the importance of this circuit for odor-driven behaviors.

Title: Odor representation changes with repeated odor exposure in the mouse piriform cortex *In vivo*

Authors: *M. L. TANTIRIGAMA, J. M. BEKKERS;
The Australian Natl. Univ., Canberra, Australia

Abstract: Olfaction employs habituation to de-emphasize static or repetitive odor inputs in order to process novel, potentially more important odors. Previous work has shown that odors are represented in a sparse and odor-specific ensemble of neurons distributed in the piriform cortex (PC). However, it is unclear whether repeated exposure to a given odor can modulate odor representation, as a circuit manifestation of habituation, or whether the representation is static over time. Here, we study the neuronal responses to repetitive odor stimuli by simultaneously measuring the activity of up to 250 neurons in the PC of anesthetized mice using 2-photon calcium imaging, employing the calcium indicator dye Cal-520 AM. A given odorant excited a unique ensemble pattern of neurons (about 15 %) in layer 2, consistent with previous findings. Repeated application of the same odorants every three or six minutes produced a long-lasting

(>60 min) decline in the number of cells excited and in their response amplitude, indicative of habituation. This long-lasting habituated state was not apparent when a second odorant was presented and a different ensemble of neurons was excited. However, subsequent presentations of the second odorant produced a similar decline in activity as the first odorant, indicating that these changes are not generalized to the circuit activity but is odor-specific. We next tested whether habituation is inherited from the input received by the PC from the mitral/tufted (M/T) cells in the olfactory bulb (OB). Imaging activity in M/T cells revealed stable and reliable responses to repetitive odor stimuli, suggesting that habituation manifests from a local cortical mechanism. Previous work has implicated metabotropic glutamate receptor (mGluR) Group II/III involvement in habituation in the PC. Surprisingly, the long-lasting decline in neuronal responses was unchanged in the presence of the mGluR II/III antagonist (RS)-alpha-cyclopropyl-4-phosphonophenylglycine (CPPG), suggesting that this form of habituation is expressed via a different pathway and further pharmacological manipulations are necessary to identify its mechanism. The findings indicate long-lasting odor-specific changes to odor representation in the PC despite maintained input from the OB.

Title: Somatostatin interneurons mediate activity gradients in piriform cortex

Authors: *A. M. LARGE, N. VOGLER, S. MIELO, A.-M. OSWALD;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Odor information is processed and encoded by the neural circuitry of the piriform cortex. Compared to primary sensory cortices, anterior piriform cortex (APC) lacks topographic representations of odor identity and appears to be a fairly homogenous structure in terms of connectivity and sensory processing. In order to observe the spatial structure of odor-evoked neuronal populations in APC, we utilized Targeted Recombination of Active Populations (TRAP) to fluorescently label neurons expressing the immediate early gene *c-fos* during odor presentation. We find that this active population decreases in density along the rostrocaudal (RC) axis of the APC. To investigate potential underlying mechanisms for an activity gradient, we

optically stimulated interneurons in APC slices from vGAT-ChR2 mice while recording IPSCs in piriform pyramidal cells, and demonstrate a clear caudal bias of inhibition onto pyramidal cells. Surprisingly, we also find that a majority of inhibitory interneurons receive biased inhibition but with an opposing RC gradient. Since FS cells are a major source of inhibition onto pyramidal cells, we believe that the activity gradient is due to modulation of inhibition onto FS cells. This suggests that the source of FS-cell inhibition needs to decrease along the RC axis. Using genetically targeted fluorescent labeling we find that somatostatin-expressing (SST) interneurons decrease in density along the RC axis. We also find that SST-cells can provide biased inhibition to inhibitory interneurons. Taken together, these results suggest a disinhibitory circuit mechanism supports an increasing gradient of inhibition resulting in enhanced odor-evoked activity of rostral pyramidal neurons but a decreased recruitment of caudal neurons.

Title: Somatostatin interneurons in piriform cortex: expectations and limitations

Authors: ***A.-M. M. OSWALD**, A. M. LARGE, N. A. KUNZ, S. MIELO;
Dept. of Neuroscience, Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Inhibitory circuitry plays an important role in regulating cortical network activity during sensory processing. One major class of inhibitory interneuron expresses somatostatin (SST) and has been extensively characterized in neocortical sensory areas. Here we describe the anatomical distributions, intrinsic properties and inhibitory connectivity of SST-cells in piriform cortex. Our working hypothesis was that SST-circuitry in piriform cortex would be comparable to descriptions of SST-circuits in neocortical sensory areas. As expected, we found that SST-cells inhibit pyramidal cells, putatively identified parvalbumin (PV) interneurons as well as a number of unidentified interneuron classes. However, we also found a number of differences between classic neocortical descriptions of SST-cells and the properties and connectivity of SST-cells in piriform cortex. We compared SST-cells in two transgenic mouse lines, SST-IRES and GIN, with PV-expressing interneurons in G42 or PV-IRES mice. We found that regular-spiking

SST-cells in the GIN-line are sparse in piriform cortex. Rather, a majority of SST-IRES cells had electrophysiological properties similar to fast-spiking, PV interneurons. Furthermore, in contrast to reports from neocortex, we find that SST-cells can strongly inhibit each other. Finally, we find that SST-cells inhibit both distal dendrites and proximal somatic regions of pyramidal cells nearly equivalently. Altogether, these findings have important implications for both the application of current experimental methodologies and the interpretation of findings with respect piriform circuits that may differ from neocortical sensory areas.

Title: Anterior olfactory nucleus and piriform cortex feedback differentially modulate olfactory bulb output neurons

Authors: ***H. CHAE**[1], G. H. OTAZU[1], D. F. ALBEANU[1,2];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Watson Sch. of Biol. Sci., Cold Spring Harbor, NY

Abstract: The olfactory bulb (OB) output neurons, the mitral and tufted cells project in a distributed fashion to several brain areas including the piriform cortex (PC) and anterior olfactory nucleus (AON). These, in turn, send massive glutamatergic projections back into the OB. We recently reported (Otazu, Chae, et al., Neuron, 2015) that pharmacological inactivation of the anterior piriform cortex (APC) increases odor responsiveness and pairwise similarity of mitral cells, but has little impact on tufted cells. Therefore, we proposed that PC feedback specifically acts on mitral cell representations to enable odor separation, while only mildly altering tufted cell responses. However, how feedback from AON controls these two classes of OB output neurons remains unknown to date. We used multiphoton calcium imaging (GCaMP) to monitor the odor responses of mitral and tufted cells in in awake head-fixed mice. Pharmacological inactivation of the AON increased odor responsiveness and pairwise similarity

of both mitral and tufted cells. We propose that feedback from PC and AON differentially modulate olfactory bulb output neurons. We are currently exploring optogenetic strategies to locally suppress distinct feedback signals to the bulb, and assess their contributions to olfactory behaviors.

Title: How feedforward and feedback inhibition shape odor responses in piriform cortex

Authors: *K. A. BOLDING, K. M. FRANKS;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: We sought to understand how odor information is transformed from olfactory bulb to piriform cortex. We first obtained simultaneous recordings from populations of olfactory bulb mitral/tufted cells (M/Ts) and layer II principal cells in piriform cortex of awake, head-fixed mice. M/T activity increased in response to odor and remained elevated through the inhalation phase of the sniff. In contrast, piriform spiking showed only a small, transient odor response at inhalation onset, followed by marked suppression – as if the cortex were only responding to the earliest bulb inputs. We examined this transformation more directly using Thy1-ChR2 mice, which express channelrhodopsin (ChR2) in M/Ts, allowing us to precisely control the strength and duration of olfactory bulb output using light. Indeed, we found that sustained M/T spiking evoked a sharp but very brief increase in piriform spiking at light onset. This result indicates that inhibitory circuits within piriform cortex must truncate the cortical response to sustained bulb input. Principal cells in piriform receive inhibitory inputs from two distinct populations of inhibitory interneurons: feedforward interneurons (FFIs) in layer I, which receive excitatory inputs from M/Ts, and feedback interneurons (FBIs) in layer II/III, which receive excitatory inputs from principal cells themselves. To determine how these different types of inhibition shape cortical odor responses we next recorded from optogenetically identified GABAergic neurons in VGAT-ChR2 mice, which selectively express ChR2 in inhibitory interneurons. We

could distinguish between FFIs and FBIs by their laminar position relative to cell-dense layer II. Layer II neurons that did not show sustained light-evoked spiking were presumed to be principal cells. Again, population spiking in principal cells increased slightly and transiently at inhalation onset, followed by sustained suppression. Superficial (presumptive FFIs) and deep (presumptive FBIs) GABAergic neurons had strikingly different odor responses. Individual FFI responses were highly heterogeneous while FBIs were broadly responsive to most presented odors. Furthermore, FFI spiking increased slowly, peaked modestly, and exhibited a time course similar to the bulb odor response. In contrast, spiking in FBIs increased rapidly after inhalation, peaking ~10 ms after the peak of the principal cells' activity, and corresponding to the sharp onset of suppression in their population activity. These findings suggest that layer II/III FBIs play a dominant role in transforming odor representations in piriform cortex.

Title: Coding strategies for representing odor identity and odor intensity in piriform cortex

Authors: *K. M. FRANKS, K. A. BOLDING;
Neurobio., Duke Univ., Durham, NC

Abstract: How can an animal accurately discriminate an odor at different intensities while still recognizing that odor's identity? The number and timing of odor responsive mitral cells may change with concentration but their activation sequences are typically concentration invariant. One model, proposed by Hopfield (1995) and elaborated by many others since, suggests that a downstream decoder that attends to the earliest bulb inputs could produce a largely concentration-invariant representation of odor identity. A corollary of this model is that odor intensity may be extracted from temporal structure of the response. We tested this model by recording from populations of piriform cortex neurons in awake, head-fixed mice following presentation of different odors at multiple concentrations. Our analyses focused on activity in the first full sniff after odor onset. Different odors (0.3% v/v) evoked distinct patterns of activity in

which ~10% of neurons increased spiking while ~15% of neurons were suppressed. Although responses exhibited considerable trial-to-trial variability, responses to repeated presentations were more similar (cc: ~0.5) than presentations of different odors (~0.35). These differences were sufficient for a linear classifier, using simple spike counts as input, to accurately identify the odor. Consistent with both Hopfield (1995) and Miura et al (2012), spike timing provided little additional information about odor identity. The number of both activated and suppressed cells increased with odor concentration so that total output was nearly constant across concentrations. Responses evoked by an odor at different concentrations were therefore similar but not invariant, and our linear classifier could accurately identify a familiar odor, even when presented at a novel concentration. However classifiers performed poorly when required to determine odor concentration. As predicted, responses peaked earlier with increasing odor concentration, and classifier performance at intensity discrimination improved markedly when temporal information was included. However, the Hopfield model predicts that information about odor identity and intensity should become available concurrently yet our classifier could rapidly decode identity ~100 ms before decoding odor intensity. This occurs because concentration-dependent latency changes were largely restricted to late-responding cells while the earliest responding cells were more concentration-invariant. We therefore suggest a revised two-stage decoding model in which a rapid representation of odor identity is formed and then refined to include information about stimulus intensity.

Title: Neural relativity in dual networks

Authors: *A. KOULAKOV[1], D. KEPPLE[2], H. GIAFFAR[2], D. RINBERG[3];
[1]Cold Spring Harbor Lab., Cold Spg Hbr, NY; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]New York Univ., New York, NY

Abstract: Sensory systems are constantly facing the problem of computing the stimulus identity that is invariant wrt several features. In the olfactory system, for example, odorant percepts have to retain their identity despite substantial variations in concentration, timing, and background. This computation is necessary for us to be able to navigate in chemical gradients or within variable odorant plumes. How can the olfactory system robustly represent odorant identity

despite variable stimulus intensity? We propose a novel strategy for the encoding of intensity-invariant stimulus identity that is based on representing relative rather than absolute values of the stimulus features. We propose that, once stimulus features are extracted at the lowest levels of the sensory system, the stimulus identity is inferred on the basis of their relative amplitudes. Because, in this scheme, stimulus identity depends on relative amplitudes of features, identity becomes invariant with respect to variations in intensity and monotonous non-linearities of neuronal responses. For example, in the olfactory system, stimulus identity can be represented by the identities of p strongest responding odorant receptor types out of 1000. We show that this information is sufficient to ensure the robust recovery of a sparse stimulus (odorant) via l1 norm or elastic net loss minimization. Such a minimization has to be performed under the constraints imposed by the relationships between stimulus features. We map this problem onto a dual problem of minimization of a functional of Lagrange multipliers. The dual problem, in turn, can be solved by a neural network whose Lyapunov function represents the dual Lagrangian. We thus propose that the networks in the piriform cortex computing odorant identity implement dual computations with the sparse activities of individual neurons representing the Lagrange multipliers. Our theory yields predictions for the structure of olfactory connectivity.

Title: Correlated tuning within the olfactory tubercle

Authors: T. REDMOND, R. CHIRINOS, J. GOTTO, G. MINOGUE, C. TENUTO, *G. A. COUSENS;
Drew Univ., Madison, NJ

Abstract: Diffuse patterns of divergent and convergent projections from main olfactory bulb mitral and tufted cells contribute to an apparent lack of spatial topography in piriform cortex (PC), and evidence from studies using a range of techniques suggests that odor-selective responses of PC neurons are sparsely distributed and randomly organized. However, differences in the the topography and cellular composition of bulbar projections to other regions of the ventral telencephalon, as well as differences in the local circuit organization of these regions, suggests that features of odor representation across primary olfactory areas may be quite diverse. In particular, the finding that glomerular projections to cortical amygdaloid nuclei are patchy

suggests that olfactory tuning profiles may be spatially segregated to some extent in some olfactory areas. Here we examine correlated tuning within the olfactory tubercle (OT) using single- and multi-electrode recording techniques in urethane-anesthetized rats. Consistent with published reports, a large proportion of OT neurons exhibited odor-selective alterations in firing rate often in phase with ongoing respiration and local field potential oscillations. Cells exhibited a range of tuning breadths to molecularly distinct odorants, including monomolecular odorants and biologically significant pheromones, and adjacent cells were often similarly tuned. Preliminary evidence shows that interneuronal distance predicts the likelihood of correlated tuning between simultaneously recorded cells, suggesting a functional organization that differs from PC. Ongoing work using configurable high-density silicon probes positioned within OT and adjacent olfactory areas is examining the extent to which spatial and temporal features of odor-elicited neuronal activity compare directly across regions.

Title: Optical stimulation of an olfactory corticostriatal pathway modulates odor coding in the olfactory tubercle.

Authors: *K. A. WHITE[1], D. W. WESSON[1,2];
[1]Biol., Case Western Reserve Univ., Cleveland, OH; [2]Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: How second-order sensory structures both inform and shape one another's neural activity is critical for understanding the way in which sensory information is encoded across hierarchical networks. In the olfactory system, axonal association fibers from the piriform cortex (PCX) innervate a number of secondary olfactory structures. One of these secondary structures, the olfactory tubercle (OT), is highly unique in comparison to all others given its position within the ventral striatum. The function of this PCX-OT corticostriatal connection is entirely unknown. Thus, the aim of this study is to elucidate whether, and if so how, PCX pyramidal cells modulate odor coding within the OT. To accomplish this, PCX pyramidal cells and their axon terminals

were transduced with a viral vector carrying humanized channelrhodopsin under control of the CamKIIα promoter. This approach transduced soma primarily in layer ii of the mouse PCX, whose association fibers were visible in all layers of the OT. Pyramidal cell bodies or, separately, axon terminals from the PCX were stimulated as we recorded single-unit neural activity from the OT of mice performing an olfactory task. We found that both stimulation of PCX neurons directly within the PCX, and stimulation of their axon terminals locally within the OT, robustly altered OT neuron spontaneous activity. In addition, the encoding of odors among OT neurons differed depending on the presence or absence of PCX stimulation. In some neurons, PCX stimulation during odor presentation had an additive effect on OT neuron firing rate. In contrast, among other neurons, PCX stimulation resulted in a subtractive effect upon odor responses. Thus, our results suggest that PCX input alters OT neuron ensemble activity in a way that is important for the encoding of olfactory information. Further, this work provides insights into schemes of information processing between secondary sensory structures.

Title: The smell of fear: rodent pheromonal communication of danger

Authors: ***S. GOODMAN**[1], I. T. K. MACINTYRE[2], Q. YUAN[2];
[1]Mem. Univ. of Newfoundland Fac. of Med., St John's, NL, Canada; [2]Mem. Univ. of Newfoundland Fac. of Med., St. John's, NL, Canada

Abstract: Pheromones are substances which can communicate a variety of messages between conspecifics. Alarm pheromones, widely studied in insects but not so much in mammals, serve to alert a member of the same species about impending danger. We aimed to investigate whether classically conditioned fear may be communicated across rats and thereby transferred to a conspecific in the absence of an external aversive stimulus. Male and female adult rats were either trained to associate a novel odor (terpinene) with a shock, or they were exposed to only shock or odor, not both. Odor exposed rats were either housed alone, or with an odor/shock conditioned rat. All animals were exposed to terpinene then a novel control odor octanol on the day following training, and freezing behavior to each odor was measured. Animals given shock

and odor showed a highly convincing trend towards increased freezing behavior specifically to terpinene compared to the controls, but more animals are needed to reach statistical significance. Animals exposed only to the odor and then housed with the conditioned animals showed more robust freezing behavior specific to the terpinene than either of the control groups. These results suggest that rats may be able to communicate their own specific fear memory to one another, perhaps via pheromones. Does pheromone mediated fear learning activate distinct neural circuities from those activated by conditioned fear? To investigate this question, cellular compartmental analysis of temporal activity by *in situ* hybridization will be employed. This technique utilizes immediate-early genes Homer1A (H1A) and Arc to visualize cells that are active to two temporally distinct events. H1A is expressed in the nucleus ~30 min following a stimulus, while Arc appears in the nucleus ~5 min after stimulus presentation. On the day following testing, rats will be exposed to octanol for 5 minutes, clean air for 20 minutes, terpinene for 5 minutes, then immediately sacrificed. Therefore, cells expressing H1A are those activated by the control odor octanol, while cells expressing Arc those are activated by the conditioned odor terpinene. A control odor is used to normalize each animal's response to the conditioned odor, providing intra-animal control. By mapping the cellular activation pattern across structures involved in olfactory fear conditioning in addition to those involved in pheromone detection, a clear picture will be visible regarding the process of this memory formation. We will systematically measure the H1A and Arc expression in the main olfactory bulb, accessory olfactory bulb, sub-regions of the piriform cortex, olfactory tubercle and several nuclei of the amygdala.

Title: Representation of odors in the postero-lateral cortical amygdala

Authors: *G. IURILLI, R. S. DATTA;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Olfactory information is conveyed from primary sensory epithelium in the nose to the main olfactory bulb (MOB) in the forebrain. After processing in the MOB, mitral/tufted cells broadcast olfactory information to several higher olfactory areas including the piriform cortex (PC) and the postero-lateral cortical amygdala (plCOA). The role of these distinct, parallel pathways however remains unclear. Mitral cells from the same glomerulus disperse their axons across the whole PC, but they send patchy and stereotyped projections to the plCOA. This differential patterning suggests that PC and plCOA perform distinct sensory transformations and therefore have distinct behavioral functions; consistent with this possibility, functional experiments have implicated the PC in associative learning whereas the plCOA has been suggested to participate to odor-driven innate behaviors. These anatomic and behavioral differences suggest dramatic differences in odor coding in these two olfactory cortices; however, the odor response properties of primary neurons in the cortical amygdala have not been characterized. Here, we employ multi-array, extracellular recordings to investigate the olfactory tuning properties of plCOA neurons in awake mice. We find that single neuron and population plCOA responses are similar to those observed in PC. Moreover, plCOA neurons were not better able to categorize aversive versus appetitive odors than neurons in the PC. These results suggest that intrinsic and feedback connectivity re-formats olfactory information in plCOA to generate odor representations that are similar to PC, suggesting that the plCOA may also play an important role in odor learning.

Title: Mapping odor learning-dependent expression in FosTRAP mice using CLARITY

Authors: *S. LUO, K. XIE, J. R. AZARI, M. EINHORN, T. A. CLELAND;
Psychology, Cornell Univ., Ithaca, NY

Abstract: The direct comparison of appetitive and aversive forms of learning has been difficult with conventional training paradigms due to their substantial procedural differences. While

previous studies have examined immediate-early gene (IEG) expression following rewarded or fear learning, it is difficult to assess IEG responses to valence *per se*, owing to the procedural differences which exist between appetitive and aversive conditioning paradigms. Previously, we developed a novel olfactory training protocol for rats capable of evoking both forms of conditioning with minimal procedural differences, enabling outcomes to be directly compared using identical behavioral and physiological analyses. Using chronically implanted intra-oral cannulae, appetitive or aversive tastants (saccharin or quinine) were infused into the rats' mouths and paired (or backward-paired) with an odor conditioned stimulus (CS) such that training procedures differed only in the valence of the tastant. Rats displayed anticipatory behaviors (rapid mouth movements, tongue protrusions, gaping) in response to the odor CS predicting tastant infusions, indicating that they recognized the differing valences of the tastants and had learned the odor-tastant association. Using ultra thin-section immunohistochemistry, we have extensively mapped Egr-1 and c-Fos expression in olfactory- and valence-associated brain regions following appetitive and aversive conditioning, including olfactory bulb, anterior olfactory nucleus, anterior and posterior piriform, agranular insular, orbitofrontal, prelimbic/infralimbic, cingulate cortices, dorsal and ventral striatum, olfactory tubercle, basolateral amygdala, and hippocampus. We have quantified IEG expression along the rostrocaudal axis for a large number of subregions and sublayers, and have generated high-resolution histomicrographs illustrating their expression. Furthermore, we have quantified IEG expression along various axes in the anterior piriform and agranular insular cortices. Here, we continue to elucidate the neural networks involved in odor learning using the Targeted Recombination in Active Populations (TRAP) approach and CLARITY technique to visualize active neurons during learning in transparent brains. We use 4-hydroxytamoxifen (4-OHT) to induce recombination in FosTRAP (Fos (CreER/+) R26(AI14/+)) mice. The active cell population is identified via the expression of tdTomato (an effector gene). Subsequently, the FosTRAP brains are passively cleared using CLARITY techniques, and are imaged using light sheet (Ultramicroscope; LaVision BioTec) and confocal microscopy (Zeiss LSM 710).

Title: Neural trajectory of auditory stream segregation across development

Authors: *S. SCHWARTZ[1], L. WANG[2], H. TAGER-FLUSBERG[3], B. SHINN-CUNNINGHAM[2];
[1]Grad. Program for Neurosci., [2]Biomed. Engin., [3]Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Studies of how the brain perceptually organizes mixtures of acoustic signals and how this changes through development are important for understanding how children acquire language. Such studies will give us better insight into how children segment language from the mixture of sounds in their environment and how they learn to process spoken language in a world of complex auditory inputs. Through event-related potentials (ERPs) in adults, we can directly measure cortical responses to sounds and use this information to infer how those sounds are perceptually organized at early stages of auditory processing. However, research has yet to establish the extent to which we can measure equivalent cortical responses in young children. In this study we used a Mismatch Negativity Paradigm (the MMN) to explore passive, automatic processes governing auditory scene analysis in the young, developing brain. Specifically, we explored the degree to which spectral features of multiple, simultaneous sound streams affect sound organization in children. Children ages 3-18 passively listened to either one or two diotic sound streams while watching a silent movie with subtitles. Consistent with prior studies, we found that children of all ages exhibit sensitivity to unexpected sound events, or "deviants," occurring within a single stream of sound. When a second, higher-pitched interfering stream was presented simultaneously with the original stream, the deviant ERP response in children ages 6-18 looked similar to that present in adult listeners during similar perceptual segregation tasks. In contrast, children ages 3-5 do not produce a clear deviant ERP response in the dual-stream context. These results suggest that for children under age 6 (an age where children typically are entering formal learning environments), analysis of sound in a noisy environment cannot rely on the automatic processes that support perception in older children and adults. This work provides a foundation for comparing central auditory processing in typically developing young children with that of children with clinical disorders.

Title: Characterizing the evolution of cortical auditory evoked potentials and the influence of prepulse inhibition across decibel levels

Authors: T. POTTER[1], T. NGUYEN[1], S. LI[2], *Y. ZHANG[1];
[1]Univ. of Houston, Houston, TX; [2]TIRR Mem. Hermann Res. Ctr., Houston, TX

Abstract: Cortical auditory evoked potentials (CAEPs) are known, time-locked EEG potentials generated in response to acoustic stimuli. CAEPS Comprise primarily of the N1 and P2 peaks on EEG recordings. The presentation of CAEPs is noticeably altered by the addition of a non-startling prepulse, occurring between 50 and 350 ms prior to the focal sound. Despite their relevance and non-invasive observation, much remains unknown regarding how CAEPs evolve with varying stimulus intensity and how the presence of a constant prepulse changes this profile. In this study, 11 healthy subjects were recruited to perform an acoustic startle paradigm. Subjects were seating 12 inches in front of a JBL EON speaker, facing away. 64-channel EEG recordings (BrainVision Acticap) were performed with channels sacrificed to monitor the EKG and EMG in the Bicep, and Sternocleidomastoid muscle. The auditory paradigm consisted of a series of tasks featuring 20x 500 Hz sounds varied across 5 decibel levels (70, 80, 90, 100, and 110 dB), with and without a 70 dB prepulse occurring 50ms prior to the stimulus (10 tasks in total). Subjects were initially exposed to 5x 110 dB sounds without a prepulse to habituate the startle response, after which tasks alternated between prepulse (PP) and non-prepulse (NP) with randomized decibel levels. EEG signals from the Fz and Cz channels were processed (filtration, artifact rejection ICA, baseline correction), average peak amplitudes for the N1 CAEP component were ascertained for each subject. FFT analysis was also performed to examine the mean Theta oscillation activity. Main effects were determined using a two-way repeated-measures ANOVA (Decibel levels x5 and prepulse x2). Results showed a significant main effect of decibel levels on N1 amplitude across both Fz and Cz channels. Further analysis showed that the presence of a prepulse significantly increased the N1 amplitude at 70 dB of stimulus pulse while decreasing it at 90 and 110 dB in both the Fz and Cz channels, with significant decrease also observed in the 100 dB condition at Cz. Similarly, a significant main effect of decibel levels was shown on theta activity in the Cz electrode. The prepulse significantly increased the theta activity in the 70 dB condition and decreased at 110 dB in both Fz and Cz channels, with 80 db also showing a significant increase at Cz. These results indicate a clear evolution of the CAEP in response to stimulus intensity without a prepulse. In the presence of a prepulse, the CAEP response depends

on the interactions between the prepulse and the stimulus, arguing against the interruption or protection hypothesis of prepulse inhibition.

Title: Temporal information recovered from speech fine structure contributes to understanding temporally distorted speech: psychophysics and MEG evidence

Authors: ***X. TENG**[1,2], D. POEPPEL[3,2];
[1]Dept. of Psychology, [2]New York Univ., New York, NY; [3]Max Planck Inst., Frankfurt, Germany

Abstract: The speech envelope is often considered to be the most important temporal cue for speech perception, and the auditory system relies on the speech envelope to extract acoustic information on different timescales. Here, we show that temporal fine structure improved speech intelligibility of temporally distorted speech and entrained cortical oscillation, by supplying envelope information. We first distorted the temporal structure of speech by locally reversing speech segments and evaluated the contribution of the temporal fine structure to intelligibility. The temporal fine structure was found to help listeners restore critical temporal information of speech. We then used a method not yet widely appreciated, cochlear scaled correlation, to derive temporal information from the temporal fine structure. Using MEG and mutual information analysis, we evaluated whether the derived temporal information can entrain cortical oscillations and correlate with the original envelope of speech depending on the number of cochlear bands used. Our findings emphasize the importance of temporal fine structure in speech perception and invites us to rethink the canonical view on the relationship between amplitude envelope and temporal fine structure.

Title: Joint tuning to sound features emerges in superficial layers of human primary auditory cortex

Authors: *M. MOEREL[1,2,3], F. DE MARTINO[2,3], K. UGURBIL[3], E. YACOUB[3], E. FORMISANO[1,2];
[1]Maastricht Ctr. for Systems Biol. (MaCSBio), [2]Dept. of Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands; [3]Ctr. for Magnetic Resonance Res., Univ. of Minnesota, Minneapolis, MN

Abstract: Electrophysiological recordings in animal models[1,2] suggest there may be relevant transformations in sound processing taking place between middle primary auditory cortical (PAC) layers (receiving thalamic input) and superficial PAC. Here we use ultra-high field fMRI (7 Tesla) to measure and compare sound responses at deep, middle and superficial cortical depths of human PAC. We acquired high-resolution anatomical (0.6 mm isotropic) and functional data (0.8 mm isotropic), while volunteers (N = 6) listened to 144 natural sounds. We used the anatomical data to define cortical depths and identify the PAC based on myelin-related contrast at individual level. Cortical responses were analyzed inside and outside PAC with three encoding models, representing different hypotheses on sound processing. A first *tonotopy* model was simplest, describing sound processing by frequency preference. A second *independent modulation* model hypothesized, in addition to frequency, preference to temporal and spectral modulations. A third *joint modulation* model was most complex, describing sound processing as the frequency-specific tuning of neuronal populations to combined spectral and temporal

modulations[3,4]. In the PAC only, we observed a significant interaction such that the difference in model prediction accuracy varied with cortical depth (RM ANOVA; p = 0.006). Only at a superficial cortical depth, the *joint modulation* model performed (marginally) significantly better than the other two models (p(corrected) = 0.02 and 0.07 for the *tonotopy* and *independent modulation* model, respectively). In non-primary auditory regions, the difference in model performance did not vary with cortical depth (no significant interaction; main effect of 'model'; p =0.003). Paired t-tests confirmed that the *joint modulation* model significantly outperformed the other two models (p(corrected) = 0.02 and 0.001 for the *tonotopy* and *independent modulation* model).In accordance with previous invasive animal studies[1,2], these results suggest the emergence of joint tuning to sound features in superficial PAC. That is, while neuronal populations in middle PAC layers are tuned independently to distinct sound features, neuronal populations in superficial PAC encode specific feature combinations. Joint tuning is propagated throughout cortical depths in non-primary auditory cortex, and may be a first computational step for forming a complex representation of the physical input towards sound abstraction and perception.1. Title: "Name that tune": identifying musical pieces from fMRI data using encoding and decoding models

Authors: *S. HÖFLE[1,2], A. ENGEL[3,1,4], R. BASILIO[1], V. ALLURI[5,6], P. TOIVIAINEN[5], M. CAGY[2], J. MOLL[1];

Abstract: Introduction: The neural correlates of listening to music have been investigated in several ways (Koelsch, 2014). However, mapping ongoing brain activity during naturalistic music listening combined with detailed models of musical features is an emerging approach (Alluri et al. 2012, 2013, Toiviainen et al. 2013). The so-called "encoding models" allow capturing the effects of multiple stimulus variables on brain responses that can be used subsequently to decode or identify stimuli from brain activity (Naselaris et al. 2011). Here we apply this new concept of combining encoding/decoding models in order to identify musical content from brain activity. **Method:** We scanned 6 subjects on 4 different days on a Philips Achieva 3T scanner. Blood oxygen level dependent (BOLD) signal was measured with a T2* weighted EPI sequence while the subjects listened to 40 music pieces of different genres (total listening and fMRI scanning time: 2 h 8 min per subject across 4 days). Then, we modeled the individual brain responses in the auditory cortex and surrounding regions (superior and middle temporal gyri) by means of a multiple linear regression using 21 musical features (comprising rhythmic, timbral and tonal features, see Alluri et al. 2012). During the encoding phase, the coefficients were estimated in a leave-one-out scheme, while always two music pieces of 46 s were excluded for determining the coefficients. During the decoding phase, we identified which one of the two pieces was more likely to predict the measured BOLD signal (Stansbury et al. 2013). Identification accuracy was then determined as the percentage of correctly and incorrectly identified pieces. **Results:** For all 6 subjects identification accuracies significantly above chance level were obtained (76.8% ± 6.5%, mean ± sd of best accuracy across subjects). Accuracy levels increased both with number of voxels and time points, as expected. More specifically, accuracy levels increased linearly with time, whereas the relationship between number of voxels and accuracy was marked by a steep increase from 2 to 50 voxels but then stabilized from 50 to 300 voxels. **Conclusion:** In conclusion, in this study, we highlighted the spatio-temporal relationship of encoding/decoding models. The present work extends previous studies that focused either on encoding models (Alluri et al. 2013) or decoding models (Toiviainen et al. 2013) alone. Our results showed the importance of the combination of multivariate analysis with encoding models to improve music identification accuracy.

Title: Investigating the functional organisation of the human auditory pathway with high-resolution fMRI

Authors: *F. DE MARTINO[1], O. GULBAN[2], E. FORMISANO[2];
[1]Fac. of Psychology, Maastricht Univ., Maastricht, Netherlands; [2]Cognitive Neurocience, Maastricht Univ., Maastricht, Netherlands

Abstract: Understanding how the human brain extracts behaviorally relevant information from sounds necessitates mapping sub-cortical and cortical processing levels simultaneously. So far, technical challenges have limited the coverage and/or resolution of functional magnetic resonance imaging (fMRI) studies of the human auditory pathway [1-3]. Here we investigate the topographic organization of the auditory pathway from the cochlear nucleus to the auditory cortex at high spatial resolution. We collected anatomical (0.7 mm isotropic) and functional data (1.1 mm isotropic) at 7 Tesla. During functional imaging participants ($N = 6$) listened to natural sounds (1 s) presented in the silent gaps. FMRI encoding [4] was used to analyze the functional responses to natural sounds and investigate the spatial organization of preferences to acoustic properties for every subject independently. The consistency of the results across subjects was evaluated in a common cortical space (cortex based alignment) and a common sub-cortical space obtained through non-linear registration (FNIRT-FSL) of the anatomical data. A preliminary analysis of allowed identifying, in every subject, sub-cortical and cortical regions with a significant (FDR corrected q=0.05) response to the sounds (see Figure 1). Cortical frequency preference showed tonotopic maps in accordance with previous studies [1]. These results show that high-field fMRI can be used to investigate the functional organization of the entire human auditory pathway at a resolution sufficient to highlight the topographic organization of acoustic features across all stages. The use of natural sounds and fMRI encoding will allow tracking the transformation of sound representations throughout the brain.

Title: Longitudinal change in gamma band auditory steady-state responses in patients with schizophrenia

Authors: ***N. ORIBE**[1,2], H. KUGA[2,1], Y. HIRANO[1], H. TAKAO[2,1], T. ONITSUKA[1], T. UENO[2,1];
[1]Kyushu Univ., Fukuoka, Japan; [2]Natl. Hosp. Organization Hizen Psychiatric Ctr., Yoshinogari, Japan

Abstract: Background
Gamma band auditory steady state response (ASSR) have been reported to be abnormal and considered to be a robust biomarker in schizophrenia patients. However, the ASSR has been never investigated longitudinally in such patients as far as we know.
Methods
We measured ASSR responses at Baseline in schizophrenia patients (mostly in acute phase, SZ, N=6), as well as healthy control subjects (HC, N=7) while presenting click trains varying in rate of stimulation (20, 30, 40 and 80 Hz) and repeated the measurements after 3-15 months intervals (Follow up). EEG-evoked power and phase locking were obtained in response to each stimulation frequency.
Results
SZ showed significant reduction in phase locking to the 40Hz stimuli compared with HC at Baseline but the difference lost significance at Follow up. Interestingly, improvements of the symptom evaluated by Brief Psychiatric Rating Scale were associated with the PLF improvements in the patients.
Conclusions
These results suggest that neural circuits abnormalities indexed by the ASSR change dynamically in the course of the illness and the ASSR has the potential to be used as a marker for treatment response to antipsychotic drugs.

Title: Neural correlates of categorical auditory preprocessing of voice onset time in the brainstem

Authors: *A. BURGHARD[1,2], M. B. VOIGT[2], A. KRAL[2], P. HUBKA[2];
[1]Neurosci., UConn Hlth., Farmington, CT; [2]Inst. of Audioneurotechnology & Dept. of Exptl. Otology, ENT Clinics, Hannover Med. School, Germany, Hannover, Germany

Abstract: Detection of temporal sequences is crucial in auditory object recognition and categorization. This function of the auditory system allows phonetic analysis and determines speech understanding. The voice-onset time (VOT) is considered to be a parameter for categorization of voiced and unvoiced phonemes, but its neural correlates remain elusive. As shown in behavioral studies, this phonetical category is perceived similarly in animals and in humans. Therefore, its neurological substrates can be studied in animal models.In the present study, short and long noise bursts were used to model VOT in guinea pigs. The auditory brainstem response (ABR) was recorded to the initial noise burst (NB1, duration of 5-100 ms) and the trailing noise burst (NB2, duration of 50 ms), separated by a short gap (2-10 ms). All stimulus combinations were presented 600 times (300x each polarity) at 30 dB above hearing threshold. The ABR onset response to NB1 and NB2 was compared. The individual components (amplitude, latency, inter-peak-latency) were subsequently analyzed. In order to evaluate the general morphology of the onset ABR response, a 6 ms time window of the onset response was evaluated in the time domain (computation of RMS value and direct comparison of ABR waveforms). In addition, the time-frequency representation of the response was computed to assess speed and synchronization of the activation of the brainstem structures.In accordance with previous studies, a longer duration of the initial NB1 (30-100 ms) resulted in significantly weaker and delayed responses to the trailing NB2. However, the combination of a short initial NB1 (<30ms) with a gap duration of 10 ms significantly facilitated the onset NB2 response in the strength and speed of the sequence for ABR components II-IV (latencies of 2-5ms). In the latter stimulus combination, it is likely that the initial NB1 activation primed the brainstem structures resulting in a highly synchronized and rapid initial activation sequence. We propose that the described findings represent neural correlates of early phases of categorical auditory preprocessing in the auditory system, which might play an important role for the final categorization in the cortical structures.

Title: A system identification approach for rapid characterization of the auditory brainstem response (ABR)

Authors: D. P. DRENNAN, *E. C. LALOR;
Trinity Col. Dublin, Dublin, Ireland

Abstract: The event-related potential (ERP) has long been the canonical technique for conducting electrophysiological analyses of the human auditory system, and for good reason. As is apparent from the auditory brainstem response (ABR), ERPs can index processing along the brainstem with excellent temporal resolution. One shortcoming of the traditional ERP approach however is the relatively time-consuming nature of its acquisition, which can limit its clinical utility. An alternative approach which seeks to circumvent these limitations focuses on deriving what is known as a Temporal Response Function (TRF; Theunissen et al., 2001; Lalor et al., 2009). Typically this is done by regressing neural data against some feature of a continuous stimulus. In the context of EEG/MEG this has been done, for example, by regressing the data on each electrode against the envelope of an amplitude modulated carrier signal (Lalor et al., 2009), or even speech (Lalor & Foxe, 2010; Ding & Simon, 2012). This has been shown to elicit ERP style responses and, due to the continuous nature of the stimuli being presented, has facilitated research which could not easily be conducted using a traditional ERP approach (Power et al., 2012). However, the SNR of these TRFs is typically not as high as those of a traditional ERP. Also, it is unknown whether the approach can facilitate the resolution of ABR components. Here, we present a novel approach to deriving EEG TRFs using a stimulus that consists of a number of impulses which are pseudorandomly spaced, which we refer to as a 25% jittered (25PJ) click train. We characterize the components of these TRFs through comparison with ABRs derived using standard approaches. This novel stimulus paradigm could be useful in many subdomains of both clinical and cognitive auditory neuroscience research.

Title: The role of auditory steady-state responses in differentiating states of arousal.

Authors: *U. GÓRSKA, ESQ[1,2], M. BINDER[1], M. WYCZESANY[1];
[1]Psychophysiology Labolatory, Jagiellonian Univ., Krakow, Poland; [2]Neurophysiol. Labolatory, Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Objective: Research on auditory steady-state responses (ASSRs) has demonstrated that this kind of evoked EEG activity is sensitive to the actual level of arousal in both NREM sleep (Tlumak et al., 2012) and general anaesthesia (Plourde, 1996). The aim of present study was to evaluate the strength and information transmission after periodic ASSR stimulation with broad range of modulation frequencies during deep NREM sleep and wakefulness.
Methods: In the present study 17 healthy awake and asleep (N2 and N3 stages) subjects were presented with series of auditory stimuli (carrier frequency 1000Hz) amplitude-modulated (AM) by the set of frequencies (4Hz, 6Hz, 8Hz, 12Hz, 20Hz, 40Hz) while measuring their brain activity with 64-channels EEG system. We estimated ASSR amplitude with noise-subtracting average and intertrial phase variability with squared phase coherence (PC) index. The suprathreshold cluster test ($p<0.05$) was used for the selection of electrodes that maximize differences between states. Moreover, we quantified the direction and intensity of information flow for sleep and wakefulness with Directed Transfer Function (DTF).
Results: The analysis of ASSR amplitudes revealed significant differences for 4Hz, 6Hz and 8Hz, with substantial amount of individual variability for other modulation frequencies. In turn, the PC parameter displayed effect of subject state for all presented modulation frequencies beside 12Hz (this lack of effect might be caused by sleep spindles activity). Correspondingly, for this frequency DTF did not reveal any sleep-wake differences. More importantly, in awake state DTF analysis demonstrated transmission of information from centro-parietal to frontal brain regions in the beta frequency range for lower modulation frequencies and 40Hz. These effects were absent in NREM sleep.
Conclusion: Summing up, state-dependent AM ASSR effects vary with modulation frequency. Specifically, results for PC and DTF measures suggest that 4Hz, 6Hz, 8Hz and 40Hz remain sensitive to the level of arousal. This demonstrates a key role of phase variability of ASSR responses in determining the neuronal integrity in various states of consciousness. Furthermore, our results suggest that long-range information flow accompanying ASSRs becomes suspended during NREM sleep unconsciousness. Taken together these measures open a possibility for reliable distinction between states of altered arousal e.g. in patients after severe brain damage who may not be able to move or communicate while retaining the capacity for conscious processing.

Title: Sequential encoding of acoustic features in EEG responses to continuous speech

Authors: *B. KHALIGHINEJAD, G. CRUZATTO DA SILVA, N. MESGARANI; Columbia Univ., New York, NY

Abstract: When listening to speech, humans have the ability to simultaneously extract both the content of the speech and the identity of the speaker. This is due to a multitude of cues encoded in the acoustic signal, including distinctive features of phonemic categories that carry meaning, and identifiable features of the speaker such as pitch, prosody and accent. Recent findings from invasive human electrophysiology studies have shown the role of phonetic features in organizing the representation of speech sounds at higher level speech cortices. However, it remains unclear how the neural representation of acoustic features unfolds over time as the speech sounds propagate through the auditory pathway, and how linguistic and non-linguistic information are jointly encoded in the brain.

We recorded EEG data from 22 native speakers of American English. Participants listened to simple stories comprised of alternating sentences uttered by two speakers (one male, one female). We applied a novel analysis to electroencephalography (EEG) signals in response to continuous speech to characterize the neural representation of acoustic features and the progression of responses over time. By averaging the time-aligned neural responses to phoneme instances, we calculated the phoneme-related potential (PRP) and studied the joint representation of linguistic (phonetic) and non-linguistic (speaker) information in the PRPs. We observed four sequential time intervals during which the PRPs are organized by the acoustic similarity of phonetic categories, appearing approximately at 50 ms, 120 ms, 230 ms, and 400 ms relative to the phoneme onset. The responses are primarily organized by phonetic feature, while subtler speaker variations appear within manner groups. This is consistent with previous studies that have shown a larger role for phonetic over speaker characteristics in shaping the acoustic properties of phones. Additionally, the different scalp distributions at each time interval suggest a different underlying pattern of neural activity for each component.

A major difference between our study and previous work is that it provides a direct link between the organization of neural responses and the acoustic properties of speech sounds. Therefore, this study lays the groundwork for several research directions where explicit changes in the

representational properties of speech can be examined in speech development, as a listener learns new acoustic distinctions, second language acquisition, and through varying task demands.

Title: A computational model of temporal processing in human auditory cortex

Authors: *I. ZULFIQAR, M. MOEREL, P. DE WEERD, E. FORMISANO;
Maastricht Ctr. for Systems Biol., Maastricht Univ., Maastricht, Netherlands

Abstract: Temporal information in sounds is relevant for many general purpose and domain specific auditory functions, including amplitude modulation (AM) detection, extraction of temporal pitch and decoding of speech. Each of these functions has been extensively studied with a variety of methods (electrophysiology, non-invasive neuroimaging, psychophysics). The common neural coding mechanisms underlying these observations, however, remain unclear. Here we propose a computational framework to integrate available empirical information to derive a unified view of temporal information processing in human auditory cortex (AC).
We designed a simplified model of the AC consisting of four functional units. These units approximately correspond to two core (AI, R) areas and two belt "streams" (Fast, Slow). Each unit was simulated using the Wilson Cowan Cortical Model (WCCM)[1] of neural circuitry. The WCCM generates dynamic neural responses by interaction of excitatory (E) and inhibitory (I) populations. AI and R receive cochleotopic thalamic input, the belt streams receive cochleotopic input from AI (Fast) and R (Slow) respectively. We adjusted the main parameters of the four units, temporal and spectral integration windows, based on physiological evidence from monkeys[2,3] and recent human fMRI[4].
First, we explored the model's coding of AM. For both noise and tones (0.125-8 kHz), we observed a switch from a temporal to a rate code for modulation rates above 50 Hz. The upper limit of temporal (but not rate) code was unit dependent, in accordance with electrophysiology[2].

Interestingly, estimated modulation transfer functions followed psychophysical modulation detection thresholds[5]. Also, we observed a dependence of AM coding on carriers in agreement with psychophysics[5]. Second, we tested how this same model represents temporal pitch[6], with missing fundamental stimuli and iterated ripple noise (IRN). AI and Fast temporally decoded low (<300 Hz) missing fundamentals while the Slow area represented high frequencies as phase coherence across the network. IRN was coded temporally with comparative weaker strength matching its weaker pitch percept.
Using a simple network of E and I interactions and tuning of only two parameters, we modeled processing of temporal information in parallel cortical streams. Readout of population responses are in agreement with human psychoacoustics. Future use of the model, in particular, to simulate response to speech is planned.

Title: Electrocorticographic (ECoG) delineation of human auditory cortical fields based on effects of propofol anesthesia

Authors: *K. V. NOURSKI[1], M. M. TODD[1], M. STEINSCHNEIDER[2], M. I. BANKS[3], A. E. RHONE[1], R. N. MUELLER[1], H. KAWASAKI[1], M. A. HOWARD, III[1];

[1]The Univ. of Iowa, Iowa City, IA; [2]Albert Einstein Col. of Med., Bronx, NY; [3]Univ. of Madison - Wisconsin, Madison, WI

Abstract: Functional organization of human auditory cortex remains poorly defined. While the posteromedial portion of Heschl's gyrus (HG) is considered part of core auditory cortex, the presence of any further subdivisions remains unknown. Anterolateral HG has been variously considered to be part of core and/or surrounding belt. Propofol, used for induction of general anesthesia, affects auditory cortical activity (e.g. Plourde et al, Anesthesiology 2006 104:448-57; Davis et al, PNAS 2007 104:16032-7). This study tested the hypothesis that auditory cortical fields could be characterized by their differential sensitivity to propofol. Subjects were neurosurgical patients undergoing removal of ECoG electrodes placed to identify locations of epileptic foci. All procedures were approved by the University of Iowa Institutional Review Board. Each subject gave informed consent for this study. Stimuli were 50 Hz click trains (0.5 s duration, 1.5 s interstimulus interval), presented continuously during a baseline period and induction of anesthesia with stepwise increases in propofol infusion rate. ECoG recordings were made simultaneously from HG and superior temporal gyrus (STG) using depth and subdural grid electrodes, respectively. Anesthesia depth was monitored using spectral entropy (Viertiö-Oja et al, Acta Anaesthesiol Scand 2004 48:154-61). Averaged evoked potentials (AEP), frequency-following responses (FFR) and high gamma (70-150 Hz) event-related band power (ERBP) were used to characterize auditory cortical activity. Two distinct patterns were identified in posteromedial HG. In its most posteromedial aspect, earliest AEP deflections were preserved, and FFR increased during induction. The remainder of posteromedial HG exhibited attenuation of both the AEP and FFR. Anterolateral HG exhibited weaker activation; responses here were characterized by the lack of FFR and the presence of broad, low-voltage AEP off-response during induction. Lateral STG exhibited FFR that dissipated during induction. High gamma ERBP decreased during induction in all areas. Changes in auditory cortical activity did not always parallel changes in entropy. Differential patterns of auditory cortical activity during propofol induction are useful physiological markers for field delineation. Posteromedial HG is not uniform in its basic response properties and can be parcellated into two subdivisions. Preservation of the earliest AEP deflections and FFR likely reflects synaptic activity initiated in the medial geniculate body. Presence of FFR on the lateral STG suggests that portions of the lateral STG reflect a relatively early stage in the auditory cortical hierarchy.

Title: Using auditory brainstem responses to measure hearing loss induced increases in neural gain and its implications with tinnitus

Authors: *A. J. HARDY, J. DE BOER, K. KRUMBHOLZ;
MRC Inst. of Hearing Res., Nottingham, United Kingdom

Abstract: The homeostatic plasticity model posits that tinnitus is triggered by an increase in neural gain due to a reduced input from a damaged periphery. Evidence for this mechanism in humans has come from auditory brainstem responses (ABR). ABRs recorded from tinnitus patients were found to show a reduced wave I amplitude but a normal wave V (Schaette 2011). This was interpreted as evidence of an increase in neural gain between the auditory nerve (wave I) and the upper auditory brainstem (wave V). However, a confound in this interpretation is that wave I is more dependent on contributions from high-frequency cochlear regions than wave V. High-frequency cochlear regions are also more affected by hearing loss. As a result, hearing loss may be expected to affect the wave I amplitude more than wave V, and this could be the driving factor behind the increased wave I/V ratio. Here, we aim to address this confound by measuring ABRs from restricted cochlear frequency regions.
Frequency-specific ABRs are obtained by restricting the response using high-pass masking noise with a variable cutoff frequency. Responses for different cutoff frequencies are subtracted to derive a response that only contains contributions from a specific cochlear region. This method has been used successfully to obtain frequency-specific click-evoked wave V responses. However, relative to wave V, the click-evoked wave I requires a high stimulus level to obtain an acceptable response. This means that uncomfortably loud HP noise would be required to obtain frequency-specific wave I responses. Furthermore, click stimuli are not optimal for eliciting wave I at high stimulus levels.
In this study we aim to address these problems by measuring chirp-evoked ABRs. We will use a rising chirp stimulus which starts at a low frequency and rises to a high frequency. Rising chirps have been used successfully in previous studies to increase the SNR of wave V (Fobel, 2004), as they compensate for the cochlear travelling-wave delay, causing the auditory nerve fibers to fire simultaneously and create a larger ABR. To further optimise frequency-specific chirps, we will use chirps that are weighted towards low-frequencies.
Once the optimal paradigm for measuring frequency-specific ABR wave I responses has been developed, we will measure the wave I/V ratio in normal hearing, tinnitus and matched hearing-loss groups. If there is a neural gain increase we will expect to see an increase in wave I/ V ratio

in hearing loss regions in the tinnitus group compared to normal/hearing matched groups but not in regions where hearing is intact.

Abstract: The visual thalamus is critical hub for incoming sensory information, though the role of the abundant feedforward and feedback connectivity between the thalamus and cortex remains elusive. Primate pulvinar is topographically and functionally organized, but a more granular map is needed to understand the role of thalamocortical loops in visually guided behavior. Similarly, the secondary visual thalamic nucleus in mice (LP) has extensive connections with cortex that are tractable with novel viral techniques. To resolve the precise connectivity of these circuits, we first mapped mouse visual cortex using intrinsic signal optical imaging and then injected a retrograde tracer (cholera toxin subunit B) into six different visual areas. We find that LP has separate zones that project to specific extrastriate regions, with few cells projecting to multiple visual areas. Additional experiments will investigate the sources of cortical and subcortical inputs to LP cells with known extrastriate projection targets using a rabies tracing approach. Disentangling these circuits will yield important insight into the role of the secondary visual thalamus in sensory processing as well as guide future functional studies.

Title: Direct projection of retinal ganglion cells to mesencephalon Kölliker-Fuse nucleus

Authors: *H. LU[1], L. ZHANG[2], Z. ZHAO[2], M. TAN[2], K. CHEN[2], K.-F. SO[2], C. REN[2];

Abstract: The neural connectivity between retinal ganglion cells (RGCs) and various mesencephalon regions including lateral geniculate nucleus (LGN) has been comprehensively described. The current anatomical knowledge, however, cannot fully explain the non-imaging function of RGCs. Advanced neural tracing tools are thus required to elaborate the network of RGC projection. In this study, we used CTB as the anterograde tracing marker via intraocular injection, coupled with immunofluorescence imaging, and found prominent efferent projection of RGCs on Kölliker-Fuse (KF) nucleus in contralateral mesencephalon. This connectivity was confirmed by CTB retrograde labelling via intracerebroventricular (ICV) injection on KF nucleus. These sub-population of RGCs were identified as ON-OFF and direction selective ganglion cells by morphological and electrophysiological examinations. The function of this newly discovered circuitry is currently unknown yet, but is proposed to be related with the potential effect of visual inputs on body vital signs such as respiratory rhythm, heart rate or blood pressure, as KF nucleus directly project to medullary regions.

Title: Structural integrity of the geniculostriate pathway in schizophrenia and bipolar disorder

Authors: *E. A. REAVIS[1,4], J. LEE[1,4], J. K. WYNN[4,1], K. L. NARR[2], S. N. NJAU[3], A. C. MCNAIR[4], J. E. IGLESIAS[4], M. F. GREEN[1,4];

Abstract: Patients with schizophrenia and related psychotic disorders show specific, persistent abnormalities in visual perception. Converging evidence suggests that some such perceptual deficits are linked to structural and functional abnormalities in brain areas near the bottom of the visual processing hierarchy, including the earliest stages of cortical visual processing (i.e., V1). However, it remains an important and unresolved question whether the structure and function of subcortical visual pathways are abnormal in such disorders. Early studies that used Diffusion Tensor Imaging (DTI) to assess the integrity of white-matter connections in schizophrenia reported reduced Fractional Anisotropy (FA) in the geniculostriate pathway (i.e., the optic radiations: the primary subcortical input to V1). These findings were interpreted as evidence of reduced structural integrity for the primary input pathway to the cortical visual system. However, DTI methods have advanced substantially since those early studies, and modern methods such as high-dimensional diffusion imaging and probabilistic tractography have not been used to assess the geniculostriate pathway in schizophrenia. Moreover, the structural integrity of the geniculostriate pathway has not been investigated in bipolar disorder, which emerging evidence suggests might manifest with perceptual abnormalities similar to those in schizophrenia. Therefore, we investigated the structural integrity of the geniculostriate pathway in a population of 32 patients with schizophrenia, 31 patients with bipolar disorder, and 30 matched controls. We used 64-direction DTI imaging and bidirectional probabilistic tractography between individualized thalamus and V1 seed regions to localize the geniculostriate pathway in each participant, and calculated FA within those tracts. Contrary to early reports, we found no evidence of diminished FA in either schizophrenia or bipolar disorder. This suggests that the structural integrity of the geniculostriate pathway is relatively intact in schizophrenia and bipolar disorder. Thus, perceptual deficits in the disorders are not likely attributable to degraded transmission of visual information to visual cortex via the geniculostriate pathway.

Title: The impact of chronic amphetamine treatment on the superior colliculus

Authors: ***A. TURNER**[1], P. G. OVERTON[2], I. KRAEV[1], A. STRAMEK[1], C. L. ROSTRON[1], M. G. STEWART[1], E. J. DOMMETT[3];
[1]Life, Hlth. and Chem. Sci., The Open Univ., Milton Keynes, United Kingdom; [2]Univ. of Sheffield, Sheffield, United Kingdom; [3]King's Col. London, London, United Kingdom

Abstract: Increased distractibility refers to a reduced ability to discriminate relevant from irrelevant information. It affects many people, as it is a symptom of a number of different conditions including attention deficit hyperactivity disorder, dyslexia, schizophrenia, and depression. It can also occur naturally as a person ages. The most effective form of treatment for increased distractibility are psychostimulant drugs, such as amphetamine. Converging evidence suggests that a potential neural correlate for distractibility is the superior colliculus (SC). Alterations to this structure and its connections to the prefrontal cortex have been found to disrupt distractibility. Furthermore, dose dependent decreases in visual activity within this area have been found after acute amphetamine administration, suggesting a possible therapeutic locus of action for the drug. However, these drugs are taken therapeutically for an extended period of time, limiting the conclusions that can be drawn from acute administration. As such we investigated the effects of chronic amphetamine on collicular function. Hooded lister rats were treated chronically with a range of doses of amphetamine (2 mg/kg, 10 mg/kg and 5mg/kg) or a vehicle, using a therapeutically-relevant oral dosing method. The effect of chronic treatment was then determined using behavioural, electrophysiological and anatomical measures. Collicular-dependent behaviour was measured using a visual distractibility task and height-dependent air-righting. In addition, to rule out confounding effects of altered locomotor activity, activity monitoring was conducted. Local field potential and multiunit activity were recorded from the superficial SC under urethane anaesthesia in response to a whole field light flash, in the presence of an acute amphetamine or saline challenge. Finally, anatomical measures included SC and whole brain volume calculations using the Cavalieri principle and cell counts for both neurons and glia. Results showed no significant impact of vehicle treatment both chronically and during acute electrophysiology. There were, however, a number of significant effects of amphetamine on behaviour and electrophysiological measures, indicating the SC may be a site of action for the distractibility-modulating effects of psychostimulants.

Title: Melanopsin contributions to image forming vision in mice

Authors: *A. E. ALLEN, F. P. MARTIAL, R. J. LUCAS;
Univ. of Manchester, Manchester, United Kingdom

Abstract: Melanopsin, found in ipRGCs (intrinsically-photosensitive retinal ganglion cells), is necessary for the accurate encoding of ambient light for subconscious visual responses (e.g. entrainment of the circadian clock; control of pupil size). There is, however, an emerging role of melanopsin in perceptual vision that currently is poorly understood. Particularly lacking is a description of the spatial/temporal information conveyed by ipRGCs that arises exclusively from melanopsin's photon capture, and what functional contribution this makes towards image-forming vision.
To isolate the particular components of the visual world which melanopsin might encode, we modified a commercially-available projection system so that each R, G and B channel was instead a combination of five independently controlled wavelengths (λ_{max} 405, 455, 525, 561, 630nm). This allowed us to present temporally-controlled, patterned stimuli in spectra that provided contrast for selected mouse photopigments. In this way, we produced patterns visible only to melanopsin or only rods and cones, and recorded electrophysiological responses in the visual thalamus (dLGN) of anaesthetised mice. Spatial and temporal receptive fields (RFs) for stimuli visible to melanopsin could be recorded in ~20% of dLGN neurons. These RFs were spatially similar but temporally distinct from those of rods and cones. Melanopsin responses were uniquely slow and sustained, and the dLGN's representation of spatial patterns invisible to melanopsin decayed over several seconds of static view. Using a movie simulating the impact of head/eye movements while viewing a natural scene, we found that the representation of differences in local radiance was enhanced for stimuli visible to melanopsin during periods of relative fixation. Thus, although melanopsin signals are outside the range required for high spatiotemporal acuity vision, these data reveal they are particularly useful in encoding coarse spatial patterns in radiance over longer timescales.

Title: Modulation of visual responses by behavioral factors in mouse superior colliculus

Authors: *S. SCHRÖDER, M. KRUMIN, K. D. HARRIS, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: Cells in the superficial layers of mouse superior colliculus (SC) receive visual input from retinal ganglion cells and from primary visual cortex (V1). Previous work has shown that visual responses in V1 cells are modulated by non-visual factors such as intrinsic, ongoing activity and the animal's speed of locomotion. Does the same hold for cells of superficial SC? We used two-photon microscopy to record the activity of neuronal populations in the superficial SC of awake mice that were head-fixed and free to run on a floating ball. Our implant exposed the posterior SC, which is normally covered by a large sinus, while leaving the cortex intact. We used Gad-Cre mice to distinguish excitatory from inhibitory neurons, and expressed GCaMP6f via unconditional virus injection. We mapped receptive fields (RFs) with sparse noise stimuli and used drifting sinusoidal gratings to measure direction tuning. In addition to locomotion, we monitored eye position and pupil dilation.
We used a linear model to predict responses to gratings as a function of stimulus identity, locomotion speed, and ongoing activity, i.e. neural activity just before stimulus onset. A large number of neurons responded to the grating stimuli, and these were divided into two populations that were excited and suppressed by the stimulus. For the majority of neurons, visual responses were also influenced by behavioral factors. Both running speed and ongoing activity had diverse effects on visual responses, suppressing them in some cases and enhancing them in others. The effect distributions were similar for excitatory and inhibitory neurons. Direction tuning was affected by running speed and ongoing activity, but neither factor was correlated with a consistent increase or decrease in direction selectivity across the population of neurons. Neurons that were strongly tuned for direction, however, were less strongly modulated by running speed and ongoing activity than less strongly tuned neurons. Responses of more strongly tuned neurons were also on average more likely to be suppressed by high amplitudes of ongoing activity whereas less tuned neurons showed increased responses.

Our results show that neuronal responses in the superficial layers of superior colliculus are not solely driven by visual inputs but that for some neurons, non-visual factors such as ongoing activity and running speed are strong determinants of their responses. We plan to test whether these non-visual influences are inherited from cortex or even retina.

Title: The effect of electrode conditions for surprachoroidal-transretinal stimulation system on electrically-evoked potentials.

Authors: *K. NISHIDA[1], H. SAKAGUCHI[1], M. KAMEI[2], T. FUJIKADO[1], K. NISHIDA[1]; [1]Osaka Univ. Grad. Sch. of Med., Suita/Japan, Japan; [2]Aichi Med. Univ., Nagakute, Japan

Abstract: PURPOSE: We have developed a visual prosthesis system called the suprachoridal-transretinal stimulation (STS) system. The purpose of this study was to determine the effect of electrode conditions that would affect electrically-evoked potentials (EEPs) from the rabbit visual system. **METHODS**: A scleral pocket (3x5 mm) was created just over the visual streak in anesthetized pigmented rabbits (weight, 1.9-2.7 kg). The STS stimulating electrode system was implanted into the pocket. We varied the stimulating electrodes with different height (0.3 or 0.5 mm), the reference electrodes in the different location (in the vitreous cavity, on the sclera which is 180 degrees from the stimulating electrode, or on the sclera which is near the stimulating electrode), and the reference electrodes with different surface area. EEPs were then elicited by each type of electrode conditions. Three sessions were repeated for each group.
RESULTS: For the height of the stimulating electrode, the implicit times of the EEPs were 33.7±0.28 ms and 33.4±0.37 ms, respectively, and the amplitudes were 71.4±13.7 μV and 79.2±20.4 μV respectively. These differences were not significant (P=0.725; P=0.680). The surface area of the stimulating electrode nor the location of the reference electrodes had no significant effect on the implicit times and the amplitudes of the EEPs (P>0.05).
CONCLUSION: The height of the stimulating electrodes (0.3 or 0.5 mm) , the location of the reference electrodes, and surface area of the reference electrode do not significantly affect the implicit times and amplitudes of the EEPs elicited by the STS system.

Title: Oscillations in background and visually evoked activity of cat superior colliculus neurons

Authors: ***W. J. WALESZCZYK**, A. T. FOIK, A. GHAZARYAN;
The Nencki Inst., Warsaw, Poland

Abstract: Oscillations are ubiquitous features of neuronal activity in sensory systems and are considered as a substrate for integration of sensory information. Several studies have described oscillatory activity in the geniculate visual pathway, but little is known about this phenomenon in the extrageniculate visual pathway. Here, we describe oscillations in the background and visually evoked activity in the cat superior colliculus, a retinorecipient structure in the extrageniculate visual pathway. Extracellular single unit activity was recorded in superficial layers of the superior colliculus of anasthetized (isoflurane in O_2/N_2O) cats during periods with and without visual stimulation. Autocorrelation, FFT and renewal density analyses were used to detect and characterize oscillations in the neuronal activity. Our study indicates that oscillations are common in the background and stimulus evoked activity of the superior colliculus and they were observed in the activity of about half of the recorded cells. Oscillations in visually evoked activity could appear in two forms - stimulus phase-locked, and stimulus phase-independent oscillations. Stimulus phase-independent and background oscillatory frequencies were very similar, suggesting that stimulus phase-independent oscillations may be a form of enhanced "spontaneous" oscillations. Stimulus phase-locked oscillations were present in responses to visual moving and flashing stimuli. In contrast to stimulus phase-independent oscillations, strength of phase-locked oscillations was positively correlated with stimulus velocity and neuronal firing rate. Our results suggest that phase-independent oscillations in superficial layers of the superior colliculus may be generated by the same mechanism(s) that lie in the base of "spontaneous" oscillations, while phase-locked oscillations may result from interactions within the intra-collicular network and/or from a phase-reset of oscillations present in the background activity.

Title: Functional modulation of primary visual cortex by superior colliculus

Authors: **M. AHMADLOU**, *J. A. HEIMEL;
Cortical Structure and Function, Netherlands Inst. Neurosci, Amsterdam Zuidoost, Netherlands

Abstract: Attentional modulation of surround suppression in visual cortex is well known. However the underlying circuit is not studied yet. Here, using electrophysiological recordings and optogenetics, we show that superior colliculus, which is a key area in attentional network, modulates a part of the surround suppression in visual cortex, although the cortical response to full screen is not significantly affected. Interestingly, reduction of the surround suppression of V1 is not the only effect of silencing superior colliculus, but we saw reduction of orientation/direction selectivity of V1 neurons as well. There are two thalamic pathways from superior colliculus to visual cortex, one through lateral posterior nucleus (LP) and the other one through dorsolateral geniculate nucleus (dLGN). Therefore, in order to find out the pathways of these functional modulations, pharmacologically we silenced LP, while the superior colliculus was optogenetically manipulated. Surprisingly, the modulation of V1 effect is not through LP, but it's through dLGN. This study shows a new vital role of superior colliculus as a functional modulator of visual cortex and the importance of the tecto-geniculate pathway in cortical tunings, which was not considered before.

Title: Selective ablation of luminance-sensing RGCs reveals specificity and stringency of pretectal targeting mechanisms

Authors: *T. A. SEABROOK[1], N. ISHIKO[1], O. S. DHANDE[1], V. P. WOOLEY[2], P. L. NGUYEN[2], A. D. HUBERMAN[1,3];
[1]Dept. of Neurobio., Stanford Univ. Sch. of Med., Palo Alto, CA; [2]Dept. of Neurosciences, UCSD, La Jolla, CA; [3]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: How do neurons select their targets during development? Despite the functional importance of linking specific neuronal subtypes to their correct brain targets, the developmental mechanisms that ensure this process occurs accurately, remain poorly understood. Here we address this important question in the context of parallel visual circuits in the midbrain pretectum. The pretectum consists of a dense collection of brain nuclei that mediate different reflexive behaviors, including optokinetic reflexes essential for image stabilization and pupillary light reflexes (PLR). These targets receive input from distinct types of retinal ganglion cells (RGCs), the output neurons of the eye. Luminance-sensing RGCs are born relatively early in development and initially send their axons to several incorrect targets during development (Osterhout et al., *Cell Reports*, 2014). After this initial mistargeting, they remove their inappropriate axon projections and maintain the correct ones to the olivary pretectal nucleus (OPN) and posterior pretectal nucleus (mdPPN). By contrast, later arriving RGC axons such as those driving optokinetic reflexes, are more accurate in their targeting, bypassing OPN and mdPPN and targeting other nearby retinorecipient nuclei instead, such as the nucleus of the optic tract (NOT), which is involved in image stabilization. One idea is that competitive interactions between these functionally distinct RGC subsets are important for target selection in the pretectum. To test this, we used Cre-dependent deletion of Tbr2, a transcription factor important for RGC survival, to specifically eliminate the early-projecting cohort of luminance-sensing RGCs. We then asked whether other intact types of RGCs redirect their axonal inputs to the vacated targets. Remarkably, even when the OPN and mdPPN were rendered devoid of their normal retinal input, the axons of other RGC types continue to avoid these targets. This suggests

that axon-target matching is controlled by molecular matching mechanisms that do not tolerate cross-wiring. In other words, the process likely involves signals that direct specific axons to their targets *and* signals that actively restrict the wrong types of afferents from innervating those same targets. The relevance of these findings to visual development, function and regeneration will be discussed.

Title: Vision drives accurate approach behavior during prey capture in laboratory mice

Authors: *J. L. HOY, D. ZHEN, G. SMITHERS, C. NIELL;
Univ. of Oregon, Eugene, OR

Abstract: The ability to genetically identify and manipulate neural circuits in the mouse is rapidly advancing our understanding of visual processing in the mammalian brain. Recent studies have focused on investigating neural circuit function in mice performing simple behaviors under highly controlled, yet unnatural, conditions. However, identifying ethologically relevant visual behaviors in the mouse will strengthen efforts to understand the neural circuit basis of visual behavior. Here, we show that C57BL/6J mice robustly pursue, capture and consume live insect prey. We quantified the dependence of this behavior on visual cues by selectively blocking visual or auditory sensory input. Visual input is required for accurate maintenance of bearing to within 30 degrees of the target during pursuit, and for keeping the target at close range until final capture. Vision also significantly reduced the latency to initiate approach towards the target. While mice were able to capture prey using auditory cues alone, the accuracy of targeting and success rate for capture were much lower than for vision alone. Importantly, because mice can perform this behavior using purely visual input, we were able to estimate the specific features, such as prey size and motion, that triggered visually guided approach. These data provided an estimate of the natural operating range of the mouse visual system. These studies demonstrate that laboratory mice are capable of exhibiting dynamic and accurate approach behaviors that rely on vision. Furthermore, the robustness of this behavior will facilitate future studies that seek to identify and observe the underlying neural circuitry.

Title: Bilateral projections of the parabigeminal nucleus to the superior colliculus in Octodon degus

Authors: A. DEICHLER, 7800024[1], D. CARRASCO[3], T. VEGA[4], J. MPODOZIS[1], *G. J. MARÍN[2,5];
[1]Biol., [2]Facultad de Ciencias, Univ. de Chile, Santiago, Chile; [3]Biol., Univ. de Chile, Santiago, Chile; [4]Lehrstuhl fur Zoologie, Technische Univ. Munchen, Freising-Weihenstephan, Germany; [5]Facultad de Medicina, Univ. Finis Terrae, Santiago, Chile

Abstract: The parabigeminal nucleus (Pbn) is the mammalian homologue to the ithsmic complex of other vertebrates. A recent study has shown that optogenetic stimulation of the Pbn induces freezing and escape responses in mice, a result thought to be caused by a direct projection from the Pbn to the central nucleus of the amygdala. However the isthmic complex, including the Pbn, is tightly connected to the Superior Colliculus (SC), which upon stimulation of its medial aspect also triggers fear and avoidance reactions. As this Pbn-SC connectivity is not well understood, we investigated whether the behavioral consequences of the Pbn stimulation could be related to the topology of its projection to the SC. To that end, we studied the cytoarchitectural, neurochemical and hodological properties of the Pbn in a diurnal rodent, the *Octodon degus*. We performed immunohistochemistry for ChAT, *in situ* hybridization for VGluT2 mRNA, and neural tracer injections in the SC and Pbn. In sagittal ChAT preparations the Pbn appears as an elongated structure, with two subdivisions: a rostral Pbn, formed by a dense cluster of densely stained, large cell bodies; and a caudal Pbn, populated by less-dense and smaller somas. After *in situ* hybridization we found that both divisions are positive for VGluT2 mRNA, indicating that the Pbn neurons may co-release both acetylcholine and glutamate. Our tracer injections indicated that the two divisions of the Pbn constitute hodological specializations: in the caudal Pbn, we found labeled axon terminals and cells only in the side ipsilateral to the injected colliculus; in the rostral division, axon terminals and cells appear exclusively ipsilateral and contralateral, respectively, to the injected SC. CTb injections in the Pbn revealed a bilateral projection to the SC. The ipsilateral projection covers the whole extent

of the superficial layers of the SC especially in the central zone. The contralateral projection seems to be more specialized, as it forms a dense mesh of terminals, restricted to the medial SC, throughout its longitudinal extension. This medial projection is located where the upper visual field is represented, which in degus and other rodents has a large binocular overlap. It is known that looming visual stimulation restricted to this zone induce escape responses in mice. Thus, our results may link the functional data obtained by the visual stimulation of the upper visual field and the physiological stimulation of the Pbn and the medial SC, by suggesting that the contralateral, presumably glutamatergic projection of the Pbn drives binocular responses in the medial SC which mediates fear and escape visual reactions.

Title: Different origins of visual feature selectivity in two major subcortical structures in the mouse

Authors: ***J. BARCHINI**[1], H. ACARON LEDESMA[2], Y.-P. CHEN[1], D. KOREN[2], J. CANG[1], W. WEI[2];
[1]The Dept. of Neurobio., Northwestern Univ., Evanston, IL; [2]The Univ. of Chicago, Chicago, IL

Abstract: Direction selectivity (DS) and orientation selectivity (OS) are fundamental features of visual system function. These features have been observed throughout the visual system of many animal species, in structures including cortex, the lateral geniculate nucleus (LGN) of the thalamus, the superior colliculus (SC), and the retina. The mechanisms that give rise to these features at the different levels of visual processing are still a matter of intensive investigation. For retinorecipient regions, feature selectivity might be simply inherited from the retina. Alternatively, a more complex convergence of untuned retinal input, coupled with local processing, can lead to the emergence of those features.In this study we aim to distinguish between these possibilities by genetically manipulating these features at the level of the retina,

and assessing the consequences downstream. Our manipulation consists of a conditional knockout (KO) of the vesicular GABA transporter (Vgat) in ChAT-positive cells. We have previously shown that the KO results in a reduction of GABA release from starburst amacrine cells in the retina, leading to reduced DS in one subtype of direction selective ganglion cells (DSGCs, Pei et al., 2015). Here, we have performed new experiments using 2-photon calcium imaging to determine the response selectivity of large populations of retinal ganglion cells. These experiments show that both DS, and surprisingly, OS are reduced in the ganglion cells of these KO mice. We next studied the response properties of the two major subcortical visual structures that receive direct retinal input, the SC and LGN, in these KO mice. We have recently shown that neurons in the most superficial lamina (top 50 um) of the mouse SC are highly selective for stimulus direction (Inayat, Barchini et al., 2015), establishing it as a useful model to study the mechanisms of DS. In vivo 2-photon calcium imaging from this lamina in the SC of the Vgat-KO mice revealed a substantial decline in DS, compared to littermate controls. This phenotype closely mirrors our findings in the retina, and directly implicates DSGCs as the source of direction selectivity in the SC. In contrast, single unit recordings revealed largely normal levels of DS and OS in the LGN of the KO, suggesting that these properties might emerge de novo in the LGN through local processing of untuned retinal inputs. Together, our studies indicate that different mechanisms are at play in setting up feature selectivity in the two visual pathways.

Title: Basal forebrain provides direct projections to inhibitory neurons in mouse primary visual cortex, but not to the parvalbumin-positive inhibitory subtype

Authors: *G. A. LEAN[1], Y. LIU[2], D. C. LYON[2];
[1]UC Irvine, Irvine, CA; [2]Anat. and Neurobio., Univ. of California, Irvine, Irvine, CA

Abstract: Basal forebrain projections to the primary visual cortex (V1) have been implicated in receptive field tuning and attentional modulation by several studies. This projection is thought to be cholinergic due to the nature of the basal forebrain region. Furthermore, these inputs are thought to have more of an impact on local cortical inhibition as extensive anatomical research shows the majority of neurons with cholinergic receptors (ChR's) in V1 are GABAergic, despite these cells only representing 20% of the neural population. In higher visual mammals such as primates, the parvalbumin(PV)-positive subclass is the most abundant of the inhibitory neurons with ChR's, whereas in rodents the proportion of PV neurons with ChR's is greatly reduced (Disney & Reynolds, 2014). Basal forebrain projections to V1 neurons are primarily to layer 5, where they can make direct synaptic contact, but acetylcholine is delivered to neurons in other layers less directly via diffuse extra-synaptic modulation known as 'volume transmission'. In mouse, we previously confirmed that basal forebrain projections synapse directly onto GABAergic, but not non-GABAergic neurons in V1 using a modified rabies viral injection targeted via a helper virus containing a GAD1 promoter (Lean et al. SFN, 2015). Here we use a new helper virus containing a large fragment of the FUGU PV promoter. Compared to our approach using the GAD1 promoter, we find that neurons projecting to PV cells are primarily local in origin; short range cortical projections (see also our submission by Lyon et al. SFN, 2016). Specifically, there is a distinct lack of labeling in the basal forebrain. This result indicates that basal forebrain projections do not directly synapse onto V1 PV neurons, suggesting that other inhibitory neuron subtypes are the direct targets. This is also consistent with data noted above showing fewer PV inhibitory neurons express cholinergic receptors in rodents, suggesting less of an emphasis of cholinergic modulation of this subtype. Whether or not V1 PV neurons receive direct basal forebrain inputs in higher visual species remains to be determined.

Title: Early-life lesions of the pulvinar alter visual cortical anatomy and behaviour

Authors: *I. CARRIL MUNDIÑANO, D. M. FOX, W. C. KWAN, J. A. BOURNE; Australian Regenerative Med. Inst., Monash Univ., Clayton, Australia

Abstract: Previous studies from our laboratory showed that the medial portion of the inferior pulvinar (PIm) receives direct retinal which it relays to the middle temporal (MT) area of the visual cortex, both of which are pruned during development. This pathway is believed to underpin the early maturation of area MT and the dorsal stream network. Furthermore, after early removal of primary visual cortex (V1), this disynaptic pathway remains unpruned, which could be the neural substrate for the better preservation of vision observed in infants than adults following V1 lesions.
To study the influence of the retino-pulvino-MT pathway on the organization and maturation of the visual cortex, 4 neonatal (14-21 days) marmoset monkeys (Callithrix jacchus) received unilateral PIm ablations (NMDA, 100nl, 0.12M infusions). The anatomical changes of cortical areas post-lesion were mapped by Diffusion Tensor Imaging (DTI) analysis 6, 9, 18 and 36 weeks post-lesion, which revealed significant alterations of diffusion scalars in dorsal stream associated areas and the posterior parietal association cortex. Neural tracing experiments demonstrated that thalamic input from PIm to area MT was completely abolished. Moreover, reduced connectivity between V1 and area MT was detected. Immunohistochemical analysis of the dorsal stream tissue showed axonal damage and altered the excitatory/inhibitory balance. Two of the animals were trained to perform visually guided motor tasks with both hands. Behaviour experiments showed a significantly worse performance with the hand contralateral to the lesion site. Data presented here demonstrate that thalamocortical input from PIm in early life is critical for the correct development and maturation of cortical connections of dorsal stream visual areas, hence altering visually-guided motor behaviours.

Title: Visual discomfort symptoms and nearwork activity in latino populations

Authors: *D. A. DEL CID, T. GORJI, J. R. MIER, N. URENDA, S. A. DREW;
Psychology, Vision Sci. Information Lab. @ CSUN, Sherman Oaks, CA

Abstract: Previous studies have indicated ethnic differences in visual perception in children but have focused very little on college aged adults (Klienstein, 2003). Current research suggests that the prevalence of myopia to be at 16.8% among the Latino population (Tarczy-Hornoch, 2006).

Previously, we observed a high prevalence of visual discomfort symptoms reported in a diverse population of college students. This in itself may not be entirely surprising as symptoms including ocular fatigue, perceptual distortions, and headaches can result from nearwork tasks such as reading or viewing computer screens, tasks common to the college experience. Given current reports of differences in myopia prevalence among different ethnicities, we were interested to determine whether similar distinctions could be observed in the reports of visual discomfort symptoms. Methods: We administered a battery of questionnaires to 451 college students, including two validated surveys for assessing visual discomfort symptoms, the Convergence Insufficiency Symptoms Survey (CISS) and the Visual Discomfort Survey (VDS) (Conlon, 1999) and demographic questions. Results: We found that participants who identified as being Latino/a had a significantly different pattern of results than those who did not. These data suggest that the prevalence of visual discomfort in the college population may be confounded by ethnic differences.

Title: Defining the neural circuits that provide emotional significance to what we see

Authors: *L. D. SALAY[1], N. ISHIKO[1], P. L. NGUYEN[2], E. YAGHOUB[2], A. D. HUBERMAN[1,3];

Abstract: How do we assign emotional value to what we see? Very little is known about where and how emotional valence information interfaces with brain regions associated with visual processing. We discovered using activity-driven 'TRAPing' of neurons with the immediate early gene cFOS (Guenther et al., 2013) that specific nuclei of the midline thalamus are activated during visual fear in mice. Interestingly, subsets of these nuclei receive input from visual areas and project to both the amygdala and prefrontal cortex- regions of the brain involved in emotionality and decision-making, respectively. By manipulating the activity of these midline

thalamic nuclei with chemo- and opto-genetics, we observed they can cause marked alterations in the behavioral responses to fear-inducing visual stimuli. To further investigate the role of the midline thalamus in emotional state, we also recorded pupillary responses during their activation. This induced pupil dilation, an indication of increased arousal. Thus, the midline thalamus is ideally poised to integrate visual information with emotional-processing brain regions and thereby help select optimal behavioral decisions. The relevance of these findings to studies of normal and pathologic emotional processing will be discussed.

Title: Integrity of central visual pathways in patients with macular degeneration

Authors: ***M. MALANIA**[1], J. KONRAD[2], H. JÄGLE[2], J. S. WERNER[3], M. W. GREENLEE[1]; [1]Univ. of Regensburg, Regensburg, Germany; [2]Univ. Eye Hosp., Regensburg, Germany; [3]Univ. of California, Davis, CA

Abstract: Macular degeneration (MD) affects the central retina and leads to gradual loss of foveal vision. Although, photoreceptors are primarily affected in MD, the retinal nerve fiber layer (RNFL) and central visual pathways may also be altered subsequent to photoreceptor degeneration. Previous studies have shown that the absence of afferent stimulation due to retinal lesions causes a reduction of gray matter in the lesion projection zone of V1 (Plank et al., 2011). Ogawa and colleagues (Ogawa et al., 2014) also demonstrated compromised integrity of white matter pathways in patients with Leber's hereditary optic neuropathy and cone-rod dystrophy. Here we investigate whether retinal damage caused by MD alters microstructural properties of visual pathways using diffusion-weighted MRI. Six MD patients and 6 healthy control subjects participated in the study. Patients had large binocular central scotomas and were free from other ocular or neurological diseases. Retinal images were obtained by optical coherence tomography (OCT). Scan analysis was performed with Spectralis software. Diffusion-weighted images were acquired by a Siemens 3T head-only scanner. In addition, high-resolution T1-weighted structural images were collected for each subject. Data were processed using Vistalab software

(https://github.com/vistalab/vistasoft/). Diffusion-based tensor modeling and probabilistic fiber tractography based on ConTrack were used to identify the optic radiations (OR). We sampled 100,000 candidate fibers and kept about 30% of these by applying the ConTrack scoring algorithm. Each tract was partitioned into 100 equally sized segments. To obtain a summary of the tract profile data was averaged over 80 values of each tract profile excluding the first and last 10 segments in order to avoid partial-volume effects. Fractional anisotropy (FA), axial and radial diffusivity values (AD, RD) were calculated along the OR tract. We observed a significant main effect of subject group with respect to mean FA ($p < 0.00001$). Patients showed a significant decrease of AD ($P<0.005$) while RD ($p<0.00001$) values were increased. Analysis of OCT images revealed RNFL thickness differences with significant thinning in the eyes of MD patients compared to those of controls (average thickness: 86±5 vs. 94±3 μm, $p<0.00005$). Our results indicate that the RNFL and the white matter of the visual pathways are significantly altered in MD patients. Damage to the photoreceptors in MD leads to atrophy of the ganglion cell axons and to corresponding changes in structural properties of central visual pathways.

Abstract: Aniridia is a congenital panocular disorder resulting from mutations of the *PAX6* gene important in both eye and brain development and characterized chiefly by iris hypoplasia. In addition to ocular abnormalities, differences in global brain volume and functional brain connectivity have been reported in humans with aniridia. Examining possible abnormalities of global white matter structure may be critical to understanding structural and functional deficits of

aniridia; few studies, however, have examined white matter integrity in this population. The current study utilized diffusion-weighted imaging to assess neural white matter integrity in 11 people with aniridia and 11 healthy comparison subjects, matched for gender and age. A map of the local connectome was calculated to compare quantitative anisotropy (QA), an index of white matter structure, in all voxels of the brain, revealing subcomponents of white matter tracts displaying differences in QA between people with aniridia and healthy comparisons. This model-free analysis indicated that QA was lower for people with aniridia only in portions of visual tracts and posterior, associated pathways. These differences demonstrate that abnormalities in white matter structure exist in people with aniridia and may underlie functional differences in vision and brain connectivity.

Title: Temporal processing of sensory information in visuomotor regions of the mouse tectum and thalamus

Authors: *U. M. CIFTCIOGLU[1], V. SURESH[1], A. S. GORIN[1], K. R. DING[1], F. T. SOMMER[2], J. A. HIRSCH[1];
[1]USC, Los Angeles, CA; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: The retina has two main targets in the mammalian brain, the lateral geniculate nucleus of the thalamus (LGN) and the superior colliculus (SC). The geniculate comprises two divisions, the dorsal part (dLGN) provides input to the visual cortex and the ventral region (vLGN) is connected with subcortical sensorimotor structures including the SC. Recently we began to compare coding strategies in the vLGN with those in the SC to understand how these retino-recipient structures might communicate. The experimental techniques we used are whole-cell, single unit, and local field potential recording from anesthetized mice during the presentation of visual stimuli. Work in other species (Brecht et al., J Nphys 2004; Stitt et al., J Nphys 2013; Sridharan et al., J Nphys 2011) had shown that neurons in the SC encode visual stimuli in two

ways, by changing firing rate and by entraining gamma oscillations. Previously, we had asked if the vLGN might do the same and found that, for about a third of the population, full field stimuli evoked an increase in spike rate as well as gamma oscillations that were synchronized across trials. Moreover, for these cells, natural-movie stimuli often evoked oscillations whose strength waxed and waned during particular image sequences. Here we asked how the SC and the vLGN respond to the same classes of stimuli, with a focus on the temporal aspect of response. We found that gamma oscillations in the vLGN were typically evoked by luminance increments, whereas those in the SC were preferentially elicited by luminance decrements (also see Stitt et al., J Nphys 2013)—looming stimuli were particularly effective. Thus, the two regions integrate complementary information via oscillatory activity. A second difference between the two areas is receptive field size which, on average, is smaller in the SC than in the vLGN. We wondered if neurons with smaller receptive fields might display commensurately greater cross-trial temporal precision. Hence, we analyzed spike trains evoked by natural movies for cells whose receptive fields we had mapped quantitatively. There was not a strict relationship between receptive field size and spike precision nor a rigid dichotomy between the SC and vLGN. Temporal precision could fluctuate considerably during the time course of a given movie. For example, a thalamic neuron with a large receptive field might fire as precisely as a tectal neuron that had a small receptive field during a particular movie segment and vice versa (although firing in the SC seemed more precise overall). Future studies in which simultaneous recordings from both structures are made should shed light on how spike patterns in the SC and vLGN influence each other.

Title: Development of feed-forward and feedback connections between dLGN and TRN.

Authors: *P. W. CAMPBELL, W. GUIDO;
Anatom. Sci. & Neurobio., Univ. of Louisville, Louisville, KY

Abstract: The reciprocal connections between the dorsal lateral geniculate nucleus (dLGN) and the thalamic reticular nucleus (TRN) play an important role in regulating thalamocortical activity during different behavioral states such as attention, wakefulness, and sleep. Axon collaterals of thalamocortical neurons provide feedforward excitatory input onto GABAergic TRN neurons, which in turn convey feedback inhibition to dLGN relay neurons. Here we examined when and how these circuits arise during early postnatal life. To address this, we employed mouse transgenics to visualize when these inputs appear and optogenetics to assess when functional patterns of connectivity emerge. We used a GAD65 transgenic mouse to visualize GABAergic projections to dLGN. Reticulo-thalamic fibers begin to innervate dLGN at early postnatal ages so that by the end of the first postnatal week TRN projections form a dense and uniform network throughout the entire nucleus. We conducted in vitro whole cell recordings in acutely prepared thalamic slices in transgenic mice that express channelrhodopsin 2 (ChR2) in somatostatin (SST)-containing neurons of TRN. Blue light stimulation of SST containing fibers in dLGN evoked weak postsynaptic inhibitory activity in dLGN during the first postnatal week. Inhibitory responses matured by postnatal weeks 2-3, showing a progressive increase in strength, paired pulse depression, sustained levels of inhibition at high rates of stimulation, and a potent suppression of excitatory retinal activity evoked by optic tract stimulation. We used a CRH-Cre mouse crossed with an Ai9 reporter line to visualize dLGN thalamocortical axons and their collaterals in TRN. At birth, thalamocortical axons could be seen passing through TRN, with fibers and their collaterals expanding throughout the visual sector by the end of week 1. In vitro recordings of TRN neurons from CRH-Cre x ChR2 mice, showed that blue light stimulation of ChR2 containing dLGN axon collaterals could evoke weak excitatory postsynaptic responses during the postnatal week 1. By postnatal week 2-3, excitatory responses became stronger and were of sufficient strength to evoke Na^+ spikes as well as low threshold Ca^{2+} spikes and burst firing. Thus, the development of feedforward excitation from dLGN to TRN, and feedback inhibition from TRN to dLGN follow a similar time course, with adult-like patterns of functional connectivity emerging at about three weeks of age. At this time retinogeniculate and geniculocortical connections are well established, descending corticothalamic connections are maturing, and thalamocortical rhythms are beginning to take shape.

Title: GABAergic circuit interactions within the mouse dorsal lateral geniculate nucleus

Authors: *S. P. MASTERSON, G. GOVINDAIAH, W. GUIDO, M. E. BICKFORD;
Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: The activity of the dorsal lateral geniculate (dLGN) is influenced by a variety of circuits that use gamma amino butyric acid (GABA) as a neurotransmitter. Extrinsic sources of GABAergic input include the thalamic reticular nucleus (TRN) and pretectum. Intrinsic inhibition in the dLGN is mediated by GABAergic interneurons that release GABA via both dendritic terminals and axon terminals. In order to understand the various ways in which these intrinsic and extrinsic GABAergic circuits interact, we carried out ultrastructural and optogenetic analyses using transgenic mouse lines that express green fluorescent protein (GFP) in TRN cells (GAD65-GFP) or intrinsic interneurons and pretectum (GAD67-GFP), or mice that express cre-recombinase in all 3 sources (GAD2-cre). Viral vector injections into the TRN, dLGN or pretectum induced the expression of a channelrhodopsin variant (ChIEF) and blue light pulses were used to differentially activate these 3 sources of inhibition. Electrical stimulation of the optic tract was used to activate retinogeniculate inputs. We found that within the mouse dLGN: 1) The TRN specifically innervates and inhibits relay cells, and the strength of this inhibition is depressed during high-frequency stimulation. 2) The pretectum innervates and inhibits both relay cells and interneurons; during high frequency stimulation, pretectum inhibition of relay cells is depressed, while pretectum inhibition of interneurons is facilitated. 3) Interneurons inhibit both relay cells and interneurons; high frequency stimulation depresses both connections. 4) Interneurons are connected via axon terminals. 5) GABAergic connections can inhibit retinogeniculate transmission by inhibiting relay cells, or disinhibit retinogeniculate transmission by inhibiting the intrinsic interneurons. These results reveal a complex organization of inhibition whereby the strength of the retinogeniculate excitation of relay cells is contingent on the firing frequency and temporal order of inhibitory input.

Title: The absence of retinal input affects the targeting and morphological development of interneurons of dLGN

Authors: *N. CHARALAMBAKIS, G. GOVINDAIAH, P. W. CAMPBELL, W. GUIDO; Anatom. Sci. & Neurobio., Univ. of Louisville, Louisville, KY

Abstract: The dorsal lateral geniculate nucleus (dLGN) of the mouse is a model system to understand visual circuit development. While most studies focus on dLGN relay cells and their connections, little is known about the factors regulating the development of intrinsic interneurons. Here we examined whether the fate, migration, and dendritic maturation of interneurons relies on retinogeniculate axon innervation. To accomplish this, we took a loss of function approach and crossed GAD67-GFP mice, which express green fluorescent protein (GFP) in dLGN interneurons, with *math5* nulls, mutants that lack retinal ganglion cells and central projections. In *math5* nulls, the absence of retinal input led to 50% reduction in the number of interneurons in dLGN. The vLGN, where dLGN interneurons course through, also showed reduced numbers of interneurons. Within dLGN, interneurons were unevenly dispersed with many cells clustered in the upper tier even at late postnatal ages when migration of interneurons into dLGN is complete. Neighboring somatosensory nuclei (VPM, VPL and PO) which normally lack interneurons now contained several, suggesting that interneurons were not lost in dLGN but simply misrouted during migration. The absence of retinogeniculate axon innervation also disrupted the pattern of dendritic growth among developing interneurons. Normally, interneurons undergo a period of exuberant growth during postnatal weeks 2-3, followed by a period of moderate pruning in week 4. However, interneurons from *math5* nulls failed to follow this developmental pattern, and remained simple in structure from birth to adulthood. Confocal 3-D reconstructions of biocytin filled cells revealed that at all ages interneurons from *math5* nulls retained 2-3 primary dendrites similar to WT, but displayed a sparse dendritic architecture, with fewer branches and highly constricted dendritic fields. Normally interneurons display 12-14th order branching but in *math5* nulls, branching rarely exceeded 3-4th order. Moreover, in *math5* nulls, axons collaterals were not readily apparent and dendritic protrusions which are thought to reflect F2 profiles were largely absent, suggesting possible alterations in interneuron synaptic connectivity. These data support recent findings showing that retinal input directs the postnatal migration of interneurons into dLGN (Golding et al., 2014). Our results also suggest that retinal axons provide additional trophic cues to support the growth and elaboration interneuron dendrites.

Title: Ontogenetic investigation of thalamocortical circuits for active vision

Authors: ***N. ZHOU**, S. P. MASTERSON, J. K. DAMRON, W. GUIDO, M. E. BICKFORD; Anatom. Sci. & Neurobio., Univ. of Louisville, Louisville, KY

Abstract: To define the cortical circuits activated by the mouse pulvinar homologue (lateral posterior nucleus or LPN), we carried out ultrastructural and optogenetic analyses using wild type (WT) mice and a transgenic mouse line that expresses green fluorescent protein in cortical interneurons (GAD65-GFP). We found that the LPN projects to interconnected regions of V1, the lateral extrastriate cortex, striatum and amygdala. In all cortical regions, terminals originating from the LPN primarily contact dendritic spines. For optogenetic analyses of these synaptic connections, viral vector injections in the LPN of WT or GAD65-GFP mice induced the expression of a channelrhodopsin variant (ChIEF), and blue light pulses were used to activate thalamocortical terminals in cortical slices maintained *in vitro*. Additional injections of cholera toxin subunit B conjugated to Alexafluor 488 (CTB-488) in V1, superior colliculus, or striatum/amygdala were used to identify subtypes of cortical projection neurons and target them for recording. Biocytin was included in the recording pipettes to subsequently examine the morphology of the recorded cells. From a total of 432 neurons recorded in cortical layers IV and V, 64% responded to optogenetic activation of LPN terminals with short, fixed latency excitatory synaptic potentials/currents (EPSPs/EPSCs). These monosynaptic responses were abolished in the presence of 1μM tetrodotoxin (TTX), but could be elicited in the presence of TTX when paired with 1mM 4-aminopyridine. Responses were blocked by the addition of AMPA (CNQX, 8 μM) and NMDA (APV, 10μM) receptor antagonists. The morphology of a total of 147 responsive cells was recovered and categorized as pyramidal (69%), spiny stellate (21%), or other (10%). The majority (74%) of interneurons recorded in GAD65-GFP mice (n = 34) responded to activation of LPN terminals, and the addition of a GABAa receptor antagonist (SR95531, 20μM) enhanced responses of both interneurons and pyramidal cells (up to 4 fold). Recordings targeted to specific projection neuron subtypes within layer V (corticotectal, n = 31, corticocortical, n = 33, and corticostriatum/amygdala, n = 68) revealed that the LPN primarily targets corticostriatum/amygdala cells (76% responsive). The majority of corticocortical neurons were also responsive (55%), but corticotectal cells were rarely responsive (6%). These results indicate that the LPN can strongly influence the activity of the visual cortex, and suggest that it

may act as a hub to dynamically coordinate body movements with the perception of visual signals.

Title: Postnatal development of cholinergic input to the thalamic reticular nucleus

Authors: ***G. SOKHADZE**, W. GUIDO;
Anatom. Sci. & Neurobio., Univ. of Louisville, Louisville, KY

Abstract: The thalamic reticular nucleus (TRN) is composed of inhibitory neurons that surround the thalamus and act to modulate the transfer of sensory information to and from the primary sensory thalamic nuclei and cortex. A major input to TRN originates from cholinergic neurons of the basal forebrain and brainstem. Together these inputs are involved in modulating TRN activity in a behavioral state-dependent context, such as during sleep, wakefulness, and attention. Although the presence of cholinergic elements in TRN has been well documented, it is not known how this input initially develops. Moreover, TRN is subdivided into distinct sensory sectors, yet it is not clear whether the pattern of cholinergic innervation develops uniformly or differently across sensory sectors. To address these questions we utilized the ChAT-Cre transgenic mouse, crossed to a reporter line (Ai9), which allowed for selective visualization of cholinergic input within the visual and somatosensory sectors of TRN. At birth, cholinergic neurons of the basal forebrain and brainstem exhibited robust expression of red fluorescent protein tdTomato. By P7, extensive cholinergic axon innervation was seen in the ventral somatosensory sector of TRN, but not in the dorsal visual region. Cholinergic innervation of the visual sector began at P9 and resembled the adult like pattern by P14. To assess the synaptic properties of cholinergic input to TRN during postnatal development, we performed whole-cell patch clamp recordings in acute thalamic slices in ChAT-ChR2 mice, which express channelrhodopsin-2 (ChR2) in cholinergic terminals. We recorded light-evoked synaptic responses in TRN neurons of mice aged P5-P21 while activating cholinergic terminals with 3 ms. pulses of blue light. In the first postnatal week, cholinergic responses were purely excitatory,

and mediated by nicotinic receptors. By the second postnatal week, blue light stimulation evoked biphasic excitation-inhibition (E-I) responses, with the inhibitory component mediated by muscarinic receptors. During the first two weeks, the prevalence of cholinergic responses and peak amplitudes of excitatory component were greater for neurons located in the somatosensory sector (23/27 cells, 85.2%, 4.32 mV), compared to the visual sector of TRN (7/17 cells, 41.2%, 1.51 mV). Thus, the ventro-dorsal pattern of cholinergic of structural innervation matched the emergence and maturation of cholinergic synaptic responses in TRN. These data further suggest that the timing of functional cholinergic innervation of visual TRN occurs well after the establishment of adult-like patterns of retino- and reticulo-geniculate connectivity.

Title: Hand position modulates visually-driven fMRI responses in premotor cortex

Authors: *J. DE JONG[1], B. KLEIN[2], A. KEIZER[2], C. DIJKERMAN[2], S. DUMOULIN[2]; [1]Dept. of Exptl. Psychology, [2]Utrecht Univ., Utrecht, Netherlands

Abstract: While moving through our environment, it is crucial to monitor the immediate surroundings of our body to avoid harmful contact. Earlier studies suggest that neural populations in premotor cortex are responsive to visual space surrounding individual body parts and employ a body-centered reference frame. Thus, whereas most visual receptive fields are linked to retinal coordinates, these receptive fields are anchored to the space surrounding certain body parts. Here, we aim to characterize these neural populations in humans by examining how hand position modulates fMRI responses to a strong visual stimulus. Healthy participants viewed a contrast-defined, full-field stationary checkerboard pattern while we acquired fMRI-responses elicited by the visual stimulus using ultra-high field (7T) functional MRI (TR = 2 seconds, 2 mm isotropic). Participants were instructed to position their hand at different locations surrounding the visual stimulus. We define several regions of interest (ROI) based on strong co-activation with the visual stimulus in several parts of the brain, including premotor cortex. We compare the BOLD-amplitude within these ROIs between different hand positions. We find strong co-activation with our stimulus throughout the brain. The fMRI response elicited by the visual stimulus is modulated by hand position in several visually responsive regions, including premotor cortex. In contrast, responses in early visual cortex, including primary visual cortex,

are not modulated by hand position. Our results demonstrate that visually-driven neural responses in premotor cortex are modulated by hand position. We speculate that these neural populations may have their receptive fields anchored to the hand. Moving the hand to different locations near the visual stimulus modulates the amount of overlap between these receptive fields and the visual stimulus. These results provide opportunities to study these premotor neurons in more detail, paving the way for methods such as population receptive field (pRF) mapping.

Title: Coding of viewpoint, posture and identity of bodies in the macaque midSTS body patch.

Authors: *S. KUMAR, R. VOGELS;
KU Leuven, Leuven, Belgium

Abstract: FMRI studies in primates show body-category selective activations in temporal cortex. Single unit studies in the midSTS body patch revealed greater activity to images containing bodies compared to faces and objects. However, these neurons showed a marked body image selectivity, responding only to some body images. The body image selectivity may reflect encoding of body identity, posture and viewpoint. Here we examined the selectivity of the fMRI-defined macaque midSTS body patch neurons for these three variables. We designed a novel computer-generated stimulus set (n= 120 stimuli) depicting monkeys that differ in anthropometric features (identity; fat, normal and thin), with 5 different postures (2 threat, 2 submissive and 1 neutral posture), rendered at 8 viewpoints (45 deg step; rotated around the vertical axis). The internal facial features of the head were minimized and kept constant across all stimuli. The images were presented for 200 ms each during passive fixation in 2 rhesus monkeys. Single unit recordings showed a marked selectivity for viewpoint and posture. We

employed linear SVM with cross-validation to decode viewpoint, posture and identity from the responses of 88 midSTS neurons. First we asked whether we could decode one variable (e.g. viewpoint) when varying the two other variables (e.g. posture and identity). Decoding of identity and posture invariant viewpoint (classification accuracy: 73%; 200 ms bin; chance level : 12.5%) and viewpoint and identity invariant posture (50%; chance level: 20%) was well above chance (permutation test with shuffled stimulus labels; $p < 0.005$) but viewpoint and posture invariant identity decoding (36%) was barely above chance level (33%; $p = 0.04$). However, it was possible to decode identity for particular view and posture combinations (accuracy ranging between 57 and 95%; chance = 33%). Second, we asked how tolerant the decoding of one variable is for changes of the other variables by training e.g. viewpoint decoding at one particular identity and posture and testing at the same and other combinations of the latter two variables. This analysis revealed little generalization of posture and identity decoding with viewpoint, in line with the viewpoint selectivity of midSTS body patch neurons. Posture and viewpoint decoding generalized well across identities. Analysis of the viewpoint-dependent errors in pose decoding suggested a representation of head orientation. Viewpoint decoding generalized across the threat postures but not across the others. These data suggest that the output of midSTS body patch neurons are useful to decode the posture and orientation of bodies, with a contribution of head orientation.

Title: macaque face patch AM codes linear axes rather than exemplars in the face space

Authors: *L. CHANG[1], D. TSAO[2];
[1]Div. of Biol., [2]CALIFORNIA INSTITUTE OF TECHNOLOGY, Pasadena, CA

Abstract: One central question about sensory systems is how sensory stimuli are represented by sensory neurons. Different approaches have been employed to study this question in lower sensory areas like retina and V1, but have not been successfully applied to higher areas due to

the complexity of computation. The use of natural images like animal or human faces has been successful in characterizing basic properties of higher level visual neurons. However, the difficulty in parameterizing natural images precludes a detailed characterization of these higher level neurons. To explore the full geometry of higher level sensory neurons in the stimulus space, we recorded responses of cells in face patches ML/MF and AM to a large set of realistic faces generated using an "active appearance" model that allowed us to link each image to a point in a 50 dimensional face space. This model separates the shape of the face, determined by the positions of a set of landmarks, from the intensity variation independent of the shape, i.e., shape-free appearance features. Principle component analysis was performed to extract the top 25 shape and the top 25 shape-free appearance dimensions from 200 real faces in FEI face database. Facial images were randomly drawn from the 50-d face space. To quantify tuning to these 50 dimensions, responses of each neuron were used to calculate a "spike-triggered average" (STA) stimulus, i.e., the average stimulus that triggers the neuron to fire. We found that middle face patch neurons were better tuned to shape features, while AM neurons were better tuned to shape-free appearance features. Furthermore, we found face cells were tuned along the "STA" axis in a ramp-like manner, with extreme responses occurring at extreme feature values. To distinguish between a model measuring the "distance" to an exemplar face and a linear model measuring projection along an axis in the space, we inspected tuning of AM neurons along axes orthogonal to "STA". Interestingly, we found AM neurons show nearly no tuning along the orthogonal axes. Furthermore, responses of face cells could be fitted by linear combination of 50-d features rather well (R^2=58±14%), much higher than models using exemplars. Linear tuning of AM neurons in the face space seems to be inconsistent with previous studies advocating the use of nonlinear mixing in representing complex cognition tasks[1]. Using computational modeling, we found that a linear model is more efficient and robust to noise than a nonlinear "exemplar" model in a face identification task, if the dimensionality of face space is high enough (≥10). 1 Rigotti, M. *et al.* The importance of mixed selectivity in complex cognitive tasks. *Nature* **497**, 585-590 (2013).

Title: A hierarchical probabilistic model of natural face and non-face images explains selectivity and tuning properties of macaque face processing neurons

Authors: *H. HOSOYA[1], A. HYVÄRINEN[2];
[1]ATR Inst., Kyoto, Japan; [2]Univ. of Helsinki, Helsinki, Finland

Abstract: Faces may be the socially most important visual stimuli for primates. Recent macaque studies in the inferotemporal (IT) cortex identified several clusters of neurons specific to face processing and revealed various tuning properties regarding facial features. In this study, to shed light into the theoretical principles underlying such facial coding, we investigate a probabilistic model of naturalistic face and non-face images. Specifically, we constructed a hierarchical neural network model that starts with a simple fixed Gabor-analysis stage (which crudely approximates computation from V1 to V4) and proceeds to a mixture of two sparse-coding submodels, a "face submodel" and an "object submodel". The two submodels were each trained with face or non-face object images, after which, as expected, the internal representations in the face submodel looked like facial parts while those in the object submodel looked like object parts. The model neurons in the face submodel exhibited significant selectivity to face images compared to non-face images. This was due to the property of the mixture model that one submodel explains away an input image that is likely to belong to its class so that the other submodel needs no activity. Such selectivity could not be obtained from a sparse coding model trained only with face images. To further clarify how close the face-selective units are to the actual face-selective neurons, we simulated an experiment conducted by Freiwald and Tsao (2009) on the middle patch of face processing in macaque IT cortex. To this end, we input cartoon faces to the model network, while varying 19 parameters controlling the geometric layout of facial features (e.g., face aspect ratio, inter-eye distance, mouth size). The model units most often showed monotonic tuning to such parameters, responding maximally to one extreme parameter value and minimally to the other extreme, which is similar to the experimental results. Moreover, the average number of tuned dimensions per unit was around 3 and the tuned dimensions were most often related to face outline and hair; these were also consistent with the macaque experiment. Taken together, our results indicate that the coding strategy of facial geometric layout employed by the middle patch of face processing in macaque IT may be closely related to the sparse coding principle.

Title: Distinct tuning for scene content across macaque face patches revealed through single-unit and fMRI responses to social movies

Authors: *N. PERWEZ, B. E. RUSS, D. A. LEOPOLD;
Cognitive Neurophysiol. and Imaging, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: A growing body of work has shown naturalistic videos, together with free viewing, can be used to probe aspects of visual processing that cannot easily be studied using more conventional flashed static images or short dynamic clips. For example, in simply measuring the consistency in the responses of a neuron or cortical area to repeated viewing of complex dynamic scene, one can assess its involvement in processing the information contained therein. Here we applied such an inter-viewing method to investigate the extent to which regions of the macaque face processing system depend on the presence of faces and bodies. We designed two types of five-minute movies, one replete with primate social content and one containing dynamic scenes of storms and natural disasters, but devoid of animals. We showed these movies to seven macaques. In three animals, viewings were conducted during whole-brain fMRI scanning. In five animals (including one who participated in the fMRI study) neural activity was recorded in the middle lateral (ML), anterior fundus (AF), or anterior medial (AM) face patches using chronic microwire electrode bundles. The fMRI results demonstrate that the majority of the ventral visual stream, including the face patches, in the three animals responded consistently across viewings, regardless of whether animals were present in the videos. A bilateral region, that was overlapping the middle face patch, did not to show significant inter-viewing correlations during viewing of the non-social movies, indicating that activity in these areas is contingent on social stimuli. To better understand how neurons in this region and complementary face patches were responding to the movie content, we implanted microwire bundles in 3 of the face patches in the anterior temporal lobe. Similar to the results of the fMRI, single-unit responses differed across the three face patch regions. ML face patch neurons responded more consistently to the movies that contained animals, whereas AF and AM neurons responded with similar consistency to the two movie types. These preliminary results demonstrate a fundamental difference in the nature of selectivity in different fMRI-defined face patch, and illustrate the complementary information offered by free-viewing naturalistic paradigms in efforts to understand the neural mechanisms of high-level visual processing.

Center, Shiraz Univ. of Med. Sci., Shiraz, Iran, Islamic Republic of

Abstract: Despite a large number of neuroimaging work, it remains to be determined to what extent the power and time of onset of activity within the category-specific populations of neurons in the human ventral temporal cortex (VTC) are varied in response to non-preferred stimuli or different sub-categories of the preferred stimuli. We recorded intracranial ECoG signals from epilepsy patients implanted with subdural electrodes over their VTC while they viewed different categories of faces (e.g., human, mammal, and bird faces) and many other non-face categories. Here, we present a comprehensive map of the profile of neuronal population activities across many sub-regions of the human VTC in response to various categories and sub-categories of visual stimuli.

Title: From agents to actions to interactions: Uncovering multiple social networks in the primate brain

Authors: *J. SLIWA, W. A. FREIWALD;
The Rockefeller Univ., New York, NY

Abstract: Our brain continuously decodes the complex visual scenes unwinding in front of us: both the nature of material entities we perceive, such as objects and individuals, and their immaterial interactions. Interactions are recognize quickly and effortlessly by primates: They understand fights, grooming and plays, but also colliding objects that exchange forces following physical laws of classical mechanics. Interactions are fundamental in that they reveal hidden properties of objects, e.g. their weight or material, and of individuals, e.g. their dominance status or relationship, and by doing so they determine and teach the observer about its own position and prospects regarding those entities. However little is known about the brain regions that track and process social and physical interactions. In order to chart these regions, videos of three types of interactions 1) social interactions between monkeys, 2) interactions between monkeys and objects or their environment and 3) physical interactions between objects, were projected to four rhesus monkeys being scanned for fMRI acquisition with contrast agent. Whole-brain activity for watching blocks of interactions was compared to the activity for watching control videos of monkeys making no actions, objects moving with no interactions, landscapes and scrambled motion videos using Fixed Effects (FFX) Generalized Linear Model (GLM) group analysis and conjunction analyses. We show that watching interactions over-activates the STS, but engages also two sets of regions located outside: 1) it activates the fronto-parietal mirror neuron system (mapped independently using a classic localizer) more than watching non-interactive goal directed behaviors that define the system; 2) in the case of social interactions, it additionally exclusively activates the medial-prefrontal cortex (mPFC), a putative temporo-parietal junction homolog and the temporal pole (TP) that appear to correspond to the human mentalizing network. These two networks are fed differentially by patches of STS cortex (mapped independently using a classic Face-Object-Body patch localizer): face patches co-activate with the social brain, while body patches co-activate with both the mirror neuron system and the social brain. These results demonstrate that combining individuals or objects into evocative units

modulates basic mechanisms of object and individual perception in the STS, they reveal the mirror neuron system's nature of node of convergence between the social and non-social brain, and suggest that human unique and sophisticated mind-reading ability evolved from the faculty shared with our monkey kin to read social interactions.

Title: Multiplex representation of information in face responsive neurons of monkey area TE

Authors: *H. ICHIKAWA[1], Y. IGARASHI[2], Y. MASUTANI[2], K. KAWANO[3], M. OKADA[2], Y. SUGASE-MIYAMOTO[4];
[1]Tokyo Univ. of Sci., Noda, Japan; [2]The Univ. of Tokyo, Kashiwa, Japan; [3]Kyoto Univ., Kyoto, Japan; [4]Natl. Inst. of Advanced Industrial Sci. and Technol., Tsukuba, Japan

Abstract: Neurons in the temporal visual cortex are known to be responsive to faces. We previously reported that face-responsive neurons in monkey area TE represent information about a global category, namely human faces vs. monkey faces, earlier than information about more detailed categories about the faces, i.e. facial expression and/or identity. To investigate how the information about the global category and that about the fine categories (facial identity and expression) were represented by each single neuron, we analyzed activities of 119 face-responsive neurons in area TE of two rhesus monkeys (*Macaca mulatta*), performing a fixation task. The test stimuli were colored pictures of monkey faces (4 models with 4 expressions) and human faces (3 models with 4 expressions). Each stimulus was presented for 400 ms. The number of spikes was counted in a 50-ms time window slid by 50 ms from 50 ms to 500 ms after the stimulus onset. To determine activity dependent on the global category, one-way ANOVA

(factor = human vs. monkey) was applied to the spike counts in each time window for each neuron. To determine activity dependent on the fine category in the human faces and that in the monkey faces, two-way ANOVAs (factors = identity and expression) were applied. Sixty-four of the 119 neurons (53%) showed significant dependence on both the global and fine categories. Fifty-three of the 64 (82%) showed significant dependence on the global category simultaneously or earlier than the effect of the fine category. The distribution of the timing of the earliest time window of the global category effect was significantly earlier than that of the fine category effect (Wilcoxon signed rank test, p=0.004), replicating the results of our previous studies. Eighty-five of the 119 neurons showed significant dependence on the fine category; 37 and 25 neurons showed dependence exclusively on the monkey faces and on the human faces, respectively, while the remaining 23 neurons showed dependence both on the monkey and human faces. Of the 37 neurons showing the fine category dependence only on the monkey faces, more than half the neurons (23/37, 62%) had dependence on the expression, but the dependence was frequently observed (13/23) together with the identity and/or interaction between them. Similarly, of the 25 neurons with the fine category dependence only on the human faces, most of them (22/25, 88%) showed dependence on the identity, but the dependence was frequently observed (12/22) together with the expression and/or interaction between them. These results suggest that different types of the fine information, even across different global category members, are multiplexed in single neurons.

Title: Enhansive and suppressive face neurons form two distinct physiological networks for course and fine face representations in inferotemopral cortex

Authors: S. SALEHI[1,2], M.-R. A.DEHAQANI[2], *H. ESTEKY[2,3];
[1]Shiraz Neurosci. Res. Center, Shiraz Univ. of Med. Sci., Shiraz, Iran, Islamic Republic of; [2]IPM Sch. of Cognitive Sci., Tehran, Iran, Islamic Republic of; [3]Brain and Cognition, Shaheed Beheshti Med. Sci. Univ., Tehran, Iran, Islamic Republic of

Abstract: A network of clusters of face selective neurons in the inferior temporal (IT) cortex of monkeys has been found mostly by studying the excitatory responses to face stimuli. But the

spiking activities of a relatively large proportion of neurons in IT are suppressed following presentation of faces. Most of these neurons are located outside the face clusters. Contribution of these suppressive neurons in face representation is not clear. We recorded the spiking activities of single neurons in the inferior temporal cortex of two macaque monkeys while they passively viewed face and non-face images and compared the contribution of enhanced (ENH) and suppressed (SUP) face selective neurons in face representation. Fifty-six of 176 neurons selectively responded to faces by either increasing or decreasing their spiking activities compared to their baseline. The neural code for fine and coarse face information was largely different between the ENH and SUP face selective neurons at single cell and population levels. Compared to ENH neurons, SUP neurons showed higher (lower) sparseness values for highly similar individual faces (face category). Pattern of activity in the SUP neural population discriminated highly similar face images better than ENH face neural populations. But ENH neural population discriminated faces from non-face objects better than SUP neural population. Our data show that ENH and SUP neurons form two distinct physiological neural networks in IT cortex with widely different coding properties: a course-scale (ENH neurons) and a fine-scale (SUP neurons) system. These face processing functional subunits may index fine-to-course shape similarity in parallel depending on task at hand.

Title: A face-selective ventral occipito-temporal map of the human brain with intracerebral potentials

Authors: *J. JONAS[1,2], C. JACQUES[1], L. MAILLARD[2], B. ROSSION[1];
[1]Catholic Univ. of Louvain, Louvain-la-Neuve, Belgium; [2]Neurol. Unit, Univ. Hosp. of Nancy, Nancy, France

Abstract: Human neuroimaging studies have identified a network of distinct face-selective regions in the ventral occipito-temporal cortex (VOTC) with a right dominance. To date, there is no evidence for this hemispheric and regional specialization with direct neural measures. To address this issue we recorded neurophysiological activity from 1678 contact electrodes

implanted in the VOTC of 28 epileptic patients. They were presented with natural images of objects at a rapid fixed rate (6 Hz), with faces interleaved as every 5th stimulus (1.2 Hz, Fig. 1A). High signal-to-noise ratio face-selective responses were objectively identified and quantified (at 1.2 Hz and harmonics) throughout the whole VOTC (Figure 1B). Face-selective responses were widely distributed across the whole VOTC (Fig. 1B-2A), but also spatially clustered in specific regions (Fig. 2B). Among these regions, the right lateral fusiform gyrus (latFG) showed the largest face-selective response by far (quantification analysis in Fig. 1C), offering the first supporting evidence of 2 decades of neuroimaging observations with direct measures. In addition, 3 distinct face-selective regions were disclosed in the anterior temporal lobe (Fig. 1B), a region that is undersampled in neuroimaging due to artefacts. Contacts responding only to faces were found in these regions, suggesting that they are involved in dedicated face processing functions. These observations provide a comprehensive mapping of visual category-selectivity in the human VOTC.

Title: How distributed is the face selective information in the temporal cortex: an ECoG study

Authors: *J. V. SCHROUFF[1,2], V. RANGARAJAN[3], J. PARVIZI[1];
[1]Lab. of Behavioral and Cognitive Neurosci., Stanford Univ., Palo Alto, CA; [2]Dept. of Computer Sci., Univ. Col. London, London, United Kingdom; [3]Dept. of Psychology, Univ. of California, Berkeley, CA

Abstract: Introduction Previous fMRI studies have shown that face processing is distributed over the ventral temporal cortex (VTC). In Haxby et al., 2001, it is further suggested that after removing highly face selective areas (determined by a univariate analysis), combining the remaining signals allows significant discrimination between faces and non-face stimuli using a multivariate approach. In our current study, we performed a similar analysis using electrocorticographic (ECoG) signals recorded from grids and strips of electrodes covering the human VTC surface. **Material and Methods** ECoG data were obtained from 6 subjects with refractory epilepsy implanted with electrodes as part of their clinical assessment. Three patients had electrodes implanted on the left and three on the right hemisphere. Patients performed two experimentally controlled tasks involving the presentation of images of faces and of non-faces (places, limbs, objects, words, numbers, false fonts). The data from the first task was used to detect 'face-selective' VTC channels based on a locally multivariate analysis of the power of the signal epoched between 0 and 350ms after onset in the high frequency broadband (HFB, 70 to 177Hz). The data from the second task was then analyzed to discriminate between faces and non-face epochs based on (i) all VTC channels, (ii) all VTC channels except the 'face-selective' channels from task 1 after FDR correction, (iii) all VTC channels except the 'face-selective' channels from task 1 without FDR correction ($p<0.05$) and (iv) the 'face-selective' channel with the highest selectivity score. **Results** The number of channels identified as 'face-selective' in the first task varied from subject to subject: S1: 2 with FDR correction (5, without correction), S2: 4 (8), S3: 5 (11), S4: 0 (5), S5: 1 (4), S6: 11 (13). Discriminating between faces and non-faces epochs in the second task led to significant classification (balanced accuracies ranged from 68.76 to 96.67%) for all subjects (i). However, when discarding the 'face-selective' channels, the discrimination reached chance level accuracy for 4 out of 6 subjects (ii) and 5 out of 6 (iii). This decrease in performance cannot be attributed to a loss of multivariate power, as only one 'face-

selective' channel (iv) led to significant detection of face processing. Therefore, the considered ECoG data suggests that face information present in 'face-selective' channels is sufficient and necessary for the modeling of face processing in the VTC.

Title: Do rhesus macaques show the same visual preference for average faces as humans?

Authors: *O. TOMEO, L. G. UNGERLEIDER, N. LIU;
Lab. of Brain and Cognition, NIMH, Bethesda, MD

Abstract: In humans, facial attractiveness is a long-standing topic of active study in both neuroscience and social science, motivated by its positive social consequences. Non-human primates share similar social behaviors related to face processing and their underlying neural mechanisms with humans. For example, like humans, non-human primates can read information from conspecific faces about another's identity, mental state, and emotional state. However, it is unclear in non-human primates whether faces might also play a role in attraction as in humans and, if so, what kind of facial characteristics make a face preferred. To address these questions, we investigated the effect of averageness, a well-accepted factor that influences judgments of facial attractiveness in humans, on face preferences in monkeys. We tested three adult male rhesus macaques using a visual paired comparison task design in which they viewed pairs of faces (both individual faces, or one individual face and one average face). We found that monkeys looked longer at certain individual faces than other individual faces. However, unlike humans, monkeys did not prefer the average face over individual faces. Interestingly, looking times to individual faces reflected the norm-based face space, in which faces are encoded by their deviation from the average face: the more the individual face differed from the average face, the longer the monkeys looked at it. Taken together, our study provides new information about visual preferences for facial characteristics and behavioral evidence for the norm-based face space theory in monkeys.

Title: Parallel effects of adaptation and distinctiveness on neural responses to faces

Authors: *O. S. GWINN, S. F. O'NEIL, M. A. WEBSTER;
Psychology, Univ. of Nevada, Reno, Reno, NV

Abstract: Current models of face processing postulate a norm-based code in which individual faces are represented according to how they differ from an average face or norm. However, evidence for this model remains contested. We compared neural responses to an “average” vs. “distinctive” face and how these responses are biased by prior adaptation to the faces. An average female face was distorted by local expansion or contraction to create variations in distinctiveness while retaining common low-level image properties. Subjects passively viewed a rapid alternation between faces shown on a CRT monitor while electrophysiological responses were recorded with a 128-channel BIOSEMI system and analyzed in the frequency domain. In the first condition, 20 s sequences of faces alternated sinusoidally through contrast modulation between -50% contraction and +50% expansion at a rate of 6 Hz. In the second condition, the faces instead alternated between +100% expansion and the original undistorted face (0%). Responses to the +50/-50 alternation occurred only at the stimulation frequency of 6 Hz, indicating that responses to each distortion were equal. In contrast, the 0/100 alternation produced responses at both 3 Hz and 6 Hz, indicating different response amplitudes for the two faces, and consistent with a weaker response to the average face. Both conditions were repeated after 20 s adaptation to one of the face pairs. Adapting to either the +50% or -50% distortion produced a response at 3 Hz where before it was absent, consistent with a loss in sensitivity to the adapting distortion. Adapting to the 0% undistorted face increased the 3 Hz signal, such that the response to the average face was reduced. Adaptation to 100% distortion decreased the 3 Hz signal, such that the response to the average face was increased. This pattern is consistent with previous single-cell and fMRI studies suggesting weaker neural responses to average faces, and with EEG studies showing neural correlates of face adaptation. The present results further implicate a norm-based code by showing that variations in distinctiveness and adaptation have functionally similar effects on sensitivity (as measured by the evoked responses) to the faces.

Title: Asymmetric neural responses for expressions, anti-expressions, and neutral faces

Authors: ***C. MATERA**, O. GWINN, S. O'NEIL, M. WEBSTER;
Univ. of Nevada-Reno, Reno, NV

Abstract: Face recognition requires identifying both the invariant characteristics that distinguish one individual from another and the variations within the individual that correspond to emotional expressions. Both have been postulated to be represented with a norm-based code in which identity or expression are represented by the deviation from an average or neutral prototype. Different neural circuits have been characterized for different expressions, but it remains unclear how the encoding supporting the extraction of expression information maps onto the encoding supporting shape information and identity. We compared neural responses for expressions and anti-expressions, which are created by projecting an expression (e.g. a happy face) through the neutral face to form the opposite facial shape (anti-happy). The two faces thus differ from the norm by the same "physical" amount and thus have equivalent but opposite status with regard to their shape, but differ in their emotional salience. We asked whether neural responses to these complementary stimulus pairs were equivalent or asymmetric, and also tested for norm-based coding by comparing whether stronger responses are elicited by expressions than neutral faces. Stimuli were computer-generated facial images displaying the expressions 'happy', 'angry' or 'surprised' created using the program FaceGen, or photo-realistic images of actual individuals displaying the same expressions taken from the RADBOUD face database. Anti-expressions in the FaceGen images were controlled by inverting the sign of the expression magnitude, with the identity selected for an average male or female exemplar. Electrophysiological responses were measured for 7 observers with a 128 channel BIOSEMI system while observers passively viewed 30 sec of 6 Hz alternations of two facial images between each expression and its anti-expression or neutral face. Using a Fast Fourier Transform (FFT), recordings were analyzed in the frequency domain. A 3 Hz response was observed for all conditions except expression vs. neutral

for the FaceGen stimuli. This response was stronger in parietal-occipital regions and suggests an asymmetry between both expressions and anti-expressions and expressions vs. neutral (for photographic faces). An asymmetric response also occurred for male vs. female neutral faces but was stronger in occipital regions (possibly reflecting low-level image differences). Our results are consistent with a norm-based code for expressions but suggest stronger neural engagement for configurations denoting recognizable expressions.

Title: How the human brain recognizes text-based emoticons.

Authors: *K.-W. KIM[1,2], B. JEONG[2], D. SHIN[2];
[1]Samsung Med. Ctr., Seoul, Korea, Republic of; [2]Grad. Sch. of Med. Sci. and Engin., Korean Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Introduction: An emoticon is a graphic of a facial expression that provides a sender's intention or emotion to a receiver in the absence of non-verbal communication such as body language and prosody. However, the question of how the human brain recognizes emoticons wasn't fully understood. Materials and Methods: Forty healthy volunteers (19 female age: mean ± s.d. =24.03 ± 3.28years) participated in the experiment. *fMRI and MEG experimental design:* Event-related design tasks consisted of 6 conditions: happy emoticons, happy faces, sademoticons, sad faces, scrambled emoticons, and neutral faces. *fMRI analysis:* First- and second-level analyses were performed with FSL'sFEAT. *MEG analysis:* Three distinct components were found in grand mean global field power (GFP) data corresponding to the M100, M170 and EPN to both text-based emoticons and face expressions. Then source analyses were performed on the three MEG components. Source reconstruction was implemented in the MATLAB package Brainstorm (Tadel et al., 2011). Results: *fMRI:* Two-way ANOVA was conducted with type of stimuli (emoticons, faces) and emotional valence (happy,sad, and neutral). Significant main effects of stimuli were found in the conjoined area, lateral occipital gyrus (LOC) and superior parietal lobule(SPL), the V1, the lingual gyrus, bilaterally, the left inferior temporal gyrus, the right ventromedial prefrontal cortex (VMPFC), and the right fusiform gyrus. Significant main effects of emotional valence were found in the inferior frontal gyrus (IFG), the paracingulate gyrus, bilaterally, the left orbitofrontal gyrus, and the left AIC.

MEG: Overall activity illustrated that the first source activity was estimated to the primary visual cortex at around 80ms (M100) after stimulus onset. This source disseminated anteriorly along the inferior occipito-temporal area, predominantly right side peaking at around 140ms (M170), and further onto the parietal regions at around 220ms (EPN). Time-courses extracted from source maps of the emoticons vs. faces differences also showed a dynamic pattern of activity.
Discussion: This study provided a text-based emoticon perception model. The input stimuli were processed first at around 80ms in the primary visual cortex as indexed by M100. Then face-specific appearances were processed in the FFA at around 150ms (M170) especially on the right.

Title: Task-dependent representations in visual cortex during face perception

Authors: *H. KIM, S.-H. LEE;
KAIST, Daejeon, Korea, Republic of

Abstract: When we see human faces, we can quickly and accurately recognize various information such as gender and race. Yet, despite the quick holistic processing in face perception, some aspects of the face are often emphasized whereas other aspects are not, depending on behavioral goal. Then, how is face information represented in the visual cortex when different aspects are emphasized? To address this question, we performed functional magnetic resonance imaging (fMRI) experiment, comprising two face tasks emphasizing either gender or race of the faces. In the gender task, participants were asked to decide whether the gender of the sample face image is the same with that of the test face image, whereas in the race task, they had to determine whether the sample face and the test face are from the same race category. We first found that there was no significant difference in behavioral performance

between the tasks. They showed comparable level of percent correct and reaction time for both tasks. Also we found that there was no difference in the BOLD response magnitude between the tasks. However, using multi-voxel pattern analyses, we found that anterior face-selective areas showed significantly discriminable patterns of response to individual faces during the gender task whereas the areas did not show the specific patterns during the race task. These results suggest that the distinctiveness of face representations in visual cortex is dependent on the nature of the task.

Title: Temporal dynamics of neural process relevant to intended percept of a face: An ERP study

Authors: *H. URATA, T. URAKAWA, K. MIZUNO, O. ARAKI;
Tokyo Univ. of Sci., Tokyo, Japan

Abstract: Face perception is indispensable for our lives. A number of previous EEG studies investigated early face-specific visual processing and reported an ERP component (N170) peaking at around 170 ms after the face image's onset. Since most of these studies employed experimental paradigms in which participants passively viewed face images, it remains largely unclear whether and how intention to perceive a face (a top-down process) would modulate early visual processing. We hypothesized that the top-down process for a face percept compared to that for other percepts would peculiarly affect the early visual processing, and tried to clarify this issue using morphed (ambiguous) face images. Seven healthy subjects participated in the present study. We made two morphed images using two unambiguous images (face and house). One of the morphed images was more perceived as a face (F) than a house (H), and the other was more perceived as H than F (these image were set based on a preceding behavioral experiment). The mean luminance was set identical for the two morphed images. There were two conditions: the intention to face (IF) condition in which participants were asked to perceive a face and the intention to house (IH) condition in which they were asked to perceived a house. In these

conditions, two morphed images were randomly presented. Results showed that the N170 was more enhanced in amplitude for the IF condition than for the IH condition. This response enhancement was comparable between F and H. As for a preceding VEP component P1, there was no such significant difference. These findings indicate that the top-down process for a face percept begins to appear at a latency of around 170 ms, and that the response enhancement in the IF condition compared to the IH condition reflects emergence of the top-down-mediated face-specific N170 component regardless of the difficulty to perceive a face. Furthermore, amplitude of the late positive component (LPC) under the IF condition was more augmented for H than for F at a latency of around 350-550 ms. In contrast, LPC amplitude under the IH condition was larger for F than for H. These findings imply that enhancement of LPC amplitude reflects the perceptual difficulty/conflict. The preset study suggests a temporal profile of top-down-mediated visual process of a face: the top-down process for a face percept would be implemented as early as around 170 ms regardless of the difficulty to perceive a face, and then the difficulty-dependent process would appear at around 350-550 ms.

Title: The ventral and dorsal visual pathways are functionally connected during configural face processing.

Authors: *V. ZACHARIOU[1], S. J. GOTTS[2], Z. N. SAFIULLAH[2], L. G. UNGERLEIDER[2]; [1]LBC:Section on Neurocircuitry, [2]LBC, NIH/NIMH, Bethesda, MD

Abstract: Configural face processing, the processing of the spatial relationships among the features of a face, is a vital component of face perception. If configural processing depends on spatial information, might this process involve interactions between the face-processing regions of the ventral stream and visuospatial processing regions of the dorsal stream? We explored this question in healthy adults by examining the pattern of functional connectivity between the right FFA as a seed (individually defined) and the rest of the brain in a same-different face detection task. Detection of configural relative to featural face differences led to significantly stronger functional connectivity between the right FFA and a-priori localized spatial processing regions of

the dorsal stream. In contrast, detection of featural relative to configural face differences led to stronger functional connectivity between the right FFA and other face-processing regions of the ventral stream, such as the right OFA and left FFA, as well as with the insula bilaterally. Further, these connectivity patterns correlated with reaction time performance: participants that responded slower on configural difference trials showed stronger functional connectivity between the right FFA, the left FFA and OFA and a-priori localized spatial processing regions of the dorsal stream, particularly within the left posterior parietal cortex. Conversely, participants that responded slower on featural difference trials showed stronger functional connectivity between the right FFA and anterior regions of the right inferior temporal gyrus, left insula and bilateral inferior frontal gyrus. Together, the findings suggest that the right FFA interacts with spatial processing regions of the dorsal stream during configural face processing and with face-processing regions of the ventral stream during featural face processing. Additionally, the extent of these interactions appears to depend on task demands.

Title: How children and adults represent individual faces despite image variation - an fMRI adaptation study

Authors: *M. NORDT, K. SEMMELMANN, S. WEIGELT;
Dept. of Developmental Neuropsychology, Ruhr-University Bochum, Bochum, Germany

Abstract: Behavioral studies suggest that face recognition performance reaches its peak not until age 30. However, it is not yet fully understood which aspects of face recognition contribute to this prolonged development. A crucial facet of face recognition in daily life is the ability to recognize faces despite changes, such as varying viewpoints or changes in lighting. In the present study, we investigated the development of the individual-level selectivity of face-selective regions in children (aged 7-10 years) and young adults (aged 19-23 years) by using fMRI adaptation and by including multiple varying images of individual faces. Participants watched blocks of images while performing a simple detection task. There were three main conditions

including (1) the repeated presentation of a single image of one face, (2) the presentation of images of different faces and crucially, (3) the presentation of the same face in different images. In this third condition images contained slight variations of different factors such as lighting, viewpoint and facial expression. Preliminary analyses of the right FFA—defined based on adults' data of a functional localizer—revealed a main effect of condition with the highest signal in the different-faces condition, reduced signal for the same-face-different-images condition and lowest signal for the same-face-same-image condition, thereby indicating adaptation to same faces - even when presented in different images. Furthermore, results showed a main effect of group with higher signal for adults compared to children. Although numerically, the same-face-different-image-conditon was more strongly reduced for adults than for children, there was no significant group x condition interaction, indicating similar adaptation effects between groups and suggesting that individual-level selectivity for faces in the rFFA is similar in school-aged children and young adults.

Title: Behavioral and neural mechanisms underlying visual expertise in Congenital Prosopagnosia

Authors: ***N. WEISS**[1], G. AVIDAN[2];
[1]Psychology, Ben-Gurion Univ., Beer-Sheva, Israel; [2]Psychology, Ben Gurion Univ., Beer-Sheva, Israel

Abstract: Background: A major question in the face perception literature is whether faces comprise a distinct visual category that is processed by specialized cognitive and neural mechanisms, or whether face processing merely represents an extreme case of visual expertise. Methods: We address this issue by studying two women (O.H and S.I) with congenital prosopagnosia, a lifelong impairment in face perception in the absence of an obvious brain damage. Interestingly, despite their deficit, O.H reported having superior recognition skills for horses, and S.I reported excellent visual familiarity with flowers. These unusual circumstances in which visual expertise naturally emerges despite face perception impairment allow us to

disentangle neural mechanisms mediating visual expertise and in particular, to examine the extent of the modularity of core face related regions. We first conducted behavioural experiments to examine whether these objects of expertise are processed holistically, as previously claimed in the literature. We then employed fMRI to investigate the implications of expertise on neural responses to faces, horses and flowers. Results: Both CP experts employed similar behavioural and neural mechanisms for faces and objects of visual expertise. Specifically, they used local perceptual mechanism for processing faces and objects of expertise and exhibited similar enhanced fMRI BOLD response in right lateralized face-selective brain regions for faces and objects of expertise. Importantly, this pattern was dissociated from the response in control participants, experts and non-experts, in whom faces were processed holistically and elicited a greater response compared to horses/flowers within the same regions. Conclusions: These results suggest that visual expertise can be acquired despite impaired face perception mechanisms, and may be mediated by non holistic processing stratgeis and yet recruit right lateralized core face-selective regions.

Inst. of Hlth., Bethesda, DC; [6]Pediatrics, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Patterns of functional (re)organization in patients with hemispherectomy/lobectomy offer a unique opportunity to elucidate the nature and extent of cortical plasticity. First, in contrast with more common lesions, the extent of the damage in such patients can be extreme, yet, at the same time, very well controlled - both cortical and subcortical structures of the remaining hemisphere are typically intact. Second, the extent of the recovery is often

disproportionate relative to the extent of the damage - many compromised functions are regained partly or even completely. Here, we used fMRI to explore changes in the topography of cortical category selectivity and visual field maps (VFMs) in a 15-year-old, OT, who had a resection of the entire left anterior temporal lobe (ATL, see Figure 1A) due to medically intractable epilepsy. We also assessed the consequences of this resection for visual function using behavioral tasks targeting intermediate and high level vision. OT was impaired at face recognition (prosopagnosia) post-surgically but evinced equivalent IQ scores pre- and post-surgery in the high average range. fMRI scanning revealed normal topography and magnitude of selectivity in high-level visual cortex in response to common visual categories (face, places, object, and word). Also, imaging uncovered typical bilateral VFMs in early visual areas (V1-V3) of both hemispheres using a meridian mapping task. However, abnormalities in population receptive field (pRF) properties of the left hemisphere VO2 (Figure 1B) were observed using the pRF analysis. Further analyses address the mechanisms that potentially give rise to the abnormal VO2 properties, including the absence of top-down feedback from more anterior regions. Additional analysis and consideration of the prosopagnosia is also offered as well as functional connectivity measures within and between hemispheres. Figure 1. A) Pre- and post-surgical MRI. B) Ventral pRF maps in both hemispheres.

Title: Improved estimates of spike count covariance across populations of neurons

Authors: *G. VINCI[1], V. VENTURA[1], M. A. SMITH[2], R. E. KASS[1];
[1]Statistics, Carnegie Mellon Univ., Pittsburgh, PA; [2]Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Neural recordings in large populations of simultaneously-recorded cells offer an opportunity to identify network interactions that vary across experimental conditions or behaviors. Statistical assessments of network interactions typically begin with a set of spike count variances and covariances (or correlations). For a small number of neurons these quantities, computed from data, have good statistical properties, but as the number increases a fundamental difficulty emerges: for N neurons there are on the order of N-squared variances and covariances, and as the dimensionality gets large it is hard to get good estimates of all them, together. Standard solutions to this problem involve some kind of "regularization," in which the variance-covariance matrix is stabilized somehow. A leading approach, known as Graphical Lasso, assumes sparse functional connectivity in the sense that the number of nonzero partial correlations—representing functional connections—is small; it effectively sets the smallest partial correlations to zero and "shrinks" the larger ones toward zero. This off-the-shelf method has two defects: first, functional connections may not be sparse; second, the Graphical Lasso takes no account of known neurophysiology. We introduce an alternative statistical procedure that takes advantage of a ubiquitous phenomenon: neurons that are close together tend to have correlated spiking activity. This new procedure identifies network structure by putting a soft constraint on correlations so that they tend to respect their known decreasing relationship with distance (and increase with tuning curve correlation), and it controls the false discovery rate. We have studied this new method and shown in numerical simulations that it can find true functional connections much more effectively than Graphical Lasso. We applied it to data recorded from

96-electrode Utah arrays in primary visual cortex (V1) of anesthetized macaque monkeys, where we had knowledge of the tuning curves and spatial arrangement of neurons. This work shows how knowledge of the biological factors that constrain correlated variability can be used to provide improved evidence of functional connectivity in populations of neurons.

Title: Attention modulates specific subnetworks in mouse primary visual cortex

Authors: *A. M. WILSON, A. YAN, L. L. GLICKFELD;
Duke Univ., Durham, NC

Abstract: Goal-directed attention allows for the prioritization of behaviorally-relevant sensory information and has been shown to improve both perceptual sensitivity and encoding of attended stimuli in sensory cortex. These attention-dependent changes in encoding differ according to the relationship of the neurons' tuning to the goals of the task, suggesting that perceptual changes are due to selective changes in the activity of functional subgroups of sensory cortical neurons. To determine if attention modulates specific subnetworks we monitored the activity of the diverse population of neurons in the primary visual cortex (V1) of mice performing a modality-specific, goal-directed attention task. In this task, head-fixed mice were cued on a trial-by-trial basis to switch between detecting changes in the orientation of a visual stimulus or the volume of an auditory stimulus; notably, visual stimuli before the change were symmetrical across trial types. We then tested the perceptual effect of attention by presenting rare, invalidly cued trials in which the mice were rewarded if they detected a change in the uncued modality. Mice had a lower probability of detecting invalidly cued targets, demonstrating that the cue is sufficient to set the expectation of, and attention toward, changes in the cued modality. Additionally, mice were less likely to respond to invalid targets on longer trials, indicating that they maintain, or even increase, their goal-specific attention as the trial progresses. In order to investigate the rapid neuronal modulation that occurs during task performance we monitored neuronal activity in V1

using two-photon imaging of GCaMP6. We analyzed two distinct epochs during task performance: the responses to the baseline stimuli (during anticipation of the stimulus change) and to the target stimulus. We found that, on visual trials the average responses to the baseline stimuli were transiently suppressed while responses to the target were enhanced. Interestingly, both of these effects were driven more by neurons tuned to the target stimuli than to the baseline stimulus. This suggests that attentional modulation in V1 is specific to neurons that provide the most information about the visual change. Investigation into the local and long-range circuits these neurons belong to will further elucidate the relationship of primary sensory processing to perception and behavior.

Title: Neural correlates of selective visual spatial attention in the mouse visual cortex

Authors: ***E. MCBRIDE**, S.-Y. LEE, E. CALLAWAY;
Salk Inst., La Jolla, CA

Abstract: Attention focuses our limited perceptual resources toward relevant stimuli in a distracter-filled environment. Work in primate visual cortex has shown that selectively attending to a location in the visual field enhances neural responses, signal to noise ratio, and perceptual sensitivity to stimuli presented there and suppresses responses and sensitivity to stimuli elsewhere. However, due to methodological limitations in primates, the specific neural mechanisms and circuits that influence attention remain mostly unknown. A more detailed description of these circuits requires simultaneous recordings from large populations of neurons, direct manipulation of the activity of specific neuron types, and observation of associated behavioral changes. Genetic tools in the mouse for selective manipulation of circuit components make these experiments possible.
When a mouse runs, visually-evoked neural responses are enhanced, similar to the effect of

attention. The circuit mediating this effect has been shown to involve cholinergic projections from the basal forebrain. This is likely a global alertness state primarily due to locomotion-induced processes. No study yet has examined selective spatial attention in mice, likely mediated by projections encoding a decision to attend. To investigate how neural circuitry is affected by attention and mediates changes in neural responses, we designed a mouse attention task that enables presentation of systematically varying stimuli, allowing generation of tuning curves from recorded neurons under changing attention conditions. Mice are shown identical drifting grating stimuli on two screens, one positioned in front of each eye. These stimuli can change in direction or spatial frequency from trial to trial. After a random stimulus duration, the mouse must detect a small change in contrast that could occur on either side and lick within a short time window to receive a water reward. The contrast change occurs more often on one particular side, and mice perform better on trials when the more likely change occurs, suggesting that they are selectively attending to that side. We are currently performing electrophysiological recordings using high-density laminar electrode arrays in visual cortices of these mice, and are able to record many units in both hemispheres with known laminar locations, measure receptive field properties, and compare visual responses under attended and unattended conditions. Results from these experiments will inform our choice of which neuronal populations to target with optogenetics in order to probe the role of those populations in the control of attention.

Title: Detection-related activity in the primate superior colliculus supports action selection

Authors: *J. P. HERMAN, R. J. KRAUZLIS;
Lab. of Sensorimotor Res., NEI / NIH, Bethesda, MD

Abstract: The primate superior colliculus (SC) is known to be important for orienting. SC neuronal activity is related to overt orienting movements of the eyes and head, as well as to covert orienting of attention in the absence of eye movements. Here we provide evidence that SC's role is not limited to orienting but supports action selection in general by indicating the time and location of behaviorally relevant events. We recorded SC neuronal activity in two

rhesus macaques (n=80, 58) during a challenging covert attention task. The monkeys had to detect near-threshold changes in the saturation of two peripheral dynamic color "checkerboard" stimulus patches while maintaining central fixation. They were rewarded for reporting changes of the cued stimulus by releasing a joystick, and for ignoring changes of the spatially opposed foil stimulus by keeping the joystick held down. In addition to replicating cue-related modulation during the delay period, we found that difficult-to-detect changes in saturation caused vigorous phasic increases in activity in the majority of recorded units (76/80 and 56/58, respectively). The size of this detection-related activity was comparable to that found at stimulus or saccade onset but occurred in the absence of previously shown orienting effects (i.e., no saccades and after the shift in attention). When aligned on the stimulus change, we found that individual unit detection time (DT, the time at which increased activity became significant) followed shortly after the change (100-150ms). However, dividing activity into 3 quantiles by reaction time (RT) revealed a greater covariation between DT and RT when activity was aligned on the change than when aligned on the joystick-release; this indicates that the timing of detection-related activity is not determined by the stimulus change, but rather marks the animal's detection of the event. Furthermore, by comparing activity for hits and misses, we found mean choice-probabilities of 0.61 and 0.59 in the two animals, values greater than those reported in some sensory areas. Thus, in addition to its importance for orienting, neuronal activity in the primate SC appears to play a more general role in action selection by reporting when and where behaviorally relevant events occur.

Title: Flavoprotein-based functional optical imaging reveals the distribution of attentional modulations across the surface of primary visual cortex

Authors: *S. G. WARREN, G. M. GHOSE;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: In many visual attention tasks, a small population of neurons in the brain is well-matched to the attended stimulus. Potentially, attending to a small region of space might therefore involve the selective targeting of attention modulation to those neurons whose receptive fields include the attended area. Because electrophysiological techniques measure relatively small numbers of neurons, such techniques are poorly suited to measuring the distribution of attentional modulation across a population. Conversely, because of the relatively poor spatial resolution of fMRI, it is also unable to address this question. Thus the fundamental issue of the precision of attentional targeting remains unresolved.
To address this, we collected functional optical images of flavoprotein autofluorescence from the primary visual cortex (V1) of two macaques while they performed an attention task involving a 3-by-3 array of small Gabors. Optical imaging provides a high resolution (<20 micron), spatially unbiased measurement of activity across V1, allowing us to discretely measure the pattern of V1 activity evoked by each individual stimulus under different attention conditions. We find that attention indeed enhances the evoked autofluorescence from the centers of the V1 regions stimulated by each stimulus. Consistent with electrophysiological studies in V1, these attention effects are modest (approximately 0.1% signal change) when compared to the strength of the evoked visual response (approximately 1%).
Crucially, while we observe sharply focal visually evoked responses, we found that the corresponding attentional modulations were spatially broad: the surrounding regions of V1 also exhibited attentional effects of similar magnitude. Moreover, when the subjects were cued that they should selectively attend to only a subset of the stimulus elements, we found that the pattern of attentional modulations over V1 remained crude and only grossly matched the spatial cue given to the animals. We propose that, within V1, attention is fundamentally imprecise and modulates both the center and surround and that this may explain why electrophysiologic studies of V1 often fail to observe the strong effects of attention that are suggested by fMRI.

Title: Attention modulates LFP power and phase in primate V1 and LGN

Authors: *V. L. MOCK[1], J. HEMBROOK-SHORT[2], F. BRIGGS[2];
[1]Physiol. and Neurobio., Dartmouth Col. Geisel Sch. of Med., Lebanon, NH; [2]Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Increasing evidence suggests that attention modulates the activity of specific neuronal populations within a brain area and influences how information is communicated from one neuronal population to another. Parallel lines of research suggest that different neuronal populations, separated into laminar compartments, synchronize their activity at specific frequencies measured in the local field potential (LFP). We are examining how attention alters specific frequency modulations in LFPs recorded across the layers of primary visual cortex (V1) and frequency coupling between the visual thalamus (lateral geniculate nucleus or LGN) and V1. We record LFPs through electrodes placed within retinotopically-aligned regions of the LGN and V1 in awake-behaving monkeys performing a contrast or orientation change detection task that requires covert shifts in visual spatial attention. Our results show significant differences in power across the LGN and superficial, middle, and deep layers of V1 in both the cue and visual stimulus time periods of the task. However, we do not observe differences in LFP across attention conditions in the LGN or in the V1 layers. Interestingly, we do see a shift in the phase of LFP signals relative to the visual stimulus with attention in both V1 and the LGN. First, the relationship between differential phase and frequency is linear in the beta and low gamma bands, particularly between frequencies of 20-50Hz, suggesting a fixed temporal shift in LFP signals relative to the visual stimulus. Second, the slope of the linear phase-frequency curve is negative, indicating that LFPs on attend toward trials lead LFPs on attend away trials relative to the visual stimulus. Third, amplitude cross-correlation of V1 LFPs recorded on attend toward versus attend away trials shows a lead of approximately 10ms with attention, consistent with the fixed temporal lead predicted by the phase-frequency slope analysis. Furthermore, the attention-mediated phase lead is correlated with animals' behavior as phase leads are most significant on trials in which animals complete more difficult discriminations. Together, these phase shift results suggests that attention changes the timing of neuronal population activity relative to the visual stimulus with attention, possibly indicating that attention may be able to prime LGN and V1 neurons to respond more quickly to a given visual stimulus. These results support the notion

that attention selectively modulates the activity of specific neuronal populations within a cortical area in a behaviorally relevant manner and that this specificity influences how visual information is communicated in the early visual pathways.

Title: Attentional modulation of V1 neurons differs across physiological cell types in the primate

Authors: *J. R. HEMBROOK-SHORT, V. L. MOCK, F. BRIGGS;
Physiol. and Neurobio., Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Attentional modulation of firing rate varies substantially across visual cortical neurons. For example, spatial attention directed to neuronal receptive fields can cause increases or decreases in firing rate. Whether variations in attentional modulation of neuronal firing rate depend upon physiological characteristics or laminar locations of neurons is not known. In order to explore relationships between visual physiology or laminar location and attentional modulation across visual cortical neurons, we measured attentional modulation and visual response properties of neurons spanning the cortical layers of primary visual cortex (V1) in awake-behaving monkeys. Animals performed a contrast-change detection task, which required covert shifts in visual spatial attention toward or away from gratings overlapping recorded neuronal receptive fields, and attentional modulation of firing rate was assessed by comparing spike counts across attention conditions. Visual physiology of recorded neurons was determined based on neuronal responses to drifting sinusoidal gratings varying in contrast, orientation, size, and temporal and spatial frequency. We observed significantly more attentional modulation of V1 complex cells compared to V1 simple cells ($p=0.00017$). Differences in attentional modulation of firing rate were also observed across cortical layers: complex cells in V1 granular and infragranular layers were significantly more modulated by attention compared to simple cells in V1 supergranular and infragranular layers ($p=0.0046$). We further observed relationships between visual physiology and attentional modulation across the V1 population and among

neuronal sub-populations within specific layers. Interestingly, we observed a significant relationship between contrast sensitivity and attentional modulation across all recorded V1 neurons (p=0.04), consistent with the notion that attention more strongly modulates neurons tuned to the stimulus features important for the task. We also observed relationships between feature tuning and attentional modulation among specific laminar sub-populations. Together these results suggest that attentional modulation depends upon visual physiology and varies across neuronal sub-populations in different layers.

Title: Latency of stimulus onset and change transients in visual areas V1 and MT relate to reaction time

Authors: *B. SCHLEDDE, D. WEGENER;
Brain Res. Inst. / Univ. of Bremen, Bremen, Germany

Abstract: The ability to detect and respond to a relevant change in visual environment relies on the effective processing of visual information already in early visual areas. Selective visual attention actively supports the cortical processing of task-relevant information, allowing for facilitated behavioral performance, and local populations of neurons already in early visual areas are thought to play a critical role in enabling fast visual discrimination. In fact, the latency of rapid firing rate changes in response to abrupt change events was recently shown to be actively modulated by attention and to correlate closely with reaction time (RT). We here address the question of the underlying time course. Particularly, we ask whether response latencies to behaviorally relevant speed changes depend on the configuration of the network just before the change, or whether they indicate a more general characteristic of attentional modulation that persists throughout the trial. Furthermore, we ask whether attention-dependent latency shifts emerge within area MT, or alternatively, are inherited from a presynaptic population in primary visual cortex. We recorded from single neurons and local neuronal populations in visual areas MT and V1 while a macaque monkey performed a speed-change detection task requiring to detect an instant 100% speed increase at a spatially pre-cued moving Gabor patch. We found that

latencies and peak amplitudes of transient responses to abrupt changes in the visual stimulation differ substantially in trials resulting in fast or slow RTs. In area MT, this included the latencies of both early stimulus and motion onset transients as well as the speed-change transient occurring later in the trial. Interestingly, latency shifts in area MT were about twice as large as in area V1. Our results show that not only the transient response to the behaviorally relevant event, but also preceding changes to the target stimulus relate to RT, suggesting a persistent attentional impact throughout the trial. Furthermore, the fact that latency shifts from fast to slow trials in area MT are larger than latency shifts in V1 argues for an accumulation of latency advances along the processing pathway.

Title: Feature-based enhancement precedes object-based attentional modulation of MT responses in a delayed match-to-sample task

Authors: ***P. SCHWEDHELM**[1,2], S. TREUE[1,2,3];
[1]German Primate Ctr., Goettingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany; [3]Fac. of Biol. and Psychology, Goettingen Univ., Goettingen, Germany

Abstract: A rapid and accurate identification of behaviorally relevant stimuli is often mediated by the deployment of attention. If target stimuli requiring a behavioral response are identified based on their stimulus features (e.g. their color or motion direction), feature-based attention enhancing searched-for features constitutes an efficient mechanism to enhance the neuronal representation of targets and reduce the one of distractors.
We measured feature-based enhancements of neurons in motion-selective area MT of two macaque monkeys while they performed a delayed match-to-sample task. Stimuli were identified as targets either based on their motion component, their color, or a conjunction of motion and color.
The responses to target stimuli matching the searched-for motion direction were enhanced by

attention, but we also found significant modulations of firing rates when animals did not attend to the motion but the color of the stimuli. Here, the time-courses of the attentional modulation in area MT revealed latency differences between feature-based modulations; with attention to the primarily encoded feature occurring earlier in time. This finding is consistent with a sequential activation of cortical modules and supports the notion of a unified, object-based attention system. However, when monkeys identified target stimuli based on a unique conjunction of color and motion, the observed modulation was not the sum of color- and motion-based matching tasks. Instead, we observed the biggest attentional effects for "partial targets" - distractor stimuli matching only one of the two searched-for features - consistent with a role of area MT in signaling potential targets, rather than targets. This finding suggests that feature-based attentional modulation represents an intermediate step preceding object-based attentional enhancement and will guide future research of attentional control circuits.

Title: Maintenance of spatial information modulates the gain and reliability of neuronal responses in areas V4 and MT

Authors: *Y. MERRIKHI[1], M. PARSA[2], B. NOUDOOST[3];
[1]school of cognitive sciences, Inst. For Res. In Fundamental Sci. (IPM), Tehran, Iran, Islamic Republic of; [2]computer science, [3]Cell biology and neuroscience department, Montana state university, Bozeman, MT

Abstract: Holding a location in working memory has been shown to produce perceptual benefits at that location. Our lab has found that prefrontal cortex sends a persistent signal indicating the content of spatial working memory to extrastriate visual cortex during the delay period of a spatial memory task. Delay-period firing rates in extrastriate visual cortex, however, do not reflect the location held in memory, suggesting that any effect of this input from prefrontal

cortex must be sub-threshold. Such sub-threshold input could nevertheless render extrastriate neurons more sensitive to incoming visual signals. To test this hypothesis, we recorded the neural activity of areas V4/MT in rhesus monkeys while they performed a memory-guided saccade task. In this task, the monkey fixated for 1 second (baseline period) to start the trial. Then the target was presented for 1 second (visual period) and the monkey remembered its location for another 1 second (delay period). The fixation point then disappeared, and the monkey moved his eyes to the remembered cue location to receive a reward. To test whether the location held in memory alters the gain of visual responses, we presented brief (200 ms) visual probes in a 7x7 grid of locations near the one of cue locations, during both the baseline and the delay period. We compared the probe-evoked visual responses for trials with different target locations to see if the peak magnitude of the response changed based on the contents of spatial working memory. Remembering a location near the probe increased the peak response of single and multi units in areas V4/MT. Next, we used trials in which no visual probes were presented to examine the effect of spatial memory on the response reliability of single neurons in extrastriate cortex. The variability of neural responses in extrastriate cortex decreased when remembering a location near the neuron's RF. We hypothesize that these changes in reliability and sensitivity to visual signals are the result of sub-threshold modulation by the persistent spatial signal from prefrontal cortex. These effects of memory maintenance on the neural activity in extrastriate cortex, which are similar to the effect of covert spatial attention, could contribute to the behavioral benefits seen at a location held in memory.

Title: Moment-to-moment fluctuations of attention in macaque area V4

Authors: *A. UMAKANTHA[1], A. C. SNYDER[4], B. M. YU[2,3], M. A. SMITH[4];
[1]Ctr. for the Neural Basis of Cognition, [2]Dept. of Electrical and Computer Engin., [3]Dept. of Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA; [4]Dept. of Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Spatial attention allows for selective processing of information in a specific area of the visual environment. Experimenters typically assess attention by comparing behavioral and neural responses between conditions with different attentional cues. However, with this approach, we lose information about meaningful trial-to-trial and moment-to-moment variability in attention. Recently, population neuronal recordings have enabled reliable estimation of spatial attention on individual trials (Cohen & Maunsell, 2010). We ask how the population level signatures of attention fluctuate from moment to moment in a trial. We recorded V4 population activity in macaques performing a cued spatial attention task in which they need to detect a gradual speed change in one of two drifting gratings (the target). On some trials, there was no speed change (catch trials). Considering catch trials in which the subject correctly withheld a response, we decoded the location of the attentional cue, and thereby the subjects' attentional state, using a linear classifier (support vector machine) from moment to moment. Classification accuracy peaked at 80% and had a time course that matched the statistics of target onset in the task. In other words, even though no targets were presented on catch trials, attentional fluctuations matched expected target saliency from validly cued trials. Furthermore, a classifier trained on population activity directly preceding stimulus onset also had 80% accuracy, but performed poorly when tested on neural activity from times after stimulus onset. This suggests that the representation of attention is capable of shifting dynamically from moment to moment, allowing maintenance of attention during adaptation to a changing visual field.

Title: Decoding V4 laminar population response during covert and overt attention

Authors: *W. W. PETTINE[1,2], N. STEINMETZ[3], T. MOORE[1,2];
[1]Neurobio., Stanford Med. Sch., Stanford, CA; [2]Howard Hughes Med. Inst., Chevy Chase, MD; [3]Dept. of Neuroscience, Physiology, and Pharmacol., UCL Inst. of Neurol., London, United Kingdom

Abstract: The cerebral cortex's functional architecture is characterized by distinct lamination patterns, defined in part by cell type, connectivity and response properties. Previous studies of attentional modulation of V4 neural activity have found laminar differences in local field potentials, but not in spiking activity. We recorded spiking activity across the cortical layers of single cortical columns of area V4 in two rhesus macaques using a linear array microelectrodes during a selective attention task. For this task, the monkey fixated on a central point, while four gabor patches appeared, one in each quadrant. A cue then was presented indicating the gabor patch that was most likely to change orientation. If the orientation changed after a delay, the monkey was rewarded for saccading to the opposite gabor patch. The two gabor patches orthogonal to attended locations were considered controls. This task dissociated overt attention (the preparation and execution of orienting eye movements), from covert attention (selective processing without overt orienting). We then used machine learning classification to distinguish between behavioral conditions (covert, overt and control) on a trial-by-trial basis from population activity. Feature vectors consisted of neuronal ensemble firing rates and inter-spike interval distributions. Alternative pseudo-populations were also created through multi-ensemble feature grafting, which permitted independent testing of waveform classes, as well as the location of neurons within superficial or deep layers. Classification was applied to data during the epoch following the presentation of a cue that indicated which of four stimuli was the target of covert (or overt) attention. We found that neuronal ensembles and pseudo-populations of V4 neurons were able to distinguish between conditions in which overt, covert or no attention was directed toward the receptive field stimulus. The effect was significant for both narrow-spiking (putative interneurons) and broad-spiking (putative pyramidal) neurons, as well as for both superficial and deep layer neurons. These results suggest that the source of attentional modulation in V4 operates equally across cortical layers. Furthermore, our methods also provide a novel way to preserve raw population spike dynamics on a trial-by-trial basis when analyzing neural ensembles.

Title: The impact of "nuisance" variability on neural task performance

Authors: *N. ROTH[1], N. C. RUST[1,2];
[2]Dept. of Psychology, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Task performance is determined not only by the amount of task-relevant "signal" present in our brains, but also by the presence of "noise". While the relationship between signal and noise has been extensively described under conditions in which noise is limited to "trial variability", the impact of the noise introduced by task-irrelevant "nuisance" parameters is much less well understood. Generally, when noise is limited to trial variability, neural task performance (quantified by the measure d'[2]) grows with time; this relationship serves as a benchmark for many models of task performance. In contrast, we have determined that the presence of nuisance variability causes task performance to saturate at a time dependent not only on the amount of nuisance variation present but also on the overall firing rate. This result suggests that there may be a point beyond which neurons continue to fire but considering those spikes will leads to no net gain in information. To investigate the effect of nuisance variation on neural task performance in the brain, we analyzed neural responses recorded in inferotemporal cortex (IT) as macaque monkeys performed an "invariant delayed match to sample task" that required them to identify when a target object appeared in the presence of considerable nuisance variation. We found that neural task performance did in fact saturate at a time consistent with the monkeys' reaction times, and that a large component of this saturation could be attributed to nuisance variability. However, we also found that as a consequence of relatively low firing rates in our population, the amount of saturation was blunted relative to a high firing rate regime.

Title: Effects of parietal inactivation on saliency-driven eye movements

Authors: M. ZIRNSAK[1,2], *X. CHEN[1,2], M. PLITT[1], S. G. LOMBER[3], T. MOORE[1,2];
[1]Dept. of Neurobio., [2]Howard Hughes Med. Inst., Stanford Univ. Sch. of Med., Stanford, CA;
[3]The Brain and Mind Inst., The Univ. of Western Ontario, London, ON, Canada

Abstract: Salient regions in visual scenes draw attention and predict the direction of scanning eye movements, as well as modulate the activity of neurons within a number of structures which thought to be involved in visual attention. In particular, neurons within prefrontal and parietal cortex have been reported to represent stimulus saliency. We recently found evidence that the representation of saliency within prefrontal cortex, specifically within the frontal eye field (FEF) depends on the activity within parietal cortex. Following parietal inactivation, the ability of FEF neurons to signal the presence of a unique (popout) stimulus within an array of others was strongly reduced, while there was no change in their responses to single visual stimuli. In this study, we test whether this apparent reduction in saliency signals within the FEF is reflected by a reduction in the saliency driven visually guided eye movement within visual images. To inactivate parietal cortex, we implanted two stainless steel cryoloops within the intraparietal sulcus of a macaque monkey. Chilled methanol was pumped through the loops to induce localized hypothermia in the surrounding cortical tissue, thus silencing nearby neuronal activity. Simultaneously, we recorded the eye movements of the monkey while it freely viewed a large number (>1000) of static, complex images (eg. landscapes, cityscapes, fractals.) For each image we quantified the average saliency of the fixated regions using known saliency algorithms (Harel, Koch, & Perona, 2006). Our results thus far indicate that the average saliency of fixated regions for scanning eye movements directed into the intact hemifield is unchanged during parietal inactivation. However, the average saliency of fixated regions by eye movements directed into the inactivated hemifield is significantly reduced following parietal inactivation.

Abstract: We aimed to determine differences in top-down and bottom-up control of attention using hyperpolarizing optogenetics in monkeys. Macaques were trained to covertly detect a random dimming of a small target occurring with equal probability at one of four locations in each quadrant while distractors were presented in the other quadrants. Target location was cued either using a change in color of the target (bottom-up) or the fixation point (top-down, symbolic cue for each quadrant), respectively. After the cue, a delay period occurred during which the distractors dimmed, which had to be ignored by the animals. After a random delay period, the monkeys had to indicate the dimming of the target with a manual response in order to obtain a reward. Monkeys were trained to perform this covert spatial attention task while bottom-up and top-down cued trials were randomly presented. Consistent cue-dependent accuracy and reaction time effects were observed in unperturbed animals, as well as relatively small differential fMRI activations between bottom-up versus top-down cued trials in frontal, parietal and visual cortex (N =3, see Balan et al. SfN 2015).
Guided by the fMRI maps, we injected an AAV2/5-CaMKII-Jaws-KGC-eGFP-ER2 viral vector in specific task-driven compartments of both LIP and FEF. After 6 weeks, we aimed to focally reduce neuronal activity in these task-driven foci. Optogenetic inactivation using red light (635nm) was focused on the cue period of randomly selected bottom-up or top-down cued trials, both during fMRI and electrophysiology. For light delivery, we used an optic fiber fixed to a microdrive either with (for electrophysiology and behavior) or without (for fMRI and behavior) electrode.
Preliminary results from the LIP inactivation sessions showed mainly decreased but not completely abolished neural responses and decreased fMRI activity within the targeted section of LIP. During task performance, we also found a mixture of optogenetic-induced decreased and increased fMRI activity throughout nodes of the attention network. Furthermore, we observed decreased behavioral performance during short inactivation of the cue-period, which either affected the bottom-up or the top-down cued trials but rarely both together when the same location was inactivated. These results show that ultra-short reversible inactivation of LIP only

during the cue period can affect top-down and bottom-up driven covert spatial attention behavior, as well as local activity and network dynamics.

Title: The anatomy of the white matter pathways connecting primate dorsal and ventral attention control areas

Authors: *I. SANI[1], B. C. MCPHERSON[2], F. PESTILLI[2], W. A. FREIWALD[1]; [1]Rockefeller Univ., New York, NY; [2]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: The cerebral cortex comprises many areas involved in visual attention processing. Classical studies identify the parietal and frontal cortices as two major sources of attentional signals. Recent results highlighted that an area in the temporal cortex also plays a crucial role in visual spatial attention both in humans and monkeys (Stemmann et al., *in preparation*). The discovery of this ventral attentional-control area posits new important questions about the network organization of the primate attention. We're currently asking how dorsal and ventral attention control areas communicate in the two species by combining functional MRI localization with diffusion MRI. In the monkey (*Macaca mulatta*), we acquired high-resolution diffusion MRI (250 x 250 x 250 μm). We used probabilistic tractography to estimate the trajectories of different temporo-parietal pathways. We analyzed the data using constrained spherical deconvolution and an ensemble of tractography methods (Takemura et al., 2016). We optimized the tractography results and tested the statistical evidence for white matter connections

between the ventral and dorsal attention regions by using Linear Fascicle Evaluation methods (Pestilli et al., 2014). We successfully identified white matter pathways connecting the established dorsal attentional maps and the newly reported ventral map. We speculate that this fascicle might be crucial for transmitting attentional signals between ventral regions that encode object properties, including form and identity, and dorsal regions that map spatial information.

Title: A cluster of conspicuity representations for eye fixation selection

Authors: *J. K. TSOTSOS, Y. KOTSERUBA, C. WLOKA;
York Univ., North York, ON, Canada

Abstract: A computational explanation of how visual attention, interpretation of visual stimuli, and eye movements combine to produce visual behavior seems elusive. Here, we focus on one component: how selection is accomplished for the next fixation. The popularity of saliency map models drives the inference that this is solved, but we argue otherwise. We advocate for a cluster of complementary, conspicuity representations to drive fixation selection, modulated by task goals and fixation history. This design is constrained by the architectural characteristics of the visual processing pathways, specifically, the photoreceptor distribution in the retina, the pyramidal architecture of the visual pathways, and the poor representation of the visual periphery in the late stages of the visual pathways. Added to these are constraints due to the inappropriateness of an early attentional selection strategy for complex stimuli (eg., non-target displays, figure-ground not easily separated, etc.). Together, these factors led us to a hybrid method that combines early and late selection, i.e., feature and object-based attentional selection. We incorporate attentional microsaccades, saccades and pursuit eye movements into a unified

scheme where true covert fixations (zero eye movement) might only be appropriate if the target of a new attentional fixation is represented in the retina at a resolution sufficient for the task. Finally, elements of a visual working memory structure are included that link fixations across space and provide a means for extracting details of an attentional fixation and communicating them to the rest of the system. These elements combine into a new strategy for computing fixation targets.
Using this new fixation controller, we show results that not only out-perform saliency models with respect to human fixation patterns, but also match very well with human saccade amplitude distribution patterns. Perhaps most importantly, it provides a substrate for a richer exploration of how attention and eye movements are related than possible with other models because it is explicitly designed to be an integrative framework. It is a fully computational framework that can be tested with real images (and image sequences) with no hidden representations or statistically inscrutable elements, generating fixations that can be fully analyzed and providing the full sequence of representations than can also be inspected, analyzed and used to drive experimental testing. It is certainly the case that the specific representations presented will require many refinements; however, the framework offers the ability to understand why those refinements will be needed.

Title: Development of oculo-feedback system: Manipulation of microsaccade generation

Authors: J. EMOTO[1], *Y. HIRATA[2];
[1]Computer Sci., Chubu Univ. Grad. Sch. of Engin., Aichi, Japan; [2]Chubu Univ. Col. of Engin., Aichi, Japan

Abstract: We invented an oculo-feedback system that may modify mental states associated with specific eye movements by manipulating their oculomotor properties. Among many kinds of eye movements, we focused on microsaccades (MSCs) that are involuntarily evoked, and known to relate to spatial attention in human, envisioning that we can modify attentional states by

manipulating MSC rate via oculo-feedback. In the proposed oculo-feedback system, MSCs are automatically detected in real-time from eye positions measured binocularly with a video oculography (EyeSeeCam) running on a MacBook, by using a deep convolutional network (DCN). The DCN was configured and pre-trained to dissociate MSCs and non-MSC eye movements from eye position traces (MSC detection rate > 94 %). When a MSC is generated in a specified time window, sensory feedback is given to the subject to reinforce the involuntary behavior. To test the proposed system in manipulating MSC rate and attentional states, we conducted the following experiment. A subject wearing EyeSeeCam sat in a dark room at 45 cm from a 29-inch PC monitor with his/her head fixed. The subject was instructed to look at the first visual cue (a cross with 0.73 deg of visual angle) when it appeared at the center of the monitor. After a random delay between 1.5 and 2.5 sec it was replaced by the 2nd visual cue (left or right arrow head) that told with 80 % accuracy about the direction of a visual target appearing after a random interval between 2.0 and 2.5 sec. The subject was instructed to make a saccade to (pro-saccade condition), or away from (anti-saccade condition) the visual target as soon as it was displayed at either side of the screen simultaneously with disappearance of the 2nd visual cue. After making a pro- or anti-saccade, visual and audio feedback was given by playing an animation in which a circle was enlarged gradually with moderate beep sound, if a MSC had been generated in a 0.2 sec window set at 0.7 sec after the onset of the 2nd visual cue. In one session, this procedure was repeated until the circle reached to the largest size, usually taking about 8 min. Three sessions were conducted a day with a few min of rest, and the subjects underwent 4 days of experiment. Two subjects who participated in the experiment under pro-saccade condition knew their MSCs were evaluated, but did not know about the time window. Results from both subjects showed the numbers of MSC generation in and after the time window progressively increased as they experienced more oculo-feedback sessions, demonstrating that MSC rate is modifiable by the oculo-feedback training presently proposed. Results from the anti-saccade condition, and reaction time to saccade initiations will be presented.

Title: Automatic spread of the attentional field from a spatial cue to an underlying object in primary visual cortex

Authors: *M. EKMAN[1], P. R. ROELFSEMA[2], F. P. DE LANGE[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Dept. of Vision and Cognition, Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Introduction: Spatial attention is commonly understood as a mechanism to increase the neuronal gain in specific locations in the visual field that are associated with a relevant object. However, studies of single-unit recordings have demonstrated that the effect of spatial attention is not limited to the relevant location but also increases the gain in parts of the object that are outside of the spatial priority map [1]. Here, we sought to use a novel decoding model to reconstruct participants' attentional field from activation patterns in early visual cortex (V1) and thus test, to what extent the attention field spreads from a spatial cue to an underlying object.
Methods: Seventeen healthy individuals underwent functional magnetic resonance imaging (3T fMRI) and population-based receptive field mapping [2]. Subjects received a visual cue to attend to two partially overlapping horseshoe-like objects in the left or right visual field. Two colored dots appeared on the attended objects and also on the unattended objects. During the 'object-condition', subjects had to respond whether the two dots were on the same object, irrespective of the dot color. During the 'color-condition', subjects had to indicate whether the dots have the same color, irrespective of whether the dots were on the same object. Notably, one of the dots had a 90% chance of occurring at the intersection of the objects. Therefore, subjects particularly attended this spatial location. Importantly, if attention is object-based, it will spread from the cued location at the intersection either to the lower or to the upper horseshoe-object, depending on which object is positioned on top.
Results and Discussion: Analysis of reaction times showed that participants responded faster when the two dots were on the same object, compared to when they were on different objects ($F(1,16)=22.02$, $P=3.8 \times 10e\text{-}6$), suggesting attentional enhancement of the cued object. This was confirmed by the fMRI-based attentional field reconstruction, which revealed that the BOLD activity spread from the cued location to the underlying object - and represented the object entirely. Importantly, the spreading was also found for the 'color-condition' when the underlying object was not task relevant, suggesting that attentional object selection operates as an automatic process. In sum, our results suggest that the neuronal mechanisms governing spatial attention are closely intertwined with object-based attention.

Title: Contrasting salience and attention in the early visual pathway

Authors: *S. POLTORATSKI[1], S. LING[3], F. TONG[2];
[2]Dept. of Psychology, [1]Vanderbilt Univ., Nashville, TN; [3]Dept. of Psychology, Boston Univ., Boston, MA

Abstract: The visual system employs a sophisticated balance of attentional mechanisms: individuals can willfully guide attention to serve their top-down goals, but can also notice salient information in the environment outside of their current locus of attention. At its simplest, salience can be defined as a measure of local feature contrast across the visual field: if a local region differs from its surrounding context along one or more feature dimensions, it is deemed salient. Here, we used high-resolution fMRI at 7 Tesla to determine the stages at which modulatory effects of bottom-up salience and top-down voluntary attention emerge along the visual hierarchy, and whether these two processes interact to modulate responses in the human visual system. Observers viewed 3 x 4 arrays of gratings, wherein one of the gratings immediately to the left or right of fixation differed from all other items in the array in orientation (or motion direction). To concurrently investigate the effects of top-down attention, observers were cued to attend to the grating to the left or right of fixation, which was either salient or non-salient. Results revealed reliable additive effects of top-down attention and stimulus-driven salience throughout visual areas V1-hV4, with no evidence of an interactive effect. In contrast, the lateral geniculate nucleus (LGN) exhibited significant attentional enhancement but was not reliably modulated by orientation- or motion-defined salience. We conclude that visual salience emerges in feature-selective populations of neurons at early cortical stages of visual processing, and can be distinguished from effects of top-down spatial attention. The finding that simple salience is computed both within and outside the focus of spatial attention informs our understanding of the neural mechanisms of salience and how visual prioritization strikes a balance between the observer's goals and noteworthy stimuli in the environment.

Title: Feature-tuned normalization modulates spatial attention

Authors: *I. M. BLOEM[1,2], S. LING[1,2,3];
[1]Psychological and Brain Sci., [2]Ctr. for Systems Neurosci., Boston Univ., Boston, MA; [3]Donders Inst. for Brain, Cognition & Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Although attention is known to boost the gain of early visuocortical responses, the neural computations and circuitry underlying these gain changes remain unclear. Recent computational models proposed that attentional modulation arises through interactions with divisive normalization, tipping the balance between excitation and inhibition, resulting in a release from gain control. Normalization strength can be assessed utilizing the feature-tuned, weighted nature of normalization, whereby responses to similar features normalize each other more so than responses to dissimilar features. Previous work from our lab has demonstrated that normalization strength and the ability of attention to boost a stimulus-evoked response are related, suggesting that these two measures potentially share a common mechanism (Bloem, & Ling, 2015). In this study, we directly assessed the role that normalization plays in attentional modulation by manipulating spatial attention while simultaneously measuring normalization strength in early visual cortex. We measured fMRI BOLD responses to stimuli that consisted of two orientation bandpass filtered noise patterns, combined in either collinear or orthogonal configurations. Participants were asked to allocate their covert spatial attention to one of two stimuli appearing simultaneously to the left and right of a central fixation point. Observers performed a demanding probe detecting task on the attended side, detecting and discriminating the location of a visual probe appearing within the stimulus. Consistent with our previous work, we found robust attentional and normalization modulation across early visual cortex (V1-V3). Interestingly, the magnitude of attentional modulation depended on the stimulus configuration: we found larger attentional effects when the orientation content of the stimuli was similar (collinear), compared to stimuli with disparate orientation content (orthogonal). Taken together, our results suggest that a neural population's capability for attentional benefits appears contingent upon normalization, whereby a more strongly normalized population results in greater potential for release from suppression driven by attention.

Title: The modulatory impact of global feature-based attention on feedfoward and feedback processing in human visual cortex

Authors: *H. G. GARCIA-LAZARO[1], M. BARTSCH[3], H. STRUMPF[2], M. A. SCHOENFELD[1,3], J.-M. HOPF[2,3];
[1]Dept. of Neurol., [2]Otto-von-Guericke Univ., Magdeburg, Germany; [3]Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: Global feature-based attention (GFBA) refers to a selection bias of attended feature values outside of the spatial focus of attention. Studies analyzing GFBA with spatially unattended feature probes have shown that the bias arises from gain modulations in extrastriate visual cortex starting around 200 ms after probe onset. Importantly, these modulations were found to propagate in reverse hierarchical direction, suggesting that GFBA reflects a bias of feedback processing in visual cortex. Other studies have documented that GFBA modulations can appear as early as 100 ms after the feature probe, leading to the conclusion that GFBA reflects a bias of the initial feedfoward sweep of processing. Here we investigate an important, yet untested, explanation of the discrepancy: studies reporting modulations during feedfoward processing used experimental designs with a continuous presentation of the target feature, permitting feature-selective units to remain continuously biased across experimental trials, hence the modulation of the initial feedfoward stage of processing. In contrast, studies reporting modulations during feedback processing used target-onset stimulation requiring to bias feature-selective units anew on each trial. To address the issue we recorded the neuromagnetic brain response in human observers performing two versions of an irrelevant feature-probe experiment. An attended color-target shown in one visual field (VF) was combined with the presentation of an irrelevant color probe in the unattended VF. On the "continuous" version, the target was a continuously presented patch of color smoothly moving through color space in a random way, whereas on the "onset" version the target color was presented in a trial-by-trial manner. In both versions subjects had to count the number of occurrences of the target color. The GFBA effect was assessed by analyzing the brain response to the color probes. We observed that during the continuous version of the experiment, attended-color probes elicited a gain modulation as early as 80-90ms in early visual cortex areas. During the onset version, in contrast, target-color probes elicited extrastriate modulations around 180 ms, but no early effect. These observations together

suggest that for feature attention to modulate the feedforward sweep of processing, a continuously driving input to feature-selective units is required. Without such input, the attended feature bias can only be established with the feedback sweep of processing in extrastriate visual cortex.

Title: Feature-specific attentional selection in human prefrontal cortex

Authors: ***N. P. MLYNARYK**, X. ZHANG, S. JAPEE, L. G. UNGERLEIDER;
NIH, Bethesda, MD

Abstract: When features such as motion or color serve as the targets of visual attention, cortical responses to all stimuli with that feature are enhanced. How feature-based attention relays this effect from attended to unattended locations in the visual field remains unclear. Here we used functional magnetic resonance imaging (fMRI) to investigate the mechanism of this global modulation as human subjects performed motion- (Experiment 1) and color- (Experiment 2) based attention tasks. In Experiment 1, subjects were asked to attend one direction of motion within a display of overlapping upward and downward moving dots (the attended stimulus) on one side of a central fixation point, and ignore a single field of dots moving either up or down (the ignored stimulus) on the other side. In Experiment 2, the attended stimulus was comprised of overlapping fields of stationary red and green dots on one side of a central fixation point, and the ignored stimulus was a single field of either red or green dots on the other side. Results indicated that, in Experiments 1 and 2, early visual areas, parietal areas, prefrontal areas, and subcortical areas, as well as the respective sensory areas (MT+ for motion and V4 for color), all showed the classical feature-based attentional effect, with responses to the ignored stimulus significantly elevated when it shared the same feature as the attended stimulus. Further, effective connectivity analysis showed that feature-similar gain modulation outside the attended location was closely associated with feedback from prefrontal areas rather than parietal or subcortical areas. Together, these findings indicate a crucial involvement of the prefrontal cortex in the global effects of feature-based attention.

Title: The color of distraction: the influence of distractors on global color-based attention

Authors: ***M. V. BARTSCH**[1], S. E. DONOHUE[2], Z. PASSAND[1], M. A. SCHOENFELD[1,2], J.-M. HOPF[1,2];
[1]Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Dept. of Neurol., Otto-von-Guericke Univ., Magdeburg, Germany

Abstract: Attention to color is not confined to the spatially attended location, but can operate throughout the whole visual field, with this spatially-independent selection often referred to as global color-based attention (GCBA). Most studies have documented GCBA by comparing the neural response to task-relevant colors to that of irrelevant distractor colors. Key to this comparison is the nature of the distractor (i.e., if it were previously a target color, never a target color (i.e., neutral), and where in the visual field it is presented). As no previous study has taken all of these factors into consideration, including what may be an appropriate baseline for comparison, it is unclear if the previously-observed modulations underlying GCBA reflect the attenuation of distracting colors or, alternatively, the relative enhancement of attended colors in the focus of attention (FOA). Here, we address the issue by analyzing the effect of different types of distractor colors, serving as baseline conditions to evaluate the relative direction of modulations. The general experimental setup follows (Bartsch et al. 2015). Subjects performed a simple color/orientation discrimination task while effects of GCBA were assessed by analyzing the electromagnetic (EEG/MEG) brain response to color probes presented outside the FOA, as a function of whether they matched the currently-attended color inside the FOA. We extended the paradigm by presenting the target together with a distractor color that was neutral and never served as a target color (neutral distractor, ND) or a distractor color that was irrelevant on a given trial block but served as a target on other blocks (relevant distractor, RD). Effects of those distractor colors were assessed with color probes outside the FOA. We observed that the type of distractor (RD or ND) presented with the target color did, indeed, influence effects of global color-based selection. Specifically, while the GCBA response to the attended color was enhanced when compared to the both types of distractor colors, this effect was bigger when compared

against relevant distractors. Additionally, the comparison of relevant vs. neutral distractors revealed global color-based modulations in early visual cortex. This suggests the importance of both implicit and explicit task-relevance in determining what is selected by GCBA, and underscores the importance of having a neutral condition with which to compare such modulations. Together, these observations show that the nature of distractor color determines the operation of GCBA in a qualitative way.

Title: Effects of attention on contrast response functions in foveal visual cortex

Authors: ***R. MILLIN**, M.-P. SCHALLMO, A. V. FLEVARIS, G. M. BOYNTON, S. O. MURRAY;
Psychology, Univ. of Washington, Seattle, WA

Abstract: Foveal vision is used for most tasks that involve analysis of visual form because of its high acuity. Consequently, attention is usually directed to the center of gaze. Despite the fovea's importance to everyday vision, basic visual processes such as neural contrast responses and attention have not been explored for the cortical representation of the fovea because of methodological challenges. Thus, it is unknown to what extent results obtained in the visual periphery will generalize to the fovea. We used fMRI to measure the effect of attention on the fMRI response to image contrast in foveal and peripheral vision. For the first experiment, BOLD measurements were made while subjects viewed oriented gratings and indicated the direction of an orientation change (clockwise or counterclockwise) of either a foveal (width 1 deg) or peripheral (width 3.5 deg, centered at 6 deg) grating. Foveal and peripheral stimuli were presented simultaneously in a blocked design at 5%, 25%, 50%, and 98% contrast. We then performed a second experiment using an event-related design with the same stimuli and tasks as Exp. 1. Cued and un-cued trials with 0% contrast were also included to assess baseline shifts.

The effects of attention on the BOLD response to foveal stimuli were qualitatively different than to peripheral stimuli. Attention to peripheral stimuli produced the commonly observed baseline shift across all contrasts (Buracas and Boynton 2007, Murray, 2008). Attention to the foveal stimulus, however, shifted the contrast-response function from distinctly monotonic to nearly flat. These results from foveal stimuli call into question the generality of conclusions made about the mechanisms of attention based on studies with peripheral stimuli.

Title: Parietal alpha oscillations mediate the attentional shift between different targets in uni- and multimodal paradigms

Authors: ***R. SOKOLIUK**[1], K. J. MULLINGER[4], S. D. MAYHEW[2], K. M. AQUINO[4], R. SANCHEZ PANCHUELO[4], S. T. FRANCIS[4], S. O. HANSLMAYR[3];

Abstract: A continuous stream of sensory information enters the human brain during daily life. Directing our attention facilitates selecting specific information and inhibiting processing of unimportant information. Recent work has focused on the role of alpha (8-13Hz) oscillations in attention, whereby an increase in alpha power leads to an inhibition of brain areas responsible for processing “to-be-ignored” information. While most previous studies focused on the influence of alpha oscillations within one modality, we were interested in elucidating a more global picture of alpha modulation in attention. Do uni- and multimodal attention paradigms share the same neural source of inhibitory alpha power? How does the neural pattern of alpha modulation change with increasing and decreasing attention? Two different paradigms were used: either attention was divided between the right and left visual hemifields to different degrees (40/60%, 20/80%, 0/100%), or between the visual and somatosensory modalities (40/60%, 0/100%). Each trial

started with a visual cue showing different percentages, to indicate the likelihood with which a target would appear on each side or sensory modality. In the visual paradigm, participants had to identify the orientation of Gabor patterns. In the multimodal visuo-somatosensory paradigm, participants had to discriminate between low and high frequency visual and somatosensory stimuli. The same 16 participants took part in both paradigms whilst high density EEG (128 electrodes) data were recorded. EEG data analyses were performed on the pre-stimulus interval, when subjects were directing their attention towards a specific side or modality. Beamforming analyses were performed on these data to localize the attention modulation effects. Both paradigms, showed a decrease of the mean alpha power during the pre-stimulus period over sensory specific brain regions that process the attended stimuli and an increase over regions processing "to-be-ignored" stimuli. The visual attention task further showed increasing lateralisation of alpha power between the hemispheres with increasing degree of attention, suggesting an effect of cue percentage. In both paradigms, the global source of alpha oscillations was identified in the parietal cortex, suggesting that the observed active inhibition by alpha oscillations is mediated by the same mechanism whether attention is divided spatially in one modality or between two distinct modalities.

Title: Mechanisms of spatial versus non-spatial, modality-based attention

Authors: *D. BALDAUF[1], R. DESIMONE[2];
[1]McGovern Inst., MIT, Cambridge, MA; [2]McGovern Inst. for Brain Research, MIT, Cambridge, MA

Abstract: FMRI and magnetoencephalography (MEG) were used in the same subjects to compare top-down attentional networks for spatial and non-spatial attention. Attention to spatial locations and sensory modality (auditory versus visual) caused enhanced evoked responses and BOLD signals in early sensory areas. Multiple voxel pattern analysis (MVPA) of FMRI data revealed spatial and non-spatial (modality-based) control networks in superior-frontal and inferior-frontal cortex, respectively. FMRI-guided MEG recordings showed similar coherent oscillations between these two frontal control networks and sensory sites according to the

attentional cue, which were enhanced by attention. Our results suggest that different prefrontal structures are sources of top-down biasing signals for spatial and non-spatial attention, and these structures interact in a similar fashion with posterior sensory areas during sustained attention.

Title: Modulation of human medial frontal and amygdala neurons by task demands and attention.

Authors: *J. MINXHA[1], R. ADOLPHS[1], A. MAMALAK[2], U. RUTISHAUSER[2]; [1]Caltech, Pasadena, CA; [2]Neurosurg., Cedars Sinai Med. Hosp., Los Angeles, CA

Abstract: Visually tuned neurons are prominent in areas of the anterior temporal lobe, including the amygdala and the hippocampus, but not in the medial frontal lobe. Medial frontal lobe neurons instead encode task-specific parameters. We investigated the effects of task demands and attention on the visual tuning of neurons in the human amygdala and anterior cingulate cortex (ACC). We recorded from 98 neurons in the amygdala and 112 neurons in the anterior cingulate cortex of five neurosurgical patients. In parallel, we recorded eye-movements as the subjects performed three tasks. First, subjects freely scanned an array of eight images each belonging to one of six categories: fractals, flowers, human faces, monkey faces, cars, and fruits. Second, subjects were asked to fixate and identify if images presented in the periphery (6° by 6°, 18° from center of screen) belonged to a particular category (i.e. is it a car, yes or no). The image location was randomly selected from eight possible locations. Halfway through the session, the target category ("task demands") changed to one of the other image categories (i.e. is it a face, yes or no). Third, we presented two images on opposing sides of the screen and provided a cue to instruct subjects which of the two images was relevant to answer the question. In both the second and third task, we asked subjects to maintain fixation at the center of the screen. Performance was high (91± 3 % accuracy). Trials where subjects broke fixation were excluded from analysis.

Here we show three key results. First, in the free-viewing task, amygdala neurons were visually tuned (n = 30/98, 1x4 ANOVA, aligned 220ms post-fixation, $p<0.05$). In contrast, this was not the case in the ACC (n=6/112). Secondly, in tasks 2 and 3, we also found strong visual-category tuning in the amygdala (n=18/89 in task 2, n=15/35 in task 3, measured with 1x4 ANOVA, 0-500ms post stimulus onset). Thus, neurons were sensitive to where attention was deployed rather than to where the eyes fixated. Thirdly, we found that task demands were strongly encoded only in ACC neurons: both target category (n=35/78, 1x2 ANOVA, 0-500ms post stimulus onset, $p<0.05$) as well as the cued location (n= 8/15, 1x2 ANOVA, 0-500ms post cue onset, $p<0.05$) was encoded. Together, these results show that (i) visually tuned amygdala neurons are sensitive to both covert and overt attention, and that (ii) there is a functional separation between medial-frontal lobe and anterior temporal lobe in representing visual-stimuli and task demands. This suggests that studying the functional interactions between the amygdala and the anterior cingulate cortex is a fruitful approach to determine the dynamic implementation of task demands.

Title: Multi-finger cue combination depends on hand proprioception

Authors: *M. RAHMAN, J. M. YAU;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Our hands are remarkably dexterous organs that we use to sense and manipulate objects. Hand dexterity depends on the fact that the somatosensory system uniquely contains a deformable sensory sheet - The relative positions of the cutaneous receptors in 3D space depend on the conformation of the hand. The haptic perception of 3D objects clearly requires combining cutaneous signals about the local events on multiple fingers with proprioceptive signals about hand postures. Critically, how proprioception and cutaneous sensing interact is poorly understood. In a series of behavioral experiments we investigated how hand posture influences the perception of vibrations over multiple fingers, i.e., multi-finger touch. For a measure of multi-finger touch, we first established how vibration information delivered simultaneously to

two fingers is combined. Preliminary results indicate that ignored vibrations delivered to one finger systematically influence the perception of attended vibrations delivered to a different finger. These multi-finger interactions depend on relative finger position: fingers spread further apart interact less than fingers held closely together. Lastly, we found that multi-finger interactions occur similarly within and across hands. To better understand these perceptual effects, we developed a probabilistic model capturing interactions between proprioception and multi-finger touch. We modeled cue interactions over multiple fingers as a linear combination of the probabilistic sensory representations of the attended and ignored cues. In our model, proprioception determines cue weighting - increasing the separation between fingers reduces the weighting of the ignored cue and increases the weighting of the target cue. These early results imply that the nervous system accounts for the relative positions of multiple fingers when combining sensory cues over them. Conceivably, the interactions between proprioception and multi-finger touch reflect the statistical regularities in how we sense and manipulate objects using our hands.

Abstract: Speech is multisensory by nature: we must move to speak, and these movements, which are visible to our interlocutors, complement the auditory information transmitted by the voice. Cerebral cortex is also essentially multisensory: even primary sensory cortices are sensitive to stimuli from modalities other than their own. Here, we explored how human visual cortex processes naturalistic audiovisual speech using intracranial EEG (iEEG) in patients with drug-resistant epilepsy. We recorded cortical responses to 10-s long stories consisting of naturalistic speech (modalities: AV, audiovisual; V, visual only; A, auditory only). iEEG electrodes were localized by co-registering pre- and post-implantation MRI and CT scans. We quantified cortical responses to speech stimuli by computing power in the alpha (8-13 Hz) and high-gamma frequency ranges (HGP, an index of local neuronal firing; 70-170 Hz). We defined visual cortex as those electrodes that lay in the occipital lobe and showed increased HGP to V speech stimuli, compared to the pre-stimulus baseline. Visual cortex responded to V and AV speech with a robust and sustained increase in neuronal activity, which dipped lower for AV than for V speech between 600 and 1200 ms into the stimulus before reaching a stable plateau (Figure, A). In contrast, HGP increased in delayed and crescendo fashion to A speech, rising above baseline about 1 second into the stimulus. Alpha power dropped in marked and sustained fashion in response to V and AV speech (more so for V than AV speech), whereas it slowly decreased in response to A speech (Figure, B). There was a significant negative correlation between HGP and alpha power in response to A speech, but not to V and AV speech (Figure, C). Our findings extend those of Schepers and colleagues (Cereb Cortex 2015), who recorded iEEG responses to single-word stimuli. The delayed HGP increase in visual cortex in response to purely auditory speech, and its negative correlation with the reduction in alpha power, suggest that crossmodal sensory inputs modulate neuronal firing in visual cortex through oscillatory mechanisms.

Title: Haptic object representation in lateral occipito-temporal cortex depends on hand location and gaze direction

Authors: *L. STROTHER[1], Z. ZHOU[1], T. VILIS[2], J. C. SNOW[1];
[1]Dept. of Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Physiol., Univ. of Western Ontario, Brain and Mind Inst., London, ON, Canada

Abstract: Human lateral occipito-temporal cortex (LOTC) plays a central role in visual object recognition, and there is growing evidence that LOTC may also play an important role in haptic object recognition. During visual object recognition, LOTC shows gaze-centered (retinotopic) responses in fMRI experiments. The relevant reference frames for LOTC during haptic object recognition are not fully understood. For instance, reference frames for haptic object recognition processes in LOTC may be hand-based, body-based, gazed-based or all three in combination. We used fMRI to test whether or not the neural representation of familiar objects in LOTC depends on the location of the palpating hand with respect to the body. Right-handed participants palpated objects using the right hand, either on the right side of the body or on the left (by crossing the right hand over midline). Objects were always hidden from view, but a mirror enabled subjects to gaze in the direction of the object, or away from it. Our main prediction was that left LOTC would show greater fMRI responses when objects were palpated on the right side of the body as compared to the left, and the opposite for right LOTC. If so, this would parallel the known contralateral bias in LOTC (in both left and right hemispheres) for visually presented objects with respect to the visual field. Our secondary prediction was that fixating in the direction of the palpated object would result in greater fMRI responses in LOTC than looking away, in accordance with prior findings related to visually guided action. In contrast to our main prediction, the magnitude of fMRI responses in left LOTC showed no dependence on the location of the palpated object with respect to the body. Surprisingly, however, fMRI responses in right LOTC were greater for objects palpated on the right (ipsilateral) side of the body as compared to the left. This intriguing result was opposite to our main prediction, which was that LOTC would show greater fMRI responses to objects palpated on the contralateral body side. Related to our second prediction, fMRI responses in right LOTC were greatest when participants palpated objects on the right side of the body and directed gaze toward the object.

Title: Neural basis of the crossmodal correspondence between auditory pseudowords and visual shapes.

Authors: *K. MCCORMICK[1], S. LACEY[1], R. STILLA[1], L. C. NYGAARD[1], K. SATHIAN[1,2]; [1]Emory Univ., Atlanta, GA; [2]RR&D Ctr. for Visual and Neurocognitive Rehabilitation, Atlanta VAMC, Atlanta, GA

Abstract: Behavioral research has demonstrated systematic crossmodal correspondences for many perceptual domains, e.g., between pseudowords and visual shapes bearing protuberances varying from rounded to pointed: the pseudoword “kike” (pronounced kee-kay) is typically associated with pointedness and the pseudoword “lomo”, with roundedness. Such correspondences, termed “sound symbolic”, have been theorized to underlie the origins of human language. The neural mechanisms mediating these correspondences are unknown. Here we used functional magnetic resonance imaging (fMRI) to examine the neural basis of the sound symbolic crossmodal correspondence between auditory pseudowords (“kike”, “lomo”), and pointed/rounded visual shapes. Participants (n=19) were presented with audiovisual stimuli in a block design. Stimuli either congruent or incongruent with respect to the sound symbolic correspondence occurred in separate, interleaved blocks. Participants attended to either auditory or visual stimuli, performing a two-alternative forced-choice on the attended modality. Reaction times (RTs) were recorded (RTc: RT for congruent trials; RTi: RT for incongruent trials). A neural incongruency effect (IE), indexed by greater blood oxygenation level-dependent (BOLD) responses for incongruent trials relative to congruent trials in the attend-auditory condition alone, was observed bilaterally in regions implicated in attention or cognitive control, including the frontal eye fields (FEFs), middle and inferior frontal gyri (MFG, IFG), anterior insula, intraparietal sulcus (IPS), and cingulate cortex. Many of these regions had IEs correlating negatively across individuals with the behavioral IE: (RTi - RTc)/(Rti + RTc); the negative correlation indicates that people with smaller behavioral IEs had stronger BOLD IEs.
Three localizers, run to test proposed explanations for crossmodal correspondences, showed, among voxels with IEs: about a quarter, located in the MFG and IPS bilaterally and the right

anterior insula, were more active when audiovisual stimuli were asynchronous than synchronous; some foci, in the right FEF, IFG and IPS, were active during magnitude estimation; and a few left IFG foci were active during semantic processing. Our findings may reflect multiple neural processes during processing of incongruent sound symbolic stimuli, including deployment of attention and/or cognitive control, multisensory processes, magnitude estimation (e.g. of roundedness or pointedness), and only minimally, semantic mechanisms.

Abstract: Peripersonal space (PPS) defines the neural representation of the space immediately surrounding our bodies. This representation is essential for us to interact with our surrounding environment. Numerous studies have shown that PPS is plastic and can change, for example, when a subject uses an external tool. Conversely it has been shown that PPS shrinks for amputee patients around their stump. Here, we investigated the PPS for paraplegic patients produced by a

chronic spinal cord injury (SCI). This was done by implementing a new technique based on a combined audio-tactile stimulation to assess PPS boundaries. After repeated measures in seven SCI patients, we identified a smaller PPS around the lower limbs when compared to a group of healthy subjects. The PPS boundary in SCI patients was also less well defined than in healthy subjects. Moreover, we observed that just a few minutes walking using a robotic gait trainer were enough to enhance the PPS of SCI patients.

Title: Early multisensory comparison and integration in peri-hand space

Authors: ***J. LIMANOWSKI**, F. BLANKENBURG;
Educ. and Psychology, Freie Univ. Berlin, Berlin, Germany

Abstract: To guide the body's actions in the world, the brain needs to integrate information coming from visual and somatosensory systems into a coherent representation. Here we investigated the early phase of such multisensory integration by manipulating the congruence of visual and proprioceptive information about hand position and the congruence of visual and tactile touch locations on the same hand.
We assessed brain activity using functional magnetic resonance imaging (EPI, TR = 2 s, 3x3x3 mm voxel size) while thirteen healthy participants had their right hand placed in a custom rotatable apparatus that was used to change their hand's position passively, and were presented a virtual, photorealistic hand in 3D via stereoscopic goggles in a position corresponding to their real hand. The virtual hand was always in an "anatomically plausible" position, even when incongruent to the real hand's one. We applied simultaneous touches (6 s duration, 14 s rest, jittered onsets) to either the index finger or the little finger on either hand: the virtual hand model's fingers were touched by little rods that moved up and down in an unpredictable rhythm at about 1.5 Hz; the real hand's fingers were simultaneously "touched" by electrotactile impulses. In between stimulations (no virtual hand visible), the position of the participant's real hand was changed passively from palm facing to back facing, or vice versa. Thus each presentation was an unpredictable combination of real and virtual hand position (congruent or incongruent) and touch location (same finger or different finger).

We observed significant ($p < 0.05$, corrected for multiple comparisons) activity increases during visuo-proprioceptive congruence in the bilateral inferior parietal lobe and the left medial superior parietal lobe, and at uncorrected thresholds also in the premotor cortex. The cerebellum and posterior superior temporal sulcus relatively increased their activity during incongruent arm position presentations ($p < 0.001$, uncorrected). We observed significant activity increases during touch applied to the same versus different fingers in the left anterior insula ($p < 0.05$, corrected) and at uncorrected thresholds also in the left ventral premotor and prefrontal cortex, posterior parietal cortex, and lateral occipitotemporal cortex. These activations likely indicate the early phase of multisensory comparison and integration processes that ultimately help construct a coherent body representation. Our results suggest different brain networks involved in processing visuo-proprioceptive position information, and in comparing and remapping visuo-tactile reference frames.

Title: Ownership of a hand increases its visibility in binocular rivalry

Authors: *B. VAN DER HOORT, M. REINGARDT, H. H. EHRSSON;
Karolinska Institutet, Stockholm, Sweden

Abstract: In binocular rivalry both eyes receive different visual input, which leads to the alternating perception of each eye's input. Binocular rivalry is often used to investigate visual awareness, and the processes that affect it. For example, previous studies have shown that binocular rivalry can be influenced by sensory modalities other than vision, such as tactile, proprioceptive, and vestibular senses. Here, we hypothesized that if one of the competing images is a hand, its visual dominance would be enhanced when participants experience ownership of

that hand. More specifically, the brain favours the visual processing of a hand stimulus if that hand is our own.
To investigate this, we performed two within-subject binocular rivalry experiments in which the image of a hand was presented to one eye and the image of a mask to the other eye. In Experiment 1 (n=30), we manipulated the visual appearance of a touch and the tactile sensation of a touch. The "seen touch" was the presence of a moving ball attached to a stick, presented to both eyes. The "felt touch" was the tactile stimulation of a participant's veridical hand by a similar ball on a rod. In the 'visuotactile condition', the seen touch and the felt touch were synchronous and spatially congruent, which elicits the illusory percept that the hand in view is one's own hand (body ownership). Importantly, this also led to the hand image being more dominant compared to when only the seen touch was present ('visual only condition'), only the felt touch was present ('tactile only condition'), or neither was present ('baseline condition') (vs visual only: $t(29) = 2.54$, $p = 0.017$; vs tactile only: $t(29) = 4.39$, $p < 0.001$; vs baseline: $t(29) = 4.58$, $p < 0.001$). Furthermore, we found that participants that rated stronger feeling of ownership had a larger effect of visuotactile stimulation of the hand (Spearman correlation: $\rho_S = 0.61$, $p < 0.001$). In a second experiment (n=30) we manipulated ownership of the hand directly by rotating the image of the hand. A rotated hand does not allow for the sensation of ownership because it is not spatially congruent with the sensed position of one's veridical hand. Importantly, disrupting ownership of the hand this way, caused the effect of visuotactile stimulation to disappear ($F(1,29) = 6.62$, $p < 0.012$). Summarizing, we found that perceived body ownership can affect visual awareness of the image of a hand in a binocular rivalry paradigm. This finding increases our understanding of the interaction between the representation of our body and the visual system, by showing that our body representation can affect visual processing at the early stages at which binocular rivalry takes place.

Title: Neural substrate of the correspondence between abstract auditory and visual information: an investigation through crossmodal multivariate pattern analysis

Authors: *S. KANAYA[1,2], H. YAMAMOTO[1], H. YAMASHIRO[3], T. MURASE[4], M. UMEDA[4], T. HIGUCHI[4], J. SAIKI[1];
[1]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan; [2]Japan Society for the Promotion of Sci. (JSPS), Tokyo, Japan; [3]Aino Univ., Osaka, Japan; [4]Meiji Univ. of Integrative Med., Kyoto, Japan

Abstract: Certain systematic relationships between seemingly unrelated multisensory information are referred to as crossmodal correspondence. For instance, a small figure and a high pitch may be perceived as congruent. In the present study, we performed multivariate pattern analysis (MVPA) on fMRI data to investigate how the correspondence between abstract multisensory information is represented in the brain and its relation to the crossmodal representation of natural objects based on daily experience. Abstract visual and auditory stimuli included four line drawings and four complex sounds, respectively. Visual stimuli included two line drawings consisting of curved lines (curvy figure) and two drawings consisting of straight lines forming an acute angle (sharp figure). Auditory stimuli included two sounds that were judged as congruent with the curvy figures and two sounds judged as congruent with the sharp figures. Natural visual and auditory stimuli included line drawings and the sounds of a fuurin (Japanese wind chime) and a string instrument, each of which had two exemplars. In each trial, one of the visual or auditory stimuli was presented unimodally in a 3T scanner. There were two task conditions. Participants in the no-image group passively observed stimuli and pressed a button when seeing a color change at the fixation point. Participants in the image group were informed of the correspondence between visual and auditory stimuli beforehand, and instructed to image the counterpart when presented with one of the stimuli. In MVPA, we trained a classifier to discriminate 'curvy' vs 'sharp' for abstract stimuli, and 'fuurin' vs 'string instruments' for natural stimuli. The classifier was tested to discriminate unlearned data either intramodally (e.g. training and testing with visual stimuli) or crossmodally (e.g. training with visual stimuli and testing with auditory stimuli). The results of intramodal MVPA revealed that relatively broad regions, including visual and auditory areas, showed reasonably high classification accuracy regardless of the stimulus or group. To the contrary, the results of crossmodal MVPA showed an interaction between stimulus and group. For abstract stimuli, above-chance accuracies were observed in several regions in the parietal and temporal lobes in both groups. For natural stimuli, high accuracies were observed in relatively broad regions in the image group, while almost no areas showed accuracies above chance in the no-image group. These results suggest that the correspondence between visual and auditory abstract information is represented in a different way from the crossmodal representation of natural stimuli in our brain.

Title: Effects of auditory processing on tactile sensory-evoked potentials (SEPs)

Authors: *G. SHEN, P. J. MARSHALL;
Temple Univ., Philadelphia, PA

Abstract: A number of recent behavioral studies examined the interactions between tactile sensation and speech perception. Auditory stimuli have been shown to enhance tactile frequency and intensity perception, and tactile stimulations of articulatory areas can influence phonological perceptual judgment. However, the mechanism underlying those observed interactions is still unclear. Is this cross-modal interaction restricted by temporal distance and semantic congruency, or is it a global type of modulation where one sensory input modulates the overall excitability of sensory regions? The current study examines temporal and congruency effects in somatosensory-auditory interactions using tactile stimulation and meaningful sounds, focusing on the somatosensory evoked potentials (SEPs) and mu rhythm fluctuations elicited to these events. Participants were presented with speech syllables (/pa/, /ka/) and finger snapping sounds followed by tactile stimulation to either their lower lip or their right middle finger in a random order. Intervals between the two sensory stimuli were set to 600ms, 200ms, or 0ms (simultaneous presentation). EEG signals were recorded as participants received auditory and tactile stimuli in pairs, and attended to the tactile sensation by detecting double-pulse tactile stimuli that were randomly mixed with single-pulse stimuli. We observed that early contralateral tactile SEPs in response to lip stimulation were modulated by speech processing only when intervals between the two events were 200ms or shorter. Preliminary results showed that /pa/ sounds significantly increased lip SEP amplitude as early as 50ms post-stimulus compared to /ka/ and finger snap sounds, while no differences were found in finger SEPs after the three different sounds. The results suggest that perception of a bilabial speech sound, /pa/, can enhance sensory excitability of the corresponding articulator. The findings of this novel auditory/lip-tactile paradigm indicate that somatosensory-auditory interaction is dependent on the critical temporal distance and congruency between the phonetic nature of speech sounds and the location of somatosensory stimulation. The findings may also shed light on the ongoing debate on the sensorimotor involvement in speech perception.

Title: Neural correlates of visual-haptic decision making in a texture discrimination task

Authors: *I. DELIS, P. SAJDA, Q. WANG;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: The signals delivered by different sensory modalities provide us with complementary information about the environment, which is then used to make perceptual decisions. Whereas the importance of multisensory integration for perceptual decisions has been appreciated in recent years, its underlying neural mechanisms still remain elusive. Importantly, the processing of multisensory information requires the interaction of multiple brain areas over time. Here we investigated the neural underpinnings of visual-haptic integration during performance of a two-alternative forced choice (2AFC) reaction time (RT) task. We asked human subjects to discriminate the amplitude of two texture stimuli a) using only visual (V) information, b) using only haptic (H) information and c) combining the two sensory cues (VH), while electroencephalograms (EEG) were recorded. Subjects' task performance - reflected in discrimination accuracy and reaction time - improved when both types of sensory signals were available. Modelling of the behavioral performance using a hierarchical drift diffusion model (HDDM) revealed that in the VH condition subjects accumulated evidence near-optimally across modalities. Single-trial analysis of whole-scalp EEG signals identified neural components discriminating the presented stimuli and/or the subjects' choices.

Title: Prestimulus oscillatory activity can provide predictive value for false perception of somatosensory stimuli

Authors: *K. YOSHINAGA[1,2], M. MATSUHASHI[3,5], T. HANAKAWA[1], T. MIMA[3,6], H. FUKUYAMA[3], R. TAKAHASHI[2], A. IKEDA[4];

Sch. of Core Ethics and Frontier Sci., Ritsumeikan Univ., Kyoto, Japan

Abstract: [Introduction]In a discrimination task, subjects sometimes report false detection of a stimulus (false alarm) in stimulus-absent trials, but the mechanisms of the false perception remain enigmatic. Recently, pre-stimulus oscillatory activity has been shown to affect subsequent human behaviors such as subjects' ability to detect a near-threshold stimulus in a discrimination task. In the present study, we tested a hypothesis that pre-stimulus oscillatory activity could predict perception of stimuli without physical exposure to stimuli. [Method]Healthy volunteers participated in the study. The participants were asked to detect a somatosensory stimulus (electric stimulation of the right digital nerve at a subject-specific near-threshold intensity level) given simultaneously with visual stimulus (LED stimulus much above the detection threshold). The somatosensory stimulus was delivered in a half of the trials ("S+V" trial) and only a visual stimulus was given in the rest ("V" trial). Participants sometimes reported detection of a somatosensory stimulus in the "V" trials, yielding "false alarm" (FA) and "correct rejection" (CR) trials. Ongoing brain activity was recorded with the 306-channel magnetoencephalography. We calculated pre-stimulus power differences between the FA and CR trials. To investigate phase effects, we evaluated a degree of deviation of phase distribution in each condition using Mardia-Watson-Wheeler test. [Result]In the power analysis, we found

that pre-stimulus power in the left central region was stronger in the CR trials than in the FA trials, suggesting an up-state of somatosensory areas in the FA trials. This power difference was identified in the alpha and/or beta frequency range at an individual level. In contrast, we found stronger pre-stimulus alpha oscillations in the parieto-occipital region in the FA trials than in the CR trials, suggesting a down-state of visual areas in the FA trials. In phase analysis, however, we found no remarkable phase deviation in either condition. [Conclusion]This result suggests that the combination of up-state of the somatosensory system and down-state of the visual system may lead to a generation of false perception in a somatosensory discrimination task.

Title: Cross-modal motion processing after sight recovery

Authors: *F. JIANG[1], A. N. SCURRY[2], I. FINE[3];
[1]Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Psychology, Univ. of Nevada Reno, Reno, NV; [3]Psychology, Univ. of Washington, Seattle, WA

Abstract: Recently we showed that hMT+ responses to auditory motion are associated with subjects' decisions about auditory motion direction in early blind individuals (Jiang et al., 2014). Here, we examine whether these cross-modal motion responses arise 'de novo' or co-opt residual visual architecture, by comparing visual and auditory responses to motion in a sight recovery subject, MM. MM acquired vision in adulthood after becoming blind at age three. Despite severe losses in acuity, MM has no known deficits in his ability to process visual motion and shows normal hMT+ responses to moving dots. However, as a result of being blind early in life, his hMT+ also shows robust cross-modal responses to auditory motion (Saenz et al. 2008).
We examined joint tuning for motion direction across visual and auditory stimuli in MM using both multivoxel pattern classification and fMRI adaptation. The direction of auditory motion could be successfully classified based on the pattern of BOLD responses within bilateral hMT+

to a visual motion stimulus, and vice versa, indicating congruence in architecture between auditory and visual direction motion tuning within hMT+. Furthermore, significant adaptation effects were found in the right hMT+ when using a visual adaptor - responses to auditory motion were weaker when auditory motion was in the same direction as the visual motion adaptor, suggesting shared neuronal tuning across vision and audition. Our results show that in area hMT+ the directionally tuned auditory motion responses induced by early blindness share common architecture with residual visual motion responses.

Title: Oscillatory EEG activity in the ventriloquist illusion

Authors: ***M. KAISER**, D. SENKOWSKI, J. KEIL;
AG Multisensorische Integration, Charité Universitätsmedizin Berlin, Berlin, Germany

Abstract: In our environment we are faced with a vast amount of stimuli that we integrate across the different sensory modalities to a unified perception. During this process, stimuli can exert cross-modal influence to modulate perception. One prominent example for this is the ventriloquist illusion, where sound localization is shifted in the direction of a concurrent visual stimulus, exemplifying cross-modal influence from the visual to the auditory modality. Recent ERP and fMRI studies have shown that the ventriloquist illusion is linked with activity asymmetries between left and right auditory cortices. Moreover, studies using other multisensory illusion paradigms have consistently shown pre- and poststimulus modulations in alpha, beta and gamma band oscillations in sensory and traditional multisensory integration areas related to illusory perception. Thus far, it is unknown whether cross-modal influence in the ventriloquist illusion is also reflected in oscillatory activity. Additionally, the role of neural oscillations prior to stimulus onset on the subsequent perception in this illusion is unknown.
In this study, we aimed to assess these questions using high-density EEG recordings from healthy subjects. We compared oscillatory activity between trials in which the illusion occurred and trials with veridical auditory localization. That is, we compared oscillatory activity between trials with invariable physical stimulus properties, but variable perception. We performed time-frequency analysis focusing on effects in the alpha, beta and gamma bands. Dependent-samples t-tests with Monte Carlo randomization and cluster-based correction for multiple comparisons were used for statistical analysis. Source space activity was reconstructed using beamforming techniques.
Our data indicate asymmetrical poststimulus oscillatory activity across both auditory cortices in illusion, but not in no-illusion trials. Furthermore, oscillatory activity in the visual cortex differed between illusion and no-illusion trials. Our findings indicate that the ventriloquist illusion is mediated by early oscillatory activity in sensory areas. These results have implications for the question whether the ventriloquist illusion reflects a perceptual effect rather than a result of later attributing the origin of the sound towards the visual stimulus. Our findings corroborate and

extend previous findings on the cortical mechanisms underlying the ventriloquist illusion and suggest that neural oscillations play an important role in this illusion.

Title: Network flexibility during multisensory integration of real-world events.

Authors: *G. LIEBERMAN[1,2], J. O. GARCIA[1], D. S. BASSETT[2], M. J. TARR[3], J. M. VETTEL[1,4,2];
[1]U.S. Army Res. Lab., Aberdeen Proving Ground, MD; [2]Bioengineering, Univ. of Pennsylvania, Philadelphia, PA; [3]Psychology, Carnegie Mellon Univ., Pittsburgh, PA; [4]Psychology, Univ. of California, Santa Barbara, CA

Abstract: Real-world events produce both auditory and visual signals that combine to form integrated perceptual experiences. Research suggests that binding perceptual signals from different senses depends on low-level cues such as temporal/spatial structure and high-level cues such as semantic labeling (Doehrmann & Naumer, 2008; Keetels & Vroomen, 2012). Importantly, these cues may rely on separable but interconnected networks (Tsilionis & Vatakis, 2016). Here, we use community detection to investigate how making explicit judgements about temporal synchrony and semantic congruency modulates brain activity in a distributed multisensory network. Fourteen volunteers participated in an fMRI study and viewed videos of real-world events that included multiple, discrete impacts (e.g., a pencil tapping, a maraca shaking). Videos were manipulated such that the timing and/or the semantics of the impacts could be congruent or incongruent in a 2x2 factorial design. For semantically incongruent conditions, the audiovisual movies contained the sound track from one event (e.g., water splashing) and the visual track from another event (e.g., clapping). For temporally asynchronous conditions, the visual and auditory impacts were offset by 500 milliseconds. Participants completed three tasks: passively viewing the stimuli, judging temporal synchrony, and judging semantic congruency.

Using the passive viewing task, we identified four network communities subserving audiovisual integration, and we compared how network flexibility varied within these communities when participants made explicit congruency judgments. During semantic judgments, a significant decrease in flexibility was detected in the left superior parietal lobe (FDR $q < 0.05$), driven by enhanced network allegiance between this region and nodes located bilaterally within the frontal cortices. Additionally, this difference in flexibility was pervasive across the brain: more communities were identified for judgments of temporal synchrony than for judgments of semantic congruence ($p < 0.0001$). These results provide some of the first evidence that semantic and temporal judgements differentially recruit dynamic brain networks when audio and visual components of real-world events are integrated within the brain.

Title: Neural correlates of a visuo-haptic illusion

Authors: *M. MOAYEDI[1,2], K. THEMELIS[3], T. V. SALOMONS[4], R. NEWPORT[3], J. LEWIS[5,2];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Univ. of the West of England, Bristol, United Kingdom; [3]Sch. of Psychology, Univ. of Nottingham, Nottingham, United Kingdom; [4]Univ. of Reading, Reading, United Kingdom; [5]The Royal Natl. Hosp. for Rheumatic Dis., Bath, United Kingdom

Abstract: The perception of our body can be easily manipulated, as evidenced by a variety of illusions that change the shape of the body, demonstrating that the manner in which the body is perceived is highly adaptive. These illusions disrupt the body schema – a virtual, dynamic multisensory map of the body within the sensory environment. The illusory disruption of the body schema can be reinforced by simultaneously manipulating two or more sensory channels.

For example, reinforcing a visual illusion with haptic stimulation substantially enhances the robustness of the illusion, and the rates of susceptibility. The combination of visual and tactile information requires multisensory processing and binding in higher order cortical regions, such as the extrastriate body area on the temporo-occipital junction and the posterior parietal cortex. We aimed to identify the neural underpinning of a robust visuo-haptic illusion where the finger is perceived as being stretched in response to being pulled, congruent with visual elongation.
18 healthy (10f, 8m) subjects consented to procedures approved by local ethics committees, and were were naïve to the finger stretch illusion. Subjects underwent fMRI scanning while viewing a digital image of their finger either undergoing a stretch or a sham illusion, where there was no digital alteration of the finger.
Trial-by-trial subjective ratings showed that subjects were more susceptible to the the finger stretch illusion than the sham illusion ($p<0.001$). Functional brain images showed greater brain activity in the mediodorsal thalamus, the mid-cingulate cortex, the extrastriate body area, the ventrolateral prefrontal cortex, the cerebellum and the posterior parietal cortex ($p<0.05$, corrected). These regions are implicated in salience detection and body perception disturbances. No regions showed significantly greater activity in the sham illusion than the finger stretch.
In sum, this is the first study to identify the neural underpinning of a visuo-haptic illusion altering body perception.

Title: Neural basis of the crossmodal correspondence between auditory pitch and visuospatial elevation

Authors: ***S. A. LACEY**[1], K. MCCORMICK[1], R. STILLA[1], L. NYGAARD[1], K. SATHIAN[1,2]; [1]Emory Univ., Atlanta, GA; [2]RR&D Ctr. for Visual and Neurocognitive Rehabilitation, Atlanta VAMC, Atlanta, GA

Abstract: Behavioral research has demonstrated systematic crossmodal correspondences for many perceptual domains, e.g., a high-pitched auditory stimulus is associated with a visual stimulus at a high spatial elevation, whereas a low-pitched auditory stimulus is associated with a visual stimulus at a low spatial elevation. The underlying neural mechanisms are unknown. In the present study, we used functional magnetic resonance imaging (fMRI) to examine the neural basis of the crossmodal correspondence between auditory pitch and visuospatial elevation. Participants (n=18) were presented with audiovisual stimuli in an event-related design, so as to be either congruent (e.g. a high-pitched tone and a circle positioned high in space) or incongruent with respect to the pitch-elevation correspondence. Participants engaged in a one-back (same/different) task. Reaction times (RTs) were recorded (RTc: RT for congruent trials; RTi: RT for incongruent trials). A neural congruency effect (CE), indexed by greater blood oxygenation level-dependent (BOLD) responses for congruent trials relative to incongruent trials, when each trial type was preceded by a trial of a similar type, was observed in: the right superior frontal gyrus, supplementary motor area (SMA), anterior insula, superior temporal sulcus (STS) and putamen; and bilaterally in the inferior frontal gyrus (IFG), postcentral gyrus (poCG), parietal operculum (POp), precuneus and parieto-occipital fissure. The precuneus and parieto-occipital CEs correlated negatively across individuals with the behavioral CE: (RTi - RTc)/(Rti + RTc); the negative correlation indicates that people with smaller behavioral CEs had stronger BOLD CEs. Many of the regions showing the BOLD CE are implicated in multisensory processing; the involvement of somatosensory cortical regions (poCG, POp) may reflect somatosensory correspondences of the stimuli. Separate localizers, run to test proposed explanations for crossmodal correspondences, established that the right STS, IFG and SMA were sensitive to audiovisual synchrony (the first two being preferentially active when audiovisual stimuli were asynchronous and the SMA when they were synchronous), while the right STS focus was also part of a region engaged during semantic processing. However, none of the regions showing the BOLD CE were active during magnitude estimation, arguing against this as a primary mechanism. Our findings suggest that the neural substrates for the pitch-elevation correspondence are spatially distributed and involve multisensory processes.

Title: Investigating the rubber hand illusion using electrocorticography

Authors: *A. GUTERSTAM[1], K. COLLINS[2], J. CRONIN[2], K. WEAVER[2], J. OJEMANN[2], H. EHRSSON[1];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Univ. of Washington, Seattle, WA

Abstract: The question of how the brain self-attributes body parts is a central issue in both cognitive neuroscience and applied neuroprosthetics. Studies using the rubber hand illusion (RHI), a perceptual illusion in which ownership of an artificial limb is elicited through the concurrent touching of a rubber hand in view and a participant's hidden real hand (Botvinick & Cohen 1998 Nature), have highlighted multisensory integration within peripersonal space as a key mechanism for limb self-attribution. Several neuroimaging studies have found an association between the experience of the illusion and increased fMRI-BOLD responses in multisensory brain regions in the premotor and posterior parietal cortices (e.g., Ehrsson et al. 2004 Science; Guterstam et al. 2013 JOCN). To date, however, no study has characterized the direct neurophysiological correlates of the RHI in humans. To this end, we studied the RHI using electrocorticography (ECoG).

Five patients with medically refractory focal epilepsy undergoing pre-surgical invasive seizure monitoring volunteered for this study. During the experiment, the subjects rested comfortably in their hospital bed with the head of the bed titled. Their arm was hidden behind a screen, while a lifelike rubber hand was placed in front of the screen in full view. To induce the illusion, a digital touch probe was used to repeatedly deliver touches to the rubber and real hand simultaneously. In two control conditions, the touches were applied asynchronously or using a rotated rubber hand, which are established methods to break the illusion.

The synchronous condition generated significantly higher ratings of rubber hand ownership than did the asynchronous and rotated control conditions (both $p<0.05$). The ECoG results showed that the synchronous illusion condition was associated with significantly ($p<0.05$, corrected) increased high-gamma power (70-150 Hz) in electrodes located along the intraparietal sulcus and the ventral and dorsal premotor cortex. In two patients, we conducted separate fMRI experiments prior to electrode implantation, allowing for a direct comparison between BOLD and electrophysiological responses within single subjects. In sum, these results constitute the first direct electrophysiological evidence that the feeling of ownership of a seen limb is associated

with increased neuronal activity in multisensory cortical regions. Finally, the superior temporal resolution of ECoG (1220 Hz) compared to fMRI (<1 Hz) renders it possible to study dynamic interactions between cortical regions of interest, potentially revealing important clues about the underlying neuronal mechanisms of bodily self-attribution.

Title: Practice order effects of arm movements with tactile vs. visual guidance

Authors: P. J. LEE, L. SIMPSON, *S. N. KUKKE;
Biomed. Engin., The Catholic Univ. of America, Washington, DC

Abstract: Preliminary studies have provided evidence that performing touch-guided movement (TM) may promote improved performance on future visual-guided movement (VM). However, the specificity of this potential order effect to initial TM guidance remains to be tested. The overall goal of this study was to test the behavioral and electrophysiological effects of TM or VM practice on subsequent TM and VM tasks.
Twenty right-handed, healthy adults (19-34 yrs) entered this IRB-approved study. They traced 6 irregular shapes (path length=45.7±3.6 cm) with the right index finger using 1 of 2 sensory modalities for guidance. In the TM task, movement was guided by tactile feedback of bumps along the path. In the VM task, movement was guided by vision of dots along the path seen through a small circular window at the fingertip. Each participant performed 120 serial trials in one of four groups: 1) TM-VM (i.e., 60 TM followed by 60 VM trials, n=8); 2) VM-TM (n=8); 3) TM-TM (i.e., 120 TM trials, n=2); and 4) VM-VM, (n=2). The trace time of each trial and electroencephalographic (EEG) data from 28 scalp leads were recorded. Cortical activation was quantified by the drop in task-related power (TRP), the log-ratio of spectral power during the task to rest.
Trace time decreased with both TM and VM practice. Initial TM, as opposed to VM, practice

appeared to be associated with lower trace times in subsequent TM and VM trials. Cortical activation in the alpha (8-12 Hz) and beta (13-30 Hz) bands decreased to approximately zero during the VM task only when preceded by TM (and not VM) practice. There was a focal cortical activation pattern when TM was performed first, and a widespread pattern when VM was performed first. This initial sensorimotor set remained whether the subsequent task was the same or different from the first.
This study provides evidence that initial TM practice has the potential to influence the performance and neurophysiological state during future movements guided by touch or vision. After further data collection from individuals in the TM-TM and VM-VM groups, a full-factorial repeated measures ANOVA will be used to quantify effects of initial practice modality on trace time, alpha TRP, and beta TRP. Knowledge of the cross-modal transfer between TM and VM arm movements will form a scientific basis for the choice and practice order of therapeutic activities in neurorehabilitation of hand function.

Title: Sound-contingent visual motion perception: Evidence from functional neuroimaging

Authors: W. TERAMOTO[1], S. HIGUCHI[2], *Y. SUGITA[3], S. HIDAKA[4];
[1]Psychology, Kumamoto Univ., Kumamoto, Japan; [2]Div. of Ultrahigh Field MRI, Iwate Med. Univ., Morioka, Japan; [3]Dept. of Psychology, Waseda Univ., Tokyo, Japan; [4]Psychology, Rikkyo Univ., Tokyo, Japan

Abstract: After a paired presentation of visual apparent motion with the alternation of two different tones for several minutes, the tones are able to trigger visual motion perception for a static object (SCVM: sound-contingent visual motion). Here we investigated neural mechanisms underlying SCVM using an fMRI adaptation technique. In a 3-min association session, two white circles placed side by side were alternately presented. The onsets of the two circles were synchronized with high and low frequency tones, respectively. Before and after this association, test sessions were conducted while simultaneously measuring brain activity. A trial in each test session consisted of three successive conditions: apparent visual motion with the tones (3 s,

"AM1"), a blinking visual stimulus at a fixed location with the tones (6 s, "BL"), and AM2 (3 s), which is the same as AM1. The audiovisual stimuli of AM1 and AM2 were consistent with those of the association session. We expected that after the association was formed, participants would perceive visual motion in the BL as well as AM1 conditions, resulting in decreased activation in areas related to SCVM in the AM2 condition. Before the association, areas related to visual motion processing and to multisensory processing were activated in both the AM1 and AM2 conditions. In contrast, after the association, these areas were not significantly activated in the AM2 condition while continuing to be activated in the AM1 condition. These results suggest the involvement of visual motion and multisensory processing areas in SCVM. (1666 / 2300 characters)

Title: Visual cortical activation during processing of shape metaphors in congenitally blind people

Authors: *V. OCCELLI[1], S. LACEY[2], R. STILLA[2], C. STEPHENS[2], K. MCCORMICK[3], D. KEMMERER[4], K. SATHIAN[2,5];
[1]Cimec, Univ. of Trento, Trento, Italy; [2]Dept. of Neurol., [3]Dept. of Psychology, Emory Univ., Atlanta, GA; [4]Dept. of Psychological Sci., Purdue Univ., West Lafayette, IN; [5]RR&D Ctr. for Visual and Neurocognitive Rehabil., Atlanta VAMC, Atlanta, GA

Abstract: Numerous studies have shown that the visual cortex in congenitally blind people is more active than in normally sighted controls, during both language and sensory tasks. It remains uncertain whether the relevant non-visual functions reflect a combination of sensory and language processes, or whether one of these kinds of processing is dominant. It is possible that the visual cortex assumes non-visual sensory functions in those with congenital blindness, and that its recruitment during language tasks is due to the grounding of language in sensory processes. Metaphorical language is associated with sensorimotor cortical activity in areas processing domain-specific information relevant to the metaphors under consideration. For instance, metaphorical use of action verbs engages motor-related cortical activity (Desai et al.,

NeuroImage, 83: 862-869, 2013); textural metaphors recruit texture-selective somatosensory cortex (Lacey et al., Brain & Language 120: 416-421, 2012); and metaphors referring to body parts activate the extrastriate body area of visual cortex, an area responsive to visual images of body parts (Sathian et al., SfN Abstracts 204.1, 2014).
We therefore asked whether visual cortex in congenitally blind people is more responsive during processing of metaphors than in sighted people. This would be consistent with the hypothesis that sensory grounding of language drives visual cortical activation in congenital blindness. We tested this idea in the domain of shape using auditory presentation of sentences containing shape-related words in metaphorical and literal contexts, along with control sentences matched on a number of linguistic and acoustic variables, while congenitally blind and sighted control participants underwent functional magnetic resonance imaging (fMRI) in an event-related design. Analysis of the resulting fMRI data indicates that the congenitally blind group exhibited significantly greater metaphor-selective activity in multiple regions of visual cortex, compared to sighted controls. Some of these regions demonstrated shape-selectivity for visual stimuli in the sighted participants. These findings are consistent with the hypothesis that sensory grounding of language underlies visual cortical activation in congenital blindness, and offer a potential explanation for previous reports that visual cortex in congenitally blind people is responsive during both language and sensory tasks.

Title: Neural correlates and quantitative assessment of ankle joint position sense: a fMRI study.

Authors: *R. IANDOLO[1,2], A. BELLINI[3], G. BOMMARITO[3], I. MARRE[2], N. OESINGMANN[4], L. FLEYSHER[4], F. LEVRERO[3], G. MANCARDI[3], M. CASADIO[2,1], M. INGLESE[3,4];
[1]Italian Inst. of Technol., Genova, Italy; [2]Dibris, [3]DINOGMI, Univ. of Genoa, Genova, Italy; [4]Neurol., Mount Sinai school of medicine, New York, NY

Abstract: The ability to identify the position of lower limb joints in space is critical for ambulation, for maintaining balance and for any fine motor movements. The joint position sense is likely to be affected by neurological diseases since it results from a complex process of integration of sensory inputs from different peripheral receptors.
Despite its relevance, very little is known about the physiopathology underlying sensory deficits of distal lower limbs, especially in terms of neuronal correlates. Our final objective is to verify the hypothesis that, in addition to the motor dysfunction, deficits of lower limbs proprioception can induce specific neural modifications that impact daily life tasks such as standing and walking. As first step toward this goal, we investigate the ankle position sense in 23 healthy adults (12 female, 27.7 years, min 23 max 37). Proprioception was evaluated while performing the following unilateral and bilateral matching tasks with both the dominant and the non-dominant foot:
1.Unilateral matching: the ankle was passively moved toward a pre-defined inclination and back to the baseline position. Then, subjects were required to match the desired previous position with the same foot.
2.Bilateral matching: the subject's foot was moved to a predefined inclination. Subjects had to reach the same position with the contralateral foot. When the subjects reached the position, the ankles were repositioned back to the baseline position and another movement started towards a new inclination value. Four positions were presented: two for the plantar-flexion, one for the dorsi-flexion and one neutral. Each position was presented in pseudo-random order and at least four times. These tests were performed outside and inside the MRI environment with subjects lying in supine position. We used a custom built MRI-compatible device with two detached platforms that allow for the independent motion of each foot. The ankle movements were measured by two custom-made optical encoders. The protocol included also active and passive dorsi-plantarflexion motion of the dominant ankle and of both ankles (in phase). In addition to the fMRI, the MRI protocol includes structural T2 weighted and 3D T1 weighted sequences for brain volumetric assessment and Diffusion Tensor Imaging for microstructural assessment of white matter tracts. This protocol allowed us to characterize the ability to correctly identify the ankle position for each limb and to estimate the differences between the matching modalities as well as the dependence of the performance on the angular degrees of rotation.

Title: The characteristic of motor learning across lifespan

Authors: *M.-H. LEE;
Michigan State Univ., East Lansing, MI

Abstract: Do people at different ages learn motor tasks differently? One challenge is that motor learning ability in different age groups is also confounded by differences due to prior experience and changes in physical abilities such as speed and strength. Therefore, to minimize these differences, we utilized a virtual task which required participants to learn a novel upper body coordination pattern.
We examined the motor learning process at different ages (between 9 and 70 years of age) in a virtual reaching task. In this task, inertial measurement units were attached to the upper body and these movements were mapped to the position of a computer cursor. Critically, this map was customized so that each individual could complete the task using their own movement repertoire. The goal of the participants was to learn to move the cursor in a center-out reaching task to 8 different targets. There were 160 trials in total toward 4 targets during practice session. Three generalization tests were interleaved during learning (pre, during and post-practice), where participants reached toward all 8 targets. These tests were used to evaluate changes in performance with practice.
We found that in spite of using a novel virtual task to minimize usual confounds in studying age-related differences, there were clear age-related differences in learning. All groups improved with practice, but there was a U-shaped trend for movement time, with children (less than 12 years old) and older adults (more than 50 years old) taking significantly longer to perform the task than younger adults. Moreover, when we examined the rate of learning using an exponential fit, we found that the rates of learning also showed a similar U-shaped trend, with slower rates of learning in children and older adults compared to younger adults. These results show that age-related differences in motor learning cannot be explained simply as performance differences - instead, they reflect differences in underlying learning mechanisms.

Title: Building prediction models for clinical recovery after stroke

Authors: *Y. ABDEL MAJEED[1], S. AWADALLA[2], J. L. PATTON[1,3];
[1]Bioengineering, [2]Biostatistics, Univ. of Illinois At Chicago, Chicago, IL; [3]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Chronic stroke survivors respond to treatments in varying degrees, and prediction of recovery may help forecast recovery time and may even guide therapy by identifying important aspects of movement. Clinical evaluations allow some quantification of ability and function, but features captured by robotic devices allow a library of available metrics that could more accurately predict patient improvement. In this work, we use our knowledge on the first day of a study, including demographic information, to build first- and second-order predictive models that anticipate the patient's recovery over three weeks.

Twenty-six stroke survivors performed a reaching task in a 3D virtual environment. Subjects were matched through their intake Fugl-Meyer scores with scores ranging from 25 to 49 for Fugl-Meyer and from 2.59 to 49.24 for the Wolf Motor Function test. Extracted features of their movements, their demographic information, and their clinical ratings on the first day were used to predict outcomes at the end of our three-week randomized controlled clinical study. We employed two state-of-the art modeling techniques (LASSO regression and Random Forests) to obtain a robust model. This involved 100-fold cross validation and fitting each model using mean predictions.

Here, we present the results of our cross-validated predictive modeling efforts to accurately predict both clinical recovery (R^2 ranging from 33% to 99%, depending on the modeling method) and identify factors most relevant to the recovery process (speed-related metrics generally ranked higher, and were negatively correlated to clinical recovery). The best modeling method (Random Forests) predicted Fugl-Meyer at a level of 97% and Wolf Motor Function at 96%. This improves on previous predictions and also provides a ranking of the most important features. These features can then be targeted in future treatment designs to improve patients' performance and recovery time.

Title: Movement reorganization and space representation through the operation of a body-machine interface

Authors: *C. PIERELLA[1], F. ABDOLLAHI[2], E. THORP[2], A. FARSHCHIANSADEGH[3], I. SEANEZ[2], F. A. MUSSA-IVALDI[2], C. MAURA[4];
[1]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL; [3]Northeastern Univ., Chicago, IL; [4]Univ. of Genoa, Genoa, Italy

Abstract: People with paralysis must reorganize their residual mobility for performing activities of daily living. We have developed a system, the body-machine interface (BMI) that facilitates this reorganization by capturing motions of the upper body through a set of inertial sensors and by mapping the sensor signals into the coordinates of a computer cursor. By moving the computer cursor, the BMI user can perform a variety of different tasks, such as controlling the direction and speed of a virtual or real wheelchair, entering text, playing computer games and navigating the internet. Importantly, as the users interact with the BMI they also perform physical exercises so structured to aim at specific rehabilitative goals, such as increasing the range of body motions, maintaining and improving strength, enhancing movement smoothness, coordination and symmetric control of right and left body sides.The BMI exploits the abundance of degrees of freedom, which even in severe forms of paralysis are in excess of the two coordinates necessary to specify the position of the computer cursor. Because of redundancy, the cursor can be placed at any target position by the user assuming one of many "equivalent" body configurations. Therefore, the BMI allows us to investigate the mechanisms underlying movement reorganization and gain a deeper understanding of motor learning and recovery. In particular, here we investigated the representation of the BMI formed by subjects while engaging in a variety of tasks. In principle, because of redundancy subjects may learn different ways to control the motion of the cursor, depending on the task that they are practicing. Alternatively, they may learn a single representation. We found that over an extended training period of 28

sessions, subjects tended toward similar representations. However, the similarity did not become an identity. As they engaged in different tasks, the subjects appeared to maintain a small but systematic residual difference in the body configurations used to place the cursor on the same locations. This is consistent with findings from other studies suggesting that people exploit redundancy to minimize task-related costs. The "null space" variability is not simply noise but it retains structure that reflecting control optimizations orthogonal to the kinematic goals of the task.

Title: Manipulating joint angle positions and visual feedback.

Authors: ***M. SMITH**;
Biomed. Engin., Northwestern Univ., Chicago, IL

Abstract: At the Rehabilitation Institute of Chicago Robotics lab, we investigate how the nervous system is capable of gathering extrinsic information about the environment and using this to change our motor control strategy by taking advantage of redundant degrees of freedom as we become more proficient at a motor task. In our experiment, we exposed subjects to a redundant system where they controlled the three angles of a 3-link planar arm-like mechanism, ultimately controlling the cursor located at the tip of the chain in the X-Y plane. This setup allows us to observe how subjects take advantage of the redundancy of the system. In fact, there exist multiple joint angles of the kinematic chain (Θ1, Θ2, and Θ3) to arrive at the same X-Y coordinate of the screen. Over a two day training period subjects were tasked with controlling the cursor on the end of the arm mechanism and place it on various targets. Subjects were divided into two groups: the first group had complete vision (CV) of the kinematic chain and the cursor; the second group, minimal vision (MV), could only see the cursor but not the arm mechanism. I expect that the information gained from this experiment will explain how we use visual

knowledge about the structure of a redundant mechanism for learning how to control it and to take advantage of the versatility offered by the abundance of its degrees of freedom.

Title: Designing movements by injecting visuomotor noise

Authors: *E. B. THORP[1,2], F. A. MUSSA-IVALDI[1,2,3];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Biomed. Engin., Northwestern Univ., Evanston, IL;
[3]Physiol., Northwestern Univ., Chicago, IL

Abstract: The human motor system is characterized by an excess in the degrees of freedom it must control compared to the number necessary to complete most tasks. Accordingly, every movement that we make is selected from a large set of seemingly equivalent movements. Some theories assume that the central nervous system (CNS) when offered the possibility to achieve a goal with different movements, selects the movement that is least effected by motor noise. These theories make the direct prediction that if the relationship between movements and noise changed, the movements people make would also change in a predictable manner. Here, we test the hypothesis that by strategically designing artificial signal dependent noise, we can elicit desired motor behaviors. We inserted noise into a novel motor task, where subjects used hand movements (4 degrees of freedom) to control a computer cursor (2 degrees of freedom). Measurements of bilateral hand movements were linearly mapped to the location of a cursor on a computer monitor. For this task, there are infinite hand postures that result in a single cursor location. Signal dependent noise was artificially inserted such that the jitter of the cursor at each location on the screen was dependent on the hand posture. We found that this paradigm is effective at biasing subjects towards learning to make movements that were less affected by noise. Subjects who trained with the noise paradigm learned to use coordination patterns that were significantly closer to the desired policy than subjects who trained with no additional noise. Interestingly, we also found that adding signal dependent noise led to significantly improved task

performance when visual feedback was removed. To further investigate this, we studied the relationship between exploration of the control space and bothtask performance and the ability to avoid task specific noise.These results confirm that people plan movements in an attempt to minimize task specific variability. Additionally, they validate the concept that designing signal dependent noise can be an effective means to elicit desired motor behaviors. These results have broad implications for designing more effective rehabilitation paradigms to improve the performance of human-machine interfaces.

Title: Intermittency frequency modulation produces changes in movement distributions along reach to target

Authors: *A. K. SHAH[1], J. L. PATTON[2];
[1]Univ. of Illinois at Chicago, Chicago, IL; [2]Sensorimotor Physical Performance, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Excessive movement variability, especially in individuals with neurotrauma (stroke, TBI), can cause people to exceed task limits and lead to falls or accidents in the workplace or other events of "high cost". This is especially true in novel task dynamics when a person must perform a new task such as playing guitar for the first time. People often have a multitude of actions to choose from when executing complex tasks. Action-selection in these tasks can produce variable outcomes as a result. Compounded with this action-selection variability is the variability that stems from movement execution, novelty of the task and distorted conditions from prior well-learned tasks. We had previously shown how a simple agent that stores negative experiences as local regions of cost can produce movement distributions similar to a task where subjects had to learn to distribute their motions within an invisible zero-cost region through a variant of the Multi-Armed bandit principle of explore and exploit, instead choosing to use the principle of explore and avoid. Here we show the same controller can be used to observe error variations in targeted reaching by modulating intermittency frequency of replanning and submovement generation and its effect on targeted reaching. Further development of this controller has been done to show the applicability of this paradigm on a multitude of tasks. It can

potentially be used as a predictive model of movement distributions given some chosen parameter values of replanning interval, motor noise, width of influence and penalty increment.

Title: Modulating motor variability during bimanual reaching in stroke

Authors: ***R. RANGANATHAN**[1], R. GEBARA[2], M. T. ANDARY[2], J. R. SYLVAIN[2]; [1]Dept of Kinesiology, [2]Dept of Physical Med. and Rehabil., Michigan State Univ., East Lansing, MI

Abstract: There is controversy over the use of the "unaffected" hand in stroke rehabilitation - while certain therapies like constraint-induced movement therapy restrict the use of the unaffected hand, bimanual therapy encourages active use of both hands. In this study, we examined how the two hands compensate for each other during a bimanual reaching task that was redundant. Adults with chronic stroke, with mild to moderate arm impairments volunteered for the study. Markers were attached to joints on both arms to measure movement using a motion capture system. The goal of the participants was to perform a virtual reaching task - where they attempted to move a cursor on a screen to different targets by moving their hands on a table. Critically, the cursor position was "weighted" between the positions of the two hands - signifying that there were multiple solutions to perform the task. Participants completed the task in three weighting conditions with the weights on the affected hand and unaffected hand being - (i) 80%-20%, (ii) 50%-50%, and (iii) 20%-80%. Participants were not informed about which condition they were performing - they were simply asked to reach with both hands toward the targets on the screen as quickly as possible. We measured the trial-to-trial variability in the reaching direction and hand paths of both the affected and the unaffected hand. Results showed that even though participants were blinded to the varying weighted conditions, there was clear modulation of trial-to-trial variability depending on the weighting condition. Specifically, the hand that was weighted less (regardless of whether it was the affected or unaffected hand) showed higher variability, consistent with the idea of optimal feedback control, that only focuses on reducing deviations that affect the task goal. These results suggest that bimanual control of a

shared object may result in more disordered or "sloppy" control of the affected arm during practice, which may potentially affect recovery adversely.

Title: Identification of surgical training level with data from clinical scenario simulations and sensorimotor tasks

Authors: *F. C. HUANG[1], F. A. MUSSA-IVALDI[1], C. M. PUGH[2], H. MOHAMADIPANAH[2]; [1]Sensory Motor Performance Prog, Rehabil. Inst. of Chicago, Chicago, IL; [2]Sch. of Med. and Publ. Hlth., Univ. of Wisconsin, Madison, WI

Abstract: Assessment of surgical skill has traditionally relied on expert observation and qualitative scoring. The goal of this study was to develop efficient, objective tools to identify surgical skill from recorded movement. Our unique study design provided performance metrics in sensorimotor tasks (reaching error, movement time, sensitivity to task changes), as well as gross motion features in clinical procedures (task completion time, working volume, smoothness, and maximum speed). We devised an interactive virtual environment in which participants could perform multiple testing modules, including movements within visual distortion, force perturbation, and a simulated tissue puncture task. In addition, our experimental apparatus featured physical stations that simulated essential clinical procedures, including laparoscopic ventral hernia (LVH) repair, bowel anastomosis, central venous catheterization, and bladder catheterization. Our current analysis focuses on how a combination of metrics can predict a surgeon's level of training. Our approach was to determine how features of movement might be associated with a defined subset of surgeons, and hence reflect the normative skill level of that population. We considered survey responses from surgery residents, including the number of years post-graduation (PGY, four levels), research years (RY, three levels), and clinical years (CY, three levels). We performed a multivariate analysis of variance (MANOVA) to determine a linear combination of metrics and transformation matrix that best separates the defined population groupings. Next, using data transformed according to MANOVA, we performed a

linear discriminant analysis with cross-validation (90% training, 10% testing) to relate the class type to the selected metrics. Our results showed successful classification using combined metrics from the sensorimotor tasks, and separately from the combined metrics from all clinical scenarios. The sensorimotor task model successfully identified surgery residents (n=47) for all three categories, with an accuracy of 41.2% for PGY, 55.2% for RY, and 61.0% for CY. Data from clinical scenarios successfully identified surgery residents (n=38), with an accuracy of 38.0% for PGY, 42.7% for RY, and 70.3% for CY. Our findings demonstrate that data acquired from surgical simulators can be used to identify the most likely training level of a surgeon. The superior identification of clinical years over other factors suggests clinical relevance of our selected simulator tasks. Our findings will aid evaluation of surgical performance, and target specific skill deficits in surgical trainees.

Title: Coordinate representation in motor learning of object manipulation.

Authors: *A. FARSHCHIANSADEGH[1,2], F. MUSSA-IVALDI[2,1];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]NORTHWESTERN UNIVERSITY, Chicago, IL

Abstract: The selection of the frame of reference is a critical step in learning novel dynamics. There is an ongoing debate in sensorimotor learning about the frame of reference employed by the brain to represent novel dynamics. An early study (Shadmehr & Mussa-Ivaldi, 1994) asked this question by investigating generalization patterns after adaptation to velocity dependent force fields. It considered two distinct reference frames: extrinsic (endpoint based) and intrinsic (joint-level based) and made predictions of generalization patterns corresponding to each frame of reference when the arm configuration was changed. The results suggested that the dynamics was represented in intrinsic coordinates. These findings were reproduced in a number of following studies. However, other studies that focused on transfer of the learned dynamics from one limb to another or from bimanual learning to a single limb found evidence for extrinsic representations. All of these previous studies were focused on unconstrained movements of the hand in free space and when a force field disturbed these movements. In this study instead, we used object manipulation and asked participants to move the endpoint of a virtual planar double

pendulum. We have shown previously that in this task, participants started the experiment by moving along rectilinear paths. However, they eventually learned to move along the curvilinear paths that minimized the kinetic energy transferred to the transported object after they became familiar with the object dynamics. Here, the learning phase was followed by a generalization phase where the object was placed in a different orientation. In this scenario, if the dynamics are represented in an arm centered coordinate frame, the executed trajectories should remain unchanged during generalization trials. On the other hand, if the dynamics are represented in an object centered coordinate frame, the trajectories should change in order to follow the path of minimum energy corresponding to the new orientation and finally, the learned dynamics might not transfer at all to the generalization test. Our preliminary results indicate that participants revert to straight line trajectories after the object was placed in a different orientation suggesting that the learned dynamics did not transfer to a new orientation and therefore the dynamics were represented by a coordinate frame that was specific to the orientation of the object during the learning trials.

Title: Learning new gait patterns: Age-related differences in skill acquisition and inter-limb transfer

Authors: ***C. KRISHNAN**, E. P. WASHABAUGH, M. ALTHOEN, C. REID;
Physical Med. & Rehabil., Univ. of Michigan, Ann Arbor, MI

Abstract: Motor skills are important for performing many day-to-day activities and individuals need to learn, unlearn, and relearn a number these skills over the course of their lives. Many studies have shown that the ability to learn new manual skills declines with aging. Similarly, previous studies have demonstrated that older adults have impaired inter-limb transfer (i.e., the ability to transfer the learned skills to the opposite limb without actually practicing the task on

the opposite limb): although this finding is not consistent across studies. While the effects of ageing on motor skill learning and inter-limb transfer are well-studied in tasks that involve the upper limbs; less is known on tasks that involve the lower limbs. Further, the tasks used in these studies typically have less ecological validity, thereby limiting generalizability of the results to everyday activities. Here, we examined the effects of aging on motor learning, retention, and inter-limb transfer of a motor task involving the lower limb. The task involved learning of a new gait pattern while walking on a treadmill. Forty-five subjects (25 younger and 20 older adults) were tested on two consecutive days. On Day 1, subjects learned a new gait pattern by performing a target-matching task, where the target was an altered version of their regular gait. On Day 2, subjects repeated the task with their training leg to test for retention effects and then performed the target-matching task using their untrained leg (i.e., transfer leg). Trials without visual feedback were also collected on both days at the beginning and at the end of training. The changes in tracking error were computed to study the learning effects. The results indicate that training on Day 1 resulted in significant reduction of target-tracking error in both groups ($p<0.05$); however, tracking error was significantly higher in older adults at the end of training (i.e., reduced learning ability). Older adults also exhibited lower retention and inter-limb transfer in comparison with younger adults ($p<0.05$). Analysis of no vision trials indicated that older adults relied more on visual feedback in comparison with younger adults; however, this was only the case for the training leg. The differences in inter-limb transfer effects appear to be primarily due to lower learning and retention on the training leg, as both groups showed similar transfer effect when the differences in the training leg's error were accounted for. These results provide evidence supporting the decline in motor learning and inter-limb transfer of motor skills with ageing. Title: Self-powered robots to minimize motor slacking during rehabilitation

Authors: *E. P. WASHABAUGH, IV[1], E. TREADWAY[2], R. B. GILLESPIE[2], C. D. REMY[2], C. KRISHNAN[1];
[1]Physical Med. and Rehabil., [2]Mechanical Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Robotic rehabilitation is a promising approach to recover lost functions after stroke or other neurological disorders; however, "motor slacking" - a phenomenon where the motor system reduces muscle activation levels and movement excursions to minimize metabolic and movement related costs - is a known limitation of externally driven robots. We hypothesize that motor slacking could be effectively minimized if individuals provide the power to move the limb via their own body power (e.g., from their opposite limb). To test this hypothesis, we developed a wearable body-powered exoskeleton device that mechanically couples the motions of the user's elbow joints. Seven healthy adults were tested on four conditions and surface electromyography (EMG) was used to quantify slacking throughout four testing conditions. The four conditions were: 1) active self-assist, where subjects wore the device on both arms and were instructed to use both to perform a target-matching task; 2) resting self-assist**,** subjects performed the matching task with their dominant arm while resting their non-dominant arm; 3) resting external-assist, subjects rested their non-dominant arm while the researcher wore the other side of the device and performed the matching task; and 4) active external-assist, where subjects were instructed to contract their non-dominant arm along with the researcher. The matching task required subjects to follow a sinusoidal trajectory by flexing and extending their elbow for 10 minutes under each condition. Muscle activation was recorded from the elbow flexor and extensors muscles of the driven arm. For analysis, we calculated the cycle-by-cycle normalized EMG amplitude (% maximum) over each period of the sinusoidal wave. We then calculated the average activation and change in activation (slope) over each condition. In line with our hypothesis, we found that subjects had higher levels of muscle activation during the conditions that required self-assist compared to the external-assist conditions. There was a significant difference ($p<0.05$) in the average activation between the resting self-assist and resting external-assist conditions for each muscle. Additionally, resting self-assist demonstrated the highest slope of all of the conditions tested. The results of this study show that the self-assist conditions minimized slacking, as subjects unknowingly activated their driven arm even when explicitly told not to do so and maintained their average activation throughout the condition. Further testing on subjects with hemiparesis is warranted.

Title: Learning a leg visuomotor rotation task in chronic stroke survivors

Authors: *S.-C. TSENG[1], S.-H. CHANG[2];
[1]Texas Woman's Univ., Houston, TX; [2]Physical Med. and Rehabil., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: To study motor skill learning, previous studies utilize a visuomotor rotation task in which a large movement error is introduced by rotating the location of visual cursor relative to the actual hand path. Subjects therefore learned to gradually adapt their hand movements by rotating the hand path an equal amount in the opposite direction of the cursor rotation. Thus, movement errors can be reduced through trial-and-error practice. However, little is known regarding whether stroke survivors have deficits in adapting a leg visuomotor rotation task and also have deficits in recalling this newly learned leg task after a period of time, so called "savings". Growing evidence suggests that savings may be related to a process of consolidation in the motor cortex. Thus lesioning of the motor cortex may result in impaired savings of a visuomotor adaptation. To investigate the potential for adaptation and savings of a visuomotor leg task and whether it may be impaired by motor cortical damage, we induced visuomotor adaptation of leg reaching movements and tested subsequent savings in a small group of subjects with chronic stroke and hemiparesis and a small group of age-matched healthy adults. The task was a sitting planar leg reaching movement. Subjects were given visual feedback in real-time via a cursor display on a computer screen. One of four targets, equidistance from the start location at top-left, and top-right screen positions, was randomly presented per trial. To minimize visual online corrections, the real-time feedback of cursor motion was removed half way through each reach. During "Baseline", cursor motion and foot motion were matched. During "Adaptation", cursor motion was rotated 15 degrees counter-clockwise relative to the actual foot trajectory. "Savings" was tested by repeating the Adaptation condition at three time points (30 min, 24 hours, and 7 days) after the initial adaptation to the rotation. We calculated movement errors as the angular deviation of the foot path from a straight line path to the target at the time of peak velocity. We compared magnitudes of errors across Baseline, Adaptation and Savings conditions and across control and stroke groups. We hypothesized that both controls and individuals with chronic stroke and hemiparesis would be able to adapt leg reaching to the visuomotor rotation and that controls would show evidence of savings. Our preliminary results suggest that

adaptation and savings of a visuomotor leg movements does occur in healthy individuals, but are impaired in chronic stroke survivors. A better understanding of adaptation and savings of a leg task in chronic stroke survivors may help develop an effective gait intervention strategy.

Title: Relationship between beta-amyloid deposition and motor ability, but not motor memory, in patients with amnestic Mild Cognitive Impairment

Authors: *S. Y. SCHAEFER[1], K. DUFF[2], J. M. HOFFMAN[2];
[1]SBHSE, Arizona State Univ., Tempe, AZ; [2]Univ. of Utah, Salt Lake City, UT

Abstract: ^{18}F-flutemetamol is a novel radiotracer for imaging β-amyloid deposition that has shown potential for differentiating Alzheimer's disease (AD) from other neurodegenerative diseases. Although ^{18}F-flutemetamol uptake in the brain has been neuropathologically validated as a biomarker in AD and is associated with cognitive functioning in older adults, there have been no reports of ^{18}F-flutemetamol uptake related to motor functions, such as psychomotor speed, grip strength, or balance. Thus, the purpose of this study was to examine the relationship between ^{18}F-flutemetamol uptake and motor ability in non-demented older adults at risk for developing AD. Ten community-dwelling older adults diagnosed with amnestic Mild Cognitive Impairment were examined with ^{18}F-flutemetamol-PET imaging and an upper extremity motor task involving reaching, grasping, and object manipulation. Global composites of ^{18}F-flutemetamol standardized uptake value ratios in the cerebral cortex were normalized to the pons, with higher values indicating greater β-amyloid deposition. Motor ability was measured as the amount of time to complete the task, with higher values indicating poorer (slower) performance. All participants' dominant and nondominant hands were tested with the motor task. ^{18}F-flutemetamol uptake was positively correlated with motor ability for the dominant (r=0.72; p=0.017) and nondominant (r=0.55; p=0.10) hands. Because of the nondominant hand's poorer motor ability on the task relative to the dominant hand, participants were given nine additional

nondominant practice trials and were tested again one week later. ^{18}F-flutemetamol uptake was surprisingly unrelated to the nondominant hand's motor ability when re-tested (r=0.33; p=0.35), and had no association with either within-session (r=0.13; p=0.70) or one-week motor practice effects (r=0.17; p=0.64). These findings support the use of both motor and cognitive testing for identifying those at risk for cognitive decline, as both types seem to be related to β-amyloid deposition. These results also suggest potential rehabilitative approaches that could exploit intact learning systems in late life cognitive disorders.

Title: Underlying contributors to visuomotor learning change with aging

Authors: *C. PERRY[1], T. M. HERTER[2], T. SINGH[2], A. HARRISON[2], H. BOYCE[2], K. GOINS[2];
[2]Exercise Sci., [1]Univ. of South Carolina, Columbia, SC

Abstract: Introduction: Many visuomotor skills, such as driving a car, are mediated by a combination of skilled limb movement and skilled visual search (voluntary eye movements used to actively gather visual information from the environment). We know that limb movement and visual search efficacy diminish with aging, but we do not know if their contributions to visuomotor learning also change with aging. Here we examine the extent to which visuomotor learning and its underlying processes change across adulthood. **Methods:** Eighteen young adults and eight older adults used an upper-limb robotic device with a virtual display to practice a bimanual visuomotor task one day a week for six weeks. In this Object Hit and Avoidance (OHA) task, 300 objects (8 geometric shapes) moved towards participants, who used virtual paddles representing each hand to hit away target objects (2 shapes, n=200) and avoid hitting distractor objects (6 shapes, n=100). Participants completed six trials of the OHA task each week for a total of 36 trials. Hand and eye kinematics were collected and used to compute measures of *Task Performance* (percent of targets hit), *Hand Movement Efficacy* (horizontal hand speed), *Visual Search Efficacy* (percent of objects pursued with the eyes), *Eye-Hand Coordination*

(distance between the eyes and hand at the time of target contact) and *Visual Recognition Speed* (mean distractor pursuit time). **Results**: Both groups showed similar improvements in task performance, though young adults exhibited better baseline task performance. Improvements in task performance in both groups were associated with improvements in visual search efficacy and eye-hand coordination. However, young adults (but not older adults) showed improvements in hand movement efficacy, whereas older adults (but not young adults) showed improvements in visual recognition speed. **Discussion:** Our findings suggest that, across adulthood, visuomotor learning is mediated by a combination of distinct and overlapping mechanisms. Improvements in visual search efficacy and eye-hand coordination contribute to visuomotor learning at all ages. However, motor learning (hand movement) is emphasized in young adults and perceptual learning (visual recognition speed) is emphasized in older adults.

Title: Ataxia rehabilitation in multiple sclerosis through a targeted dance class

Authors: *C. LOPEZ-ORTIZ[1], A. M. SCHIEDLER[2], A. L. TISHA[2], D. L. KINNETT-HOPKINS[2], Y. C. LEARMONTH[2], R. MOTL[2];
[1]Kinesiology and Community Hlth., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Univ. of Illinois, Urbana-Champaign, IL

Abstract: Multiple sclerosis (MS) is a disease of the central nervous system with impaired neural signal transmission between the brain and the body. Walking impairment is present in MS, particularly with advanced disease. It has been noted that rehabilitation is the only way of improving function in MS. To our knowledge, there is a major gap in the existing evidence of rehabilitation and walking in MS. There is no documented evidence for improving smooth coordination of movements through exercise interventions among those with MS. We designed a targeted dance class (TDC) intervention based on classical ballet dance training for improving smoothness of movement in persons with MS who have clinical ataxia. All procedures were approved by the local IRB. Five participants with MS ages 49 to 65 participated in this study.

The participants had Expanded Disability Status Scale (EDSS) scores between 4.5 and 6.5. The clinical ataxia score on the International Cooperative Ataxia Rating Scale (ICARS) ranged between 5 and 28. The (TDC) was held twice per week for sixteen weeks with a winter pause of two weeks after the first eight weeks. During the winter break, the participants practiced at home with a TDC practice DVD. The class was taught by a researcher with classical ballet teacher certification and neurorehabilitation expertise. Paired t-tests of pre and post intervention values on the ICARS and smoothness of gait as quantified by the s-index (spectral arc length of velocity) of the top of the head marker in a 3 meter walk (Qualisys, Sweden) indicate statistically significant improvements on smoothness of movement and reduction on clinical ataxia scores ($p < 0.05$). We further investigated the partition and distribution of smoothness variability pre and post intervention across limb segments. The results give insight into the processes of motor learning and rehabilitation in MS through a whole body movement intervention in the form of a targeted classical ballet based dance class.

Title: A portable motor learning laboratory (pomlab)

Authors: *M. SHINYA[1], K. TAKIYAMA[2];
[1]Dept. of Life Sci., Univ. of Tokyo, Meguro-Ku, Tokyo, Japan; [2]Dept of Engin., Tokyo Univ. of Agr. and Technol., Koganei, Japan

Abstract: BACKGROUND AND AIM: Motor learning experiments have required a huge and expensive manipulandum in a laboratory. This makes it hard to collect behavioral data from many subjects and patients in clinical, sports and educational fields. To overcome these weak points, portable and easy-to-use experimental environment is required. METHODS: We have developed an application on Unity3D which runs on tablet devices that can measure motor learning behaviors (we refer the application as POrtable Motor learning LABoratory, or PoMLab). The application was developed using Unity 3D. In PoMLab, reaching movement to control a cursor in conventional experimental system with manipulandum was replaced with

tilting the tablet devices. Participants were instructed to bring the cursor to a target on the screen. Visuomotor adaptation was tested in a task where the motion of the cursor is rotated by a given angle with respect to the direction of actual tilt of the device. The relevance of our application was tested by a series of experiments in which 96 subjects participated. RESULTS: First, adaption to abruptly applied visuomotor rotation was confirmed in the PoMLab setup, and the results were explained by a state space model. Second, participants were able to adapt to gradually increasing visuomotor rotation without being aware of the perturbation. Then, the effect of screen size and vibration on the learning curve was tested using different tablet devices. We also compared the results obtained in our PoMLab setting and those obtained in conventional laboratory experiments using manipulandum. Notably, some participants were aware of the perturbation in the laboratory experiment, but no subject was aware of the perturbation in the PoMLab experiment. The estimated learning rate was comparable between the laboratory and PoMLab experiments, whereas the estimated retention rate tended to be lower for the PoMLab experiments than for the reaching experiments. CONCLUSIONS: We validated PoMLab application by demonstrating that it could reproduce the results obtained in conventional experiments involving reaching movements and visuomotor adaptation. The merits of PoMLab (i.e., we can conduct motor learning experiments at any time or place) would enables scientists, clinicians or teachers to measure motor learning performance from hundreds or thousands of subjects.

Title: White matter integrity and its relationship to cognitive-motor integration in females with post-concussion syndrome

Authors: ***J. HURTUBISE**, D. GORBET, C. HUGHES, A. MACPHERSON, L. SERGIO; Kinesiology & Hlth. Sci., York Univ., North York, ON, Canada

Abstract: Cognitive-motor integration (CMI) is required when performing movements where a rule is used to align the required motor output and the guiding visual information. We propose that measuring this integration under conditions which place demands on visual-spatial and

cognitive-motor processing may provide an effective behavioural means for detection of brain alterations associated with concussion. Our previous research has shown CMI declines in both university-aged[1] and child athletes[2] who had a history of concussion but were deemed recovered at the time of evaluation. The purpose of this study was to characterize the differences in symptoms, CMI, and white matter integrity (fractional anisotropy, FA) in those with post-concussion syndrome (PCS) versus healthy controls. Previously we have observed decreased white matter integrity in adults at risk for dementia related to their impaired CMI performance[3]. We hypothesize that there will be a similar decrease in white matter integrity in those suffering from PCS and that this will be correlated with performance declines on a CMI task. **Methods:** To date, 12 female participants are included in this study; 6 with post-concussion syndrome, and 6 age-matched healthy controls with no self-reported history of concussion. Participants were administered the current international sport concussion assessment tool (SCAT3), four visuomotor transformation tasks (3 of which required cognitive-motor integration), and diffusion weighted images were acquired. The visuomotor tasks were completed on a tablet linked to a desktop computer monitor. The participants displaced a cursor from a central target to one of four peripheral targets by sliding their finger on the tablet either directly to the viewed target or with decoupled eye-hand coordination (targets viewed on alternate plane, 180° cursor feedback rotation, or both). **Results:** We observed that those with PCS had worse symptom scores (both in number and severity) as well as impaired performance in CMI tasks. Those with PCS had decreased mean FA in bilateral corticospinal tracts beneath the premotor and primary motor cortices, and in the white matter underlying the right superior parietal lobule. **Conclusions:** Females with PCS had worse symptoms, decreased CMI performance, and decreased FA within the frontal-parietal-subcortical network. This decreased white matter integrity may be associated with both the CMI performance as well as symptom scores. Future work will investigate if CMI intervention may lead to better recovery for those suffering from PCS. **References:** [1]Brown et al. *BMC Sports Sci.* (2015) [2]Dalecki et al. *Conc.* (2016) [3]Hawkins et al. Title: LEARNING: Lumbar excursion activities reinforced through novel interactive gaming

Authors: *M. E. APPLEGATE, S. T. LEITKAM, S. A. WALKOWSKI, C. R. FRANCE, J. S. THOMAS;
Ohio Univ., Athens, OH

Abstract: A fundamental clinical problem among individuals with chronic low back pain (LBP) is the avoidance of the very movements that are necessary for rehabilitation due to fear of injury or reinjury (kinesiophobia). The purpose of this study was to assess the effect of a short-term graded exposure virtual reality game intervention that encouraged lumbar movement on expectations of fear and harm and movement strategies during full body reaching tasks in adults with chronic LBP and kinesiophobia. During session 1, subjects were randomized into either the control or gameplay group; all subjects completed the standardized reaching task, which involved placing a physical ball on a shelf located at a position that elicited a theoretical 15, 30, and 60 degrees of lumbar flexion (with elbows fully extended and shoulders flexed to 90 degrees). On the following three consecutive days, the gameplay group played four levels of virtual reality dodgeball. Subjects wore 3D glasses and were oriented to their avatar on a 3DTV in the third person perspective. Virtual balls launched from virtual opponents to target locations on the avatar based on the reaching task excursions encouraged movement of the lumbar spine to successfully block and duck the balls. The game levels progressively became more difficult by lowering the projected target height of the launched balls. On gameplay days 2 and 3, target heights decreased by 5% and 10%, respectively. During session 5, all subjects repeated the standardized reaching tasks. During gameplay and reaching tasks, body movements were streamed from Vicon Tracker to The MotionMonitor, which recorded segment kinematics. A repeated measures ANOVA revealed a significant group (control, gameplay) by reaching task session (baseline, post-test) interaction on movement speed ($F = 5.913$, $p < 0.05$). Baseline movement speed was not different between the control group (1544 ± 77 ms) and the gameplay group (1425 ± 70 ms). Post-test movement speed in the control group (1530 ± 66 ms) was not different compared to baseline movement speed; however, post-test movement speed in the gameplay group (1280 ± 66 ms) was significantly faster than baseline movement speed ($p < 0.05$). There were no significant differences in degree of lumbar excursions between reaching task sessions. A series of one-way ANOVAs revealed that females in the gameplay group showed greater reductions in expected harm when reaching to the lowest target than women in the control group ($p < 0.05$). These findings suggest that our virtual reality gaming intervention has the potential to safely alter lumbar movement strategies and reduce expectations of harm in individuals with kinesiophobia and chronic LBP.

Title: Rewarding task-relevant motor variability to optimize motor learning

Authors: *S. K. COLTMAN, L. E. BROWN;
Psychology, Trent Univ. Dept. of Psychology, Peterborough, ON, Canada

Abstract: It is unclear to what extent motor variability impedes performance when learning a new skill and to what extent it enables our ability to learn. Motor variability has been considered both noise that needs to be reduced to having a functional role in promoting motor learning. It has recently been shown using both a reward and error-based task that greater exploration along the task-relevant dimension of a task leads to faster learning rates during performance tasks (e.g. Wu et al., 2014). Given this finding, can performance variability be manipulated to improve learning rate? Can we task slow learners and make them learn more quickly by encouraging them (through reward) to explore the workspace more thoroughly? This study demonstrates that a participants' inherent tendency to produce what some might see as spatial errors can both predict their learning rate and be induced to improve learning. We designed an experiment to examine whether we could replicate the initial findings of this study and to assess whether levels of variability could be manipulated using a reward-based paradigm to enhance learning when adapting a simple visually guided reaching movement. Participants used their right hand to make simple point-to-point movements from a constant start position to one of four possible targets varying in direction, during baseline and visuomotor rotation tasks. Building on previous studies, we designed a reward-based feedback task intended to encourage exploration along the task-relevant dimension, specifically movement angle variability. We assessed whether we could induce task-relevant variability and whether this increase in variability would lead to an increase in learning rate during subsequent testing. Overall, we did not find a significant relationship between the amount of task-relevant variability during baseline and the initial learning rate across all participants. Additionally, we did not observe a significant increase in the portion of task-relevant variability or a significant increase in initial learning rate during subsequent testing of the visuomotor rotation task. Subsequent analyses will explore the hypothesis within individuals.

Title: Origin of descending commands from the cerebral cortex to hand motoneurons in the rat

Authors: *J.-A. RATHELOT[1], A. NWANKWO[2], P. L. STRICK[2];
[1]SNI & CNBC, Univ. of Pittsburgh, Pittsburgh, PA; [2]Dpt. Neurobiology, CNBC, SNI, Univ. of Pittsburgh Brain Inst., Pittsburgh, PA

Abstract: The descending control of voluntary movements is mediated, in part, by cortical output neurons with relatively direct access to motoneurons. In the rat, the most direct connection between cortical output neurons and motoneurons is a disynaptic linkage (Yang and Lemon, Exp Brain Res, 2003). Here, we used retrograde, transneuronal transport of rabies virus (CVS-N2c strain, 45-50µl, $>10^8$ pfu) from a single muscle of Sprague-Dawley rats (n=3) to define the cortical regions that are the origin of disynaptic inputs to hand motoneurons. The muscle we injected was the right extensor digitorum communis (EDC). We set the survival time (~3.5 days) to enable retrograde transneuronal transport to 3rd order neurons. This enabled virus to move from the injected muscle to label the EDC motoneurons that innervate it (1st order neurons). Then, virus was transported transneuronally in the retrograde direction to label 2nd order neurons that are connected with EDC motoneurons (e.g. spinal interneurons). Finally, virus was again transported transneuronally in the retrograde direction to label 3rd order neurons in the cerebral cortex that are connected with spinal interneurons (e.g., corticospinal neurons). At this survival time we found that cortical neurons infected with rabies virus were strictly confined to layer V, the cortical layer known to contain corticospinal neurons. Most labeled neurons (> 95%) were located in the hemisphere contralateral to the injected muscle. Labeled neurons formed three distinct patches on the lateral surface of the hemisphere. The largest patch, accounting to 89-92% of the neurons labeled in the contralateral hemisphere, was located in the primary motor area (M1) and in the primary somatosensory area (S1). The second patch (7-10% of the contralateral labeled neurons) was located in the secondary motor area (M2) which is rostral and medial to M1. The third patch (~1% of the contralateral labeled neurons) was located in the secondary somatosensory area (S2) which is caudal and lateral to M1. These results indicate that the cortical control of forelimb movement in the rat originates from multiple cortical areas. Although the most substantial input originates from M1, parts of M2, S1 and S2 also are potential sources of descending commands.

Title: Laminar organization and target specificity of thalamocortical inputs to primary motor cortex

Authors: ***O. K. SWANSON**, A. MAFFEI;
Neurobio. and Behavior, SUNY Stony Brook, Stony Brook, NY

Abstract: The thalamic nuclei for motor control receive converging signals from the cerebellum and basal ganglia and project their output to motor cortices. One of the major output targets of the motor thalamus is the primary motor cortex (M1), which integrates thalamocortical (TC) inputs with those from other cortical and subcortical motor areas, and sends signals down descending motor pathways to execute movement. Although the TC-M1 pathway has been well-characterized with tract tracing studies, the synaptic properties of this connection remain unclear. To identify the postsynaptic targets of the TC-M1 connection and determine the synaptic physiology of these inputs, we used optogenetic tools to selectively stimulate TC afferents while recording from M1 neurons in an acute slice preparation. Adult C57BL/6 mice of both sexes were unilaterally injected with AAV9-CAG-ChR2-Venus into the ventroanterior/ventrolateral (VA/VL) complex of the motor thalamus. Approximately 2 weeks later, brains were rapidly dissected and sectioned into acute slices containing the forelimb motor area of M1. Whole-cell recordings were obtained from M1 neurons and TC afferents were stimulated with trains of blue (470nm) light pulses at various frequencies. After recording, slices were processed to reveal morphology and laminar location of recorded neurons. Labeled TC afferents were found in all layers of M1, but were densest in Layer 2/3 (L2/3) and L5. Monosynaptic TC currents were recorded in a large proportion of M1 neurons in L2/3 and L5 (>90%). The amplitude of TC excitatory postsynaptic currents (TC-EPSCs) was similar across layers (L2/3 TC-EPSC=328.88±89.76 pA; L5 TC-EPSC=336.83±105.30 pA). Neurons in both layers showed paired-pulse depression in response to stimuli at 5Hz and 10Hz (L2/3-5Hz PPR=0.50±0.04, L2/3-10Hz PPR=0.44±0.04; L5-5Hz PPR=0.45±0.10, L5-10Hz PPR=0.46±0.10). Investigating the synaptic properties and postsynaptic targets of the connection between VA/VL and M1 is

instrumental for understanding of how cortical motor areas receive and integrate subcortical signals.

Title: The connectome for corticospinal outputs mediating distal forelimb control

Authors: *D. GIBBS, Y. TAKASHIMA, E. OVRUCHESKY, J. BIANE, M. H. TUSZYNSKI, J. M. CONNER;
UCSD Sch. of Med. - Dept of Neurosciences, UCSD - Dept Of Neurosciences, La Jolla, CA

Abstract: Skilled motor behaviors engage a widely distributed network of motor and sensory processing. Primary motor cortex is a key hub in this network, playing roles in planning and orchestrating voluntary actions. While much of motor cortex action is likely mediated by direct projections to the spinal cord, efference copies of descending motor commands are distributed to other structures via collaterals from corticospinal projections. The extent of this collateralization is currently unknown. In the present investigation, a viral intersectional approach was adopted, using cre-dependent viral vectors and cre-expressing retrogradely transported rAAV vectors. rAAV vectors expressing genetically encoded tools, including optimized fluorescent tracers and optogenetic probes were targeted specifically to C8-projecting corticospinal upper motor neurons associated with distal forelimb control. The same intersectional approach was also taken to target cre dependent anterograde transsynaptic virus (HSV129 delta TK TT) to the same CST sub-population. Using three dimensional image reconstruction we visualized the spatial organization, axonal projection pattern and synaptic connectivity from a uniquely defined sub-population of

corticospinal upper motor neurons throughout the rat brain, brainstem and spinal cord. This approach allowed us to define the entire *connectome* specifically for corticospinal projections mediating distal forelimb control, and to functionally validate the postsynaptic targeting and connectivity of collaterals. Our findings reveal an unprecedented complexity in motor command signals arising from layer V of primary motor cortex, provoking a re-assessment of the role of motor cortex in mediating motor control.

Title: Columnar organization of primary motor cortex revealed with intrinsic signal optical imaging and intracortical microstimulation in squirrel monkeys

Authors: *O. A. GHARBAWIE, A. R. SLOAN;
Dept. of Neurobio. & Systems Neurosci. Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The hand representation within primary motor cortex (M1) is central to manual dexterity. Neurophysiological studies of the M1 hand representation have shown that its intrinsic organization lacks a distinctive topographic pattern. In addition, anatomical studies have shown dense interconnections linking most of the M1 hand representation and that it lacks architectonic compartmentalization. Consequently, the columnar organization that characterizes most primary cortical areas are in question for the M1 hand representation. The goal of the present study was to examine the organization of the functional connections of sites within the M1 hand representation. We used an approach that allowed to study the connectivity of individual microelectrode sites and could therefore reveal organizational features that may have been obscured with traditional anatomical tracings. In two squirrel monkeys, we used intracortical microstimulation to map the locations of M1 sites from which digit movements were evoked. To investigate the functional connections of those sites, we delivered trains of pulses (150 pulses, 0.2 ms/pulse, 300 Hz) to the approximate location of layers II/III. We imaged the resulting changes in the intrinsic signal under 630 nm or 540 nm wavelength illumination. The most prominent activation domain (~1 mm^2) was invariably within the immediate vicinity of the stimulating microelectrode. In addition, 1-3 activation domains (200 - 400 μm^2) overlapped the M1 hand representation. The spatial locations of the activation domains shifted with site of microstimulation. The anatomical connections linking two domains within M1 were driven with equal efficacy from either domain. For comparison purposes, we mapped the functional connections of select sites within the hand representations in somatosensory areas 3b and 1. Intra-areal activation for each of those sites was limited to a single domain in the immediate vicinity of the stimulating microelectrode. Inter-areal domains of activation overlapped hand representations that matched the representations identified at the microstimulation site. Our somatosensory results confirm that our approach faithfully reveals cortical connectivity. Thus, the focal domains that we identified within the M1 hand representation are likely a reflection of its columnar organization.

Title: Neural synergies in the primary motor cortex without muscle synergies

Authors: *Z. LIU[1], A. G. ROUSE[2], M. H. SCHIEBER[3];
[1]Biomed. Engin., [2]Neurosci., [3]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY

Abstract: High-dimensional neural or muscular spaces can be reduced mathematically to low-dimensional synergies that capture most of the original variance. Such synergies can decrease the computational burden of controlling multidimensional outputs. However, the link between neural and muscle synergies remains uncertain. If muscle synergies are driven by neural synergies in the primary motor cortex (M1), muscle synergies and M1 neural synergies should share similar properties and activation patterns when used to reconstruct the original muscular and neural recordings.

Three monkeys (*Macaca mulatta*) performed a task in which they reached to, grasped, and manipulated 4 objects each in up to 8 locations. We recorded electromyographic (EMG) activity in arm and hand muscles, and spiking activity from microelectrode arrays implanted in caudal M1. Non-negative matrix factorization (NNMF) was applied to extract time-varying (spatiotemporal) muscle synergies, and time-varying neural synergies from simultaneously recorded activity.

Previous studies of time varying synergies have selected the number of synergies based on a sharp bend (genu) in the curve of reconstruction R^2 as a function of the number of synergies, all of a single fixed duration. We extracted different numbers of synergies, N (1 to 10), of different durations, T (10 to 610 ms), from muscle activity and from neural activity separately. We then examined plots of reconstruction R^2 as a function of N and T for a genu indicating an innate number of synergies. Whereas for muscle synergies none of the 3 monkeys showed such a genu, for neural synergies all 3 monkeys showed a genu—at N=3 synergies in two monkeys, and at N=2 synergies in the third. In each monkey the corresponding muscle synergies did not follow these neural synergies either in order or in amplitude of activation.

A limited number of muscle synergies have been identified in other studies that involved a limited variety of upper extremity movements. We suggest that the lack of innate muscle synergies in our data reflect the greater variety of upper extremity movements in the present study. Although we have no clear explanation for the presence of a small number of neural

synergies, our findings fail to support the hypothesis that M1 neural synergies drive muscle synergies in generating reach, grasp, and manipulate movements.

Title: Modeling the subcellular distribution of synaptic connections in cortical microcircuits

Authors: *S. DURA-BERNAL[1], B. A. SUTER[2], S. A. NEYMOTIN[3], G. M. G. SHEPHERD[4]; [1]Physiol. and Pharmacol., State Univ. of New York Downstate Med. Ctr., Brooklyn, NY; [2]Inst. of Sci. and Technol. Austria, Vienna, Austria; [3]Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [4]Physiol., Northwestern Univ., Chicago, IL

Abstract: Understanding cortical microcircuits requires not only mapping connections at the level of cell populations, but also determining the location of synapses along dendritic trees. Experimental evidence has highlighted very specific patterns of subcellular organization that depend on the brain region, cell type and cortical depth. These distinct patterns of innervation are likely to subserve important neural coding functions and have effects at multiple spatiotemporal scales, including the meso- and macro-levels. Incorporating accurate subcellular connectivity in cortical computational models is however challenging. Experimental data is generally sparse and obtained using a variety of techniques and formats, and neuronal simulators tend to lack specific tools to ease the task of synapse placement. Hence, we developed NetPyNE, a Python package to facilitate the development of biological neuronal networks in the NEURON simulator, with an emphasis on the incorporation of multiscale anatomical and physiological data. NetPyNE seamlessly converts a set of a simple, standardized high-level specifications in a declarative format, into a NEURON model. The subcellular distribution of synapses along the dendrites can be specified, and is automatically adapted to the morphology of each model neuron, which could range from a few to thousands of compartments. Different methods are available to provide subcellular synaptic location information, including 2D density maps derived from subcellular

Channelrhodopsin-2-Assisted Circuit Mapping (sCRACM) data; 1D cortical-depth maps; or using subsets of dendritic trees (section lists) based on the more common categorical data found in the literature (eg. layer 4 cells targeting the layer 1 apical tuft). Using this tool we were able to analyse the network-level effects of synaptic distribution in a multiscale model of primary motor cortex (M1) with morphologically detailed layer 5 corticospinal and corticostriatal cells. Our work demonstrates the important role of subcellular patterns in investigating cortical microcircuits, and facilitates future collaborations between anatomists, physiologists and modelers.

Title: Changes in intracortical inhibition due to an external focus of attention

Authors: *W. TAUBE, Y.-A. KUHN, J. RUFFIEUX, M. KELLER;
Univ. of Freiburg, Freiburg, Switzerland

Abstract: Introduction: Although it is well established that an external focus of attention (EF) contrasted to an internal (IF) or neutral focus of attention enhances motor performance and motor learning (Wulf, 2012), little is known about the neural mechanisms underlying these behavioral improvements. This study therefore aimed to i) clarify whether the focus of attention (EF vs. IF) influences motor performance when executing identical fatiguing tasks of the first dorsal interosseus (FDI) muscle and ii) outline differences in neural activity of the primary motor cortex (M1). For this purpose, subthreshold transcranial magnetic stimulation (subTMS) was used as this technique is known to inhibit ongoing motor cortical output without affecting spinal structures (Davey et al., 1994; Lazzaro et al., 1998). Thus, differences in subTMS-induced EMG suppression between an EF and an IF indicate distinct activity in M1. Methods: In session 1, 14 subjects performed an isometric finger abduction at 30% of maximal voluntary contraction (MVC) until task failure with either an IF or EF. In session 2, the same task was performed with the other focus. In session 3, subTMS was applied to the contralateral M1 to compare the activity of M1 during EF and IF of the same task. Results: When subjects performed the biomechanically identical tasks with an EF, the time to task failure was significantly prolonged compared to an execution with an IF (t_{13} = -2.73, p = 0.01). Analysis of subjects' RPE showed a significant main

effect of time with $RPE_{initial}$ being significantly lower than RPE_{final} ($F_{1, 60} = 160.33$, $p < 0.001$, $\omega^2 = 0.99$). However, there was no difference between conditions (IF vs. EF, $F_{1, 60} = 0.021$, $p = 0.88$, $\omega^2 = 0.0001$). In addition, there was no significant interaction effect (time × condition, $F_{1, 60} = 0.186$, $p = 0.66$, $\omega^2 = 0.001$). Subthreshold TMS resulted in a significantly larger suppression of EMG activity in the EF condition compared to the IF condition (t_9=-4.32, $p = 0.001$). Discussion: Our data shed new light on the neural mechanisms underlying attentional foci by showing that the activity of inhibitory circuits within M1 is modulated differentially by the type of attentional focus. The increased inhibition with EF may contribute to the more efficient movement execution with this kind of focus. In this respect, our results support the constrained action hypothesis suggesting a more targeted and thus, less widespread motor activation with an EF (Wulf et al., 2001).

Title: Changes in cortico-spinal excitability associated with motor learning by observing

Authors: *H. R. MCGREGOR[1], V. C. RINCHON[1], P. L. GRIBBLE[1], R. CHEN[2], M. VESIA[2]; [1]The Univ. of Western Ontario, London, ON, Canada; [2]Krembil Res. Inst., Toronto Western Hosp., Toronto, ON, Canada

Abstract: While many of our motor skills are acquired through physical practice, we can also learn how to make movements by observing others. For example, individuals can learn how to reach in novel dynamical environments (‘force fields’, FF) by observing the movements of a tutor. Previous repetitive transcranial magnetic stimulation (rTMS) and fMRI studies suggest a role for the motor system in motor learning by observing. Here, we hypothesized that changes in cortico-spinal excitability support motor learning by observing. To test this idea, we used single-pulse TMS to assess changes in cortico-spinal excitability at rest following the observation of a FF learning task. Healthy participants grasped the handle of a InMotion2 robotic manipulandum with the right hand and were instructed to perform straight reaches to visual targets in a

horizontal plane. In a baseline condition, participants performed reaches in a null field, in which the robot applied no force to the hand. Before each intervention, we assessed the offline excitability of primary motor cortex (M1) and cortico-spinal networks by using single-pulse TMS to elicit motor evoked potentials (MEPs), measured at the right first dorsal interosseous (FDI) and the right abductor pollicis brevis (APB). Participants were then randomly assigned to one of two intervention groups: a learning group (n=15) and a control group (n=15). The learning group observed a video of a tutor adapting his reaches to a clockwise FF. The control group observed a video of a tutor performing reaches in an unlearnable FF, in which the direction of the force varied randomly from trial-to-trial. Immediately after each observational intervention, we repeated the neurophysiological measures and also assessed motor learning behaviorally by asking subjects to reach to targets in the presence of a counterclockwise FF (the opposite FF to what had been learned in the video). Motor learning by observing was thus assessed in terms of proactive interference in the counterclockwise FF. For the learning group, motor learning by observing was accompanied by increases in MEP amplitudes in right FDI and right APB. In contrast, control participants who observed the tutor performing reaches in the unlearnable FF did not exhibit changes in subsequent MEP amplitudes. This suggests that motor learning by observing involves functional changes in M1 or cortico-spinal networks, or both.

Title: Effect of baclofen on coupling between hand and forearm muscles after spinal cord injury

Authors: *J. LONG[1], T. TAZOE[1], D. S. SOTEROPOULOS[2], J. C. ROTHWELL[3], M. A. PEREZ[1];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [3]Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London Inst. of Neurol., London, United Kingdom

Abstract: Although baclofen is a $GABA_B$ receptor agonist commonly used to relief spasticity after spinal cord injury (SCI) its effects on voluntary motor output remain poorly understood. We previously demonstrated that corticospinal excitability in an intrinsic finger muscle, tested during a precision grip task, changed to a different extent in SCI subjects that take or do not take baclofen (Bunday et al., 2014). Because multiple hand and forearm muscles contribute to the control of a precision grip between the thumb and index finger, we investigated the effects of baclofen on the ability to couple hand and forearm muscles during the same task. We examined intermuscular coherence between hand [first dorsal interosseous (FDI), abductor pollicis brevis (APB)] and forearm [extensor carpi radialis (ECR), flexor carpi radialis (FCR)] muscles in the alpha (8-15 Hz) and beta (15-30 Hz) frequency band during index finger abduction and a precision grip in participants with and without incomplete chronic cervical SCI. We found that coherence between FDI-FCR and FDI-ECR in the alpha and beta frequency band was reduced during precision grip compared with index finger abduction in controls but remained unchanged in SCI participants. Notably, long-term (~4.6 years) use of baclofen after SCI decreased FDI-FCR coherence during a precision grip to similar levels as present in controls. To further examine the mechanisms involved in these effects, we measured the duration of cortical silent period (CSP; likely involving $GABA_B$ mediated mechanisms) in the FDI muscle across tasks. CSP duration decreased during precision grip compared with index finger abduction in controls and in SCI subjects taking baclofen and FDI-FCR coherence in the beta band correlated with the changes in the duration of CSP. Thus, our results suggest that GABAb-ergic inter-neuronal pathways may contribute to interactions between hand and forearm muscles during a precision grip task.

Title: Distinct cortco-cortical contributions to human precision and power grip

Authors: *P. FEDERICO, M. A. PEREZ;
Department: Dept. of Neurolog. Surgery, The Miami Project to Cure Paraly, Univ. of Miami, Miami, FL

Abstract: The corticospinal tract contributes to the control of finger muscles during precision and power grip. The involvement of different sets of cortical interneuronal circuits during these distinct grasping behaviors remains unknown. To examine this in humans noninvasively we used transcranial magnetic stimulation (TMS) over the hand representation of the primary motor cortex to elicit motor evoked potentials (MEPs) in an intrinsic finger muscle during index finger abduction (control task), precision grip, and power grip. The TMS coil was oriented to induce currents in the brain in the latero-medial (LM), posterior-anterior (PA), and anterior-posterior (AP) direction to preferentially activate corticospinal axons directly and early and late synaptic inputs to corticospinal neurons, respectively. We found that AP-LM MEP latency differences were consistently longer during power grip compared with index finger abduction and precision grip, while PA-LM differences remained similar across tasks. A paired-pulse induced MEP-peak, targeting AP but not PA inputs, increased during power grip compared with other tasks. Our novel findings suggest that cortical structures activated by PA and AP stimuli are differentially active during precision and power grip. We propose that a preferential recruitment of late synaptic inputs to corticospinal neurons may be achieved when humans perform a power grip.

Title: Control of a human cadaveric hand via autonomous extraction of high-dimensional joint probabilities of command signals

Authors: *B. A. COHN[1,2], K. JALALEDDINI[3], S. CHAKRAVARTHI[4], F. J. VALERO-CUEVAS[3];
[1]Computer Sci., USC, Manhattan Beach, CA; [2]Dept. of Computer Sci., [3]Dept. of Biokinesiology and Physical Therapy, [4]Ming Hsieh Dept. of Electrical Engin., USC, Los Angeles, CA

Abstract: Motor control is the quintessential Big Data problem. How does the nervous system identify and select a particular family of command signals given the high-dimensional set of potential options? While the motor control field has emphasized optimization and cost functions, we have proposed an alternative approach where the family of all feasible muscle coordination patterns has a strong structure defined by the mechanical structure of the limb and the functional constraints defining the task. Historically, finding the structure of such subspaces has been prohibitively expensive from the computational perspective given the high-dimensionality of the problem (e.g., to produce a fingertip force, one must find the 4-dimensional feasible set embedded in 7-dimensional spaces). We describe our use of the Hit-and-Run algorithm to describe these subspaces via their joint probability functions and present a high-performance computational cluster capable of robotically controlling a human cadaveric hand to autonomously extract these joint probabilities. This methodological breakthrough now allows us to explore the way in which motor learning is coupled to motor performance when faced with a high-dimensional control problem. In particular, we emphasize that this trial-and-error, memory-based, and Bayesian-like approach is in fact technically feasible, and may be more biologically plausible for neuromuscular systems than optimization strategies driven by cost functions and gradients. This fault-tolerant approach to motor control also has important implications to motor-relearning in the context of rehabilitation, because our autonomous algorithm can continue operating and learning from the finger, even after properties of the limb have been altered. To inform modern prosthetic control algorithms & the way muscles are controlled in healthy and disease states, this research details a viable and usable big-data approach to a recursive learning algorithm implemented on a human cadaveric finger.

Title: Dissecting V1 interneuron function within the mammalian locomotor network

Authors: ***S. DI COSTANZO**[1,2], G. GATTO[2], M. GOULDING[2];
[1]Biol. Sci., Univ. of California San Diego, La Jolla, CA; [2]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The locomotor networks commonly referred to as the locomotor central pattern generator (CPG) comprise of motor neurons and five “core” interneuron (IN) populations designated as V0, V1, V2a, V2b and V3 INs. Our lab has shown that the V1 INs are important for regulating the speed of locomotion and play an essential role in the control of flexor-extensor movement. The aim of my work is to understand how V1 INs are integrated within the locomotor system by using mouse genetics in combination with viral tools to undertake a

morphological and connectivity analysis. Our strategy to analyze V1 morphology is to fill neurons using an innovative approach based on EnvA pseudotyped G-deleted rabies tagging of V1 INs in a Cre-dependent manner. In this way we can identify discrete subpopulations/cell types based on shared morphological features and correlate this with existing transcriptional profiles. To better understand how V1 INs are integrated within the spinal cord network, we also are mapping the distribution of the V1 IN presynaptic partners. This second approach is based on a tripartite intersectional genetic system that utilizes the combined activities of Cre and Flp recombinase to selectively express the EnvA receptor and the rabies G protein in V1 INs located in the caudal spinal cord. Our ultimate goal is to obtain better insights into the function of V1 INs by unveiling its anatomical organization.

Title: Activity of individual spinal neurons during forward and backward locomotion

Authors: P. V. ZELENIN[1], P. E. MUSIENKO[2,3], O. V. GORSKII[2], V. F. LYALKA[1], N. MERKULYEVA[2,3], Y. P. GERASIMENKO[2], G. N. ORLOVSKY[1], *T. DELIAGINA[1]; [1]Karolinska Inst., Stockholm, Sweden; [2]Pavlov Inst. of Physiol., St. Petersburg, Russian Federation; [3]Inst. of Translational Biomedicine, St. Petersburg State Univ., St. Petersburg, Russian Federation

Abstract: Higher vertebrates including humans are capable not only of forward locomotion but also of walking in different directions relative to the body axis [backward (BW), sideward, etc.],

as well as of stepping in place. While the neural mechanisms responsible for the control of forward (FW) locomotion were studied in considerable detail, the mechanisms controlling steps in other directions are mostly unknown. Recently we have shown that, when locomotor mechanisms of the spinal cord, brainstem, and cerebellum are activated by spinal cord stimulation, the direction of stepping is determined by sensory information from the limb signalling the direction of limb movement during stance. In the absence of this information, in-place stepping is observed. These findings suggest that the locomotor system includes two principal mechanisms, one generating a vertical component of step (limb elevation and lowering), and the other generating a horizontal component (limb transfer from one extreme point to the other). The aim of the present study was to reveal spinal neurons contributing to generation of the vertical and horizontal components of step during locomotion. For this purpose, in decerebrate cats activity of spinal interneurons from L4-L6 was recorded (by means of micro-arrays with 32 recording sites) during both FW and BW locomotion caused by epidural stimulation of the spinal cord at L5-L6. By using spike-sorting procedure, activity of individual neurons was extracted from the mass activity. 25% of neurons were modulated during neither FW nor BW locomotion, suggesting that they do not contribute to their generation. 75% of neurons were modulated during FW and/or BW locomotion. According to their activity during FW and BW locomotion, these neurons were divided into three groups. Group 1 contained neurons (33%), which had the same phase of modulation (maximal activity, burst position) during both FW and BW locomotion. We suggest that Group 1 neurons belong to the network generating the vertical component of steps (elevation and lowering the limb) during locomotion. Group 2 contained neurons, which were modulated during FW locomotion only (10%) or during BW locomotion only (10%). We suggest that Group 2 neurons belong to networks controlling direction of stepping (FW and BW, respectively). Finally, Group 3 neurons (22%) changed the phase of their modulation in locomotor cycle depending on the direction of locomotion. One can suggest that Group 3 neurons control muscles of the hip joint. At this joint, direction of the movements in swing and stance phase are opposite during FW and BW locomotion. Group 1-3 neurons were intermixed in the grey matter.

Title: Cervical propriospinal neurons regulate locomotion based on sensory input derived from spatiotemporal position of the animal

Authors: *S. K. KARADIMAS[1], K. SATKUNENDRARAJAH[2], S. GOSGNACH[3], M. G. FEHLINGS[2];
[1]Krembil Discovery Tower, Toronto, ON, Canada; [2]Genet. and Develop., Krembil Res. Inst., Toronto, ON, Canada; [3]Dept. of Physiol., Univrsity of Alberta, Edmonton, AB, Canada

Abstract: Reticulospinal input is critical for the activation of the locomotor Central Pattern Generators (CPGs). In addition to this pathway long descending cervical propriospinal neurons projecting to ventromedial regions of lumbar spinal cord are required for well-coordinated locomotion. Although, most hold the view that the propriospinal neurons play a coupling role between forelimbs and hindlimbs during quadrupedal locomotion, there is some evidence that propriospinal neurons originating in the cervicothoracic region are involved in activation of the CPG. Currently, very little is known about the identity, anatomical distribution and the specific connectivity of these neurons to components of the locomotor CPG. Most importantly, a direct functional link between these neurons and locomotor activity has thus far has not been described. First, to illuminate the identity of cervical neurons with direct synaptic connections to the rhythmogenic area of the locomotor CPG, we utilized an intersectional technology by crossing *Vglut2::cre* or *VGAT::cre* mice with *Ai65(RCFL-tdT)* line that contains FRT-stop-FRT and LoxP-stop-LoxP double cassettes ahead of tdTomato. Unilateral injections of the retrograde *CAV-FLEx^{loxP}-Flp* were targeted to the L1-2 spinal segments of these double transgenic *Vglut2::cre; Ai65(RCFL-tdT)* or *VGAT::cre; Ai65(RCFL-tdT)* mice. This strategy reliably demonstrated that cervical neurons projecting to lumbar are glutamatergic. To further understand the role of lumbar-projecting cervical neurons in motor control, we aimed to determine the identity of presynaptic populations regulating these neurons. We applied retrograde monosynaptic labeling selectively initiated from the lumbar-projecting cervical neurons. We found majority of the direct input onto lumbar-projecting cervical neurons arose from the forelimb and hindlimb areas of the somatosensory cortex. Moreover, a strong population of presynaptic cells was also detected in the medial vestibular nucleus of the brain stem. Studies have showed that the somatosensory cortical area receives real time information regarding limb position and the locomotor speed during walking. Finally, we found that both selective ablation or silencing of the lumbar projecting cervical neurons resulted in progressively decreased speed and cadence during overground locomotion compared to controls. This phenotype was also characterized by a significant increase in the inactive time and decrease in the mobile time compared to control mice indicative of a perturbed ability to initiate and maintain mobility.

Title: Synaptic connectivity patterns of spinal V3 interneurons

Authors: *J. W. CHOPEK, Y. ZHANG;
Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: V3 interneurons (INs) are excitatory, commissural INs that regulate robust, coordinated walking. Previous work from our lab utilizing dextran for synaptic tracing has demonstrated that V3 INs almost exclusively project contralateral in both the ascending and descending direction. However, dextran labelling may not be ideal to investigate local connections due to tissue damage and fluorescence saturation near the injection site. Therefore we used the Phasor spatial light modulator (SLM) system to investigate potential local V3 synaptic connections. This was achieved by exciting presynaptic neurons by uncaging MNI-glutamate over the soma with the Phasor SLM system while whole-cell patch clamp recordings were made in post-synaptic visually identified V3 INs (tdTomato fluorescence) or motoneurons (retrograde labelling) in 300 um thick slices from the lumbar spinal cord of $Sim1^{Cre/+;Rosafloxstop26TdTOM}$ mice. Using this method, we demonstrate V3 INs make local connections with ipsilateral motoneurons as well as with adjacent ipsilateral ventral V3 INs. Based on the latency from stimulation to the onset of the EPSPs recorded in V3 INs, these local V3-V3 connections are mediated at least in part by electrical coupling. The use of uncaging MNI-glutamate via the Phasor SLM system was also utilized to examine descending V3 IN connections in the horizontal slice preparation in which the ventral horn of the lumbar spinal cord remains intact. Using this horizontal slice preparation, we demonstrate that descending V3 INs synapse on contralateral motoneurons. Typically a cluster of adjacent V3 INs would need to be stimulated to elicit post synaptic potentials (PSPs) in contralateral motoneurons. These PSPs were generally excitatory although inhibitory PSPs were also noted on occasion. In addition to the different PSPs recorded, variable latencies from stimulation to the onset of the PSPs recorded in motoneurons were also found, suggesting that V3 INs have both mono- and polysynaptic connections with contralateral motoneurons. Our findings confirm previous results that demonstrate V3 INs are commissural interneurons and further our understanding of their connectivity by demonstrating local connections between adjacent V3 INs and between V3 INs and ipsilateral MNs.

Title: Spinal circuits controlling speed-dependent gait expression in quadrupeds: insights from computational modeling

Authors: ***S. M. DANNER**[1], S. D. WILSHIN[2], C. BELLARDITA[3], N. A. SHEVTSOVA[1], O. KIEHN[3], I. A. RYBAK[1];
[1]Dept. for Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Structure and Motion Laboratory, The Royal Vet. Col., Univ. of London, London, United Kingdom; [3]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: With increasing speed of locomotion, most quadrupeds, including mice, demonstrate sequential gait transitions from walk to trot, and to gallop and bound. Neural mechanisms underlying these transitions are poorly understood. We suggest that the speed-dependent gait expression results from speed-dependent changes in interactions between spinal circuits controlling different limbs and inter-limb coordination. As a result, the expression of each gait depends on (1) left-right interactions within the spinal cord mediated by different commissural interneurons (CINs), (2) fore-hind interactions on each side, and (3) supra-spinal drives to rhythm-generating circuits and CIN pathways. We developed a computational model of spinal circuits consisting of four rhythm generators (RGs; one for each limb). In this model, left-right interactions between RGs were mediated by V0 CINs ($V0_D$ and $V0_V$ sub-types) promoting left-right alternation and conditional V3 CINs promoting left-right synchronization. Fore and hind RGs on each side mutually inhibited each other. Using this model, we demonstrated that increasing external ("brainstem") excitatory drives to the RGs and V3 CINs could produce a progressive increase in the locomotor speed accompanied by sequential changes of the gait from walk to trot and to gallop and bound. The increase of locomotor speed resulted mostly from shortening the extension phase. Walk was expressed at low frequencies when the extension

phase was substantially longer than the flexion phase and transitioned to trot with the convergence of the extension and flexion phase durations. The transition from alternating (walk and trot) to synchronous gaits (gallop and bound) occurred when the activity of drive-receiving V3 CINs promoting left-right synchronization overcame the activity of V0 CIN supporting left-right alternation. The model closely reproduces and suggests explanations for the speed-dependent gait expression observed in vivo in intact mice and in mutants lacking $V0_V$ or all V0 CINs. Specifically, expression of trot is lost after removal of $V0_V$ CINs, and only bound is expressed after removal of all V0 CINs. The speed-dependent gait transitions, the existence of multi-stable regimes (coexistence of different gaits at the same speed), and the role of different neuron types, including CINs, and supra-spinal drives are analyzed with predictions for future experimental studies. The model provides important insights into the organization of spinal circuits and neural control of locomotion.

Title: Identification and characterization of thoracic neural circuits in the mammalian spinal cord

Authors: E. CABEZAS-BOU[1], *M. E. DIAZ-RIOS[2,3];
[1]Biol., Univ. of Puerto Rico-Rio Piedras Campus, San Juan, Puerto Rico; [2]Dept. of Anat. & Neurobio., Univ. Puerto Rico, San Juan, PR; [3]Inst. of Neurobio., San Juan, Puerto Rico

Abstract: The control of our trunk-related muscles is essential in order to coordinate locomotion in limbed and limbless animals. Limbless animals are able to move via a longitudinal coordinated wave of muscle contractions combined with segmental alternating contractions (half-center neural circuit organization). With the evolution of limbs, trunk neural networks had to now interact with these new limb-related networks and with sensory feedback in order to produce fluid movements. Studies regarding the control of movement in vertebrates have been mostly focused on limb-related neural networks. But the organization of trunk-related neural

networks have been largely unexplored. Thus, fundamental questions remain unanswered: Have the trunk neural networks of limbed vertebrates preserved elements of their segmentally-organized limbless ancestors? How is the trunk-related neural circuitry of limbed mammals organized? And, how does this network coordinates motor activity with or without limb-related networks? Studies have shown that the lumbar network entrains the thoracic network during locomotion suggesting a passive role of this trunk-related circuitry. We hypothesize that the trunk-related circuitry can have a principal role during posture and locomotion. Our results show that the thoracic cord coordinates with the lumbar cord during locomotor-like activity displaying a motor output with similar temporal dynamics (parameters). More interestingly, the isolated thoracic spinal cord can produce synchronous or alternating patterns of motor activity independent of lumbar (limb-related) neural networks and the motor output displays much slower temporal dynamics suggesting postural/balance-related control of movement. Alternating activity was elicited in the presence of a high-divalent solution suggesting that these rhythmic output was mostly coordinated through monosynaptic connections. Moreover, the use of blockers for inhibitory neurotransmission (strychnine and picrotoxin) disrupted this rhythmic alternating pattern. These findings support our overarching hypothesis that trunk-related motor output is at least partly produced by a half-center circuit organization which is likely evolutionarily conserved from limbless vertebrates. Further experiments will be directed toward identifying the organization of the trunk-related neural network, and the role of sensory feedback in thoracic motor control.

Title: Mapping projections of excitatory and inhibitory preBötzinger Complex neurons

Authors: ***C. F. YANG**, J. L. FELDMAN;
Neurobio., UCLA David Geffen Sch. of Med., Los Angeles, CA

Abstract: Understanding the neural control of breathing requires a detailed neuroanatomical and functional map of the breathing central pattern generator (CPG). The logical entry point in constructing such a map is the "engine" of respiratory rhythm, the preBötzinger Complex (preBötC), a bilateral microcircuit of ~3000 interconnected neurons in the ventrolateral medulla. The preBötC generates respiratory rhythm in rodents (and presumably all mammals, including humans); rhythmic activity in the preBötC is required to produce inspiratory movements. To delineate the breathing CPG circuit in mice, we used a viral strategy to identify projections from molecularly-defined populations of preBötC neurons. We located efferent projections emanating from two broad, functionally distinct classes of neurons: excitatory neurons that express somatostatin (SST) and inhibitory neurons that express the glycine transporter GlyT2, using stereotaxic delivery of Cre-dependent AAV expressing EGFP (AAV-flex-EGFP) into the preBötC of SST-Cre or GlyT2-Cre mice. Critically, we optimized the viral delivery method to restrict viral transfections within the preBötC, while sufficiently labeling neurons to visualize long distance projections, enabling reliable identification of preBötC projections. Glutamatergic SST+ preBötC neurons projected to brainstem nuclei implicated in the control of breathing including the contralateral preBötC, parahypoglossal/nucleus of the solitary tract, ventral respiratory group, and parabrachial/Kölliker-Fuse nuclei, similar to efferent projections in rats; these neurons also had suprapontine projections to multiple discrete nuclei within the periaquaductal grey, thalamus, and hypothalamus, suggesting that the preBötC relays respiratory information to higher brain regions that may modulate physiological or behavioral processes. Strikingly, glycinergic preBötC neurons send projections in parallel with glutamatergic SST+ neurons to the same brainstem and suprapontine targets.

Title: A wiring diagram of central complex in *Drosophila* larva

Authors: ***A. FUSHIKI**, A. CARDONA;
Janelia Res. Campus, Ashburn, VA

Abstract: The central complex (CX) is an anatomically recognizable structure in the insect brain. Functional studies indicate that the CX has a role in navigation and motor control, integrating inputs from multiple sensory modalities. A detailed wiring diagram with synaptic resolution remains to be elucidated. Here, we show for the first time neurons and circuits of the CX with synaptic resolution, reconstructed from serial section electron microscopy in Drosophila larva. The anatomical description of identified neurons in the CX of the adult fly led us to identify similar neurons in the larval brain. In the larval CX, we found neurons that traverse the columns of the protocerebral bridge, others that traverse the columns of the fan-shaped body, and ring neurons that define the ellipsoid body, albeit all these structures are split across the midline into two halves. We also found vertical neurons whose dendrites collect inputs from individual columns of the protocerebral bridge and fan-shaped body, and whose axons traverse the ellipsoid body and innervate a region ventrally to it--presumably the noduli. In prior work, we reconstructed the complete mushroom body (MB) and all neurons postsynaptic to the MB output neurons. We will detail both the CX circuitry and the connection between the MB and the CX, which suggests that learning can alter the motor functions associated with the CX.

Title: Testing the limits of bipedal walking coordination: interlimb coupling in extremely asymmetric conditions

Authors: *K. FJELD, D. TAN, E. VASUDEVAN;
Hlth. and Rehabil. Sci., Stony Brook Unversity, Stony Brook, NY

Abstract: Legged animals frequently adjust spatial and temporal aspects of gait in order to walk, run, gallop, or turn. However, animals in nature rarely modify the stepping ratio between their two sides (e.g., taking two steps on one side for each step on the other). Although asymmetric stepping ratios tend not to occur under normal conditions, they can be induced using a split-belt treadmill that drives one leg faster than the other in cats [1] and human infants [2], suggesting that there is some degree of autonomy in the pattern generators controlling each leg's movement. In the many studies of human adults walking on split-belt treadmills, however, there have been

no reports of asymmetric stepping ratios. This may be because adults have not been challenged with a great enough speed differential between the belts for this behavior to emerge - previous experiments have only tested up to a 4-fold differential. Alternatively, the evolution and maturation of bipedal walking may have strengthened the coupling between the two legs, restricting the ability to produce asymmetric stepping ratios. Our objective was to investigate the limits of lower limb coordination in human adults. Ten adults (age 20-31 years) with no history of neurologic or orthopedic conditions were placed in a body weight support (BWS) harness suspended over a split-belt treadmill. They walked on split-belts running at a 10-fold speed differential (0.5:5.0m/s) in three different conditions: (1) no BWS, (2) 50% BWS, and (3) 50% BWS with explicit instruction to perform a 2:1 stepping pattern. In the first two conditions, subjects were told to walk without any specific instructions. Spontaneous 2:1 steps were scarce in the two conditions without instruction: there were no occurrences of 2:1 steps in the 50% BWS condition, and only one 2:1 step occurred in one subject in the no BWS condition. Subjects varied in their ability to produce 2:1 steps when explicitly told to do so. On average 2:1 steps made up 57% of the total steps taken in the instruction condition, but this ranged between 4% (low incidence of 2:1 steps) and 100% (perfect 2:1 stepping) for individual subjects. This suggests that, while adults show some ability to modify coordination voluntarily, asymmetric stepping ratios do not emerge automatically when the two legs are driven at very different speeds. A lifetime of bipedal walking experience may have caused pattern generators to become highly interdependent, possibly reflecting a strengthening of commissural interneuronal pathways or increased voluntary control over walking.

Title: A stop signal for swimming originates from the mesencephalic locomotor region

Authors: *S. GRÄTSCH[1,2,3], F. AUCLAIR[2], D. VEILLEUX[2], A. BÜSCHGES[3], R. DUBUC[1,2]; [1]Groupe de Recherche en Activité Physique Adaptée, Univ. du Québec à Montréal, Montréal, QC, Canada; [2]Groupe de Recherche sur le Système Nerveux Central, Univ. de Montréal, Montréal, QC, Canada; [3]Zoologisches Inst., Univ. zu Köln, Köln, Germany

Abstract: In vertebrates, the mesencephalic locomotor region (MLR) plays a crucial role in controlling locomotor activity. Via a descending pathway it activates reticulospinal (RS) cells in the brainstem, which in turn project to central pattern generators (CPGs) in the spinal cord. The neural mechanisms underlying the initiation and maintenance of locomotion are partly understood, whereas the termination mechanisms are far more elusive. In the lamprey, distinct RS cell populations were found to control locomotor initiation ("Start Cells"), maintenance ("Maintain Cells"), and termination ("Stop Cells") [Grätsch et al., 2015; SfN 421.20]. During swimming, "Stop Cells" were found to generate a burst of spikes right before the end of locomotion (termination burst). Pharmacological activation and inactivation experiments demonstrated that "Stop Cells" play a crucial role in locomotor termination. We have shown that membrane properties are unlikely involved in generating the stop signal, suggesting the presence of specific synaptic inputs from other brain regions which still need to be identified. Here, we investigate the origin of the stop signal and show that the MLR is a very likely candidate. We performed experiments in the lamprey semi-intact preparation, in which swimming movements of the intact body can be recorded and correlated to the cellular activity of brainstem RS neurons. In this preparation, electrical stimulation of the MLR initiates locomotion that often outlasts MLR stimulation (28.02 ± 14.18 s; n=5). During the swimming period exceeding the MLR stimulation, we found that a stimulation pulse delivered in the MLR at a lower intensity (50 % of control) halted locomotion (within 6.83 ± 3.09 s; n=5). On the other hand, a stimulation pulse delivered at a higher intensity (100 % of control) prolonged the swimming bout. The MLR had similar effects on spontaneous or sensory-evoked locomotion. Local ejection of D-glutamate in the MLR lead to the same results: a small quantity of D-glutamate terminated ongoing swimming (within 8.41 ± 4.34 s; n=3), whereas a large quantity prolonged it. When "Stop Cells" were recorded intracellularly a termination burst was seen as locomotion was stopped by MLR stimulation. "Maintain Cells", however, repolarized in this situation. We propose that the MLR provides a synaptic input to "Stop Cells", which is the source of the termination burst. Funded by CIHR, NSERC and GLFC. SG received studentships from DAAD, UzK.

Title: Coordination of irregular bursting rhythms in central pattern generators

Authors: *I. ELICES[1], D. ARROYO[1], R. LEVI[1,2], F. B. RODRIGUEZ[1], P. VARONA[1];
[1]Ingenieria Informatica, Univ. Autonoma De Madrid, Madrid, Spain; [2]USC, Los Angeles, CA

Abstract: The motor function of Central pattern generators (CPGs) circuits relies in the production of robust yet flexible rhythms in the form of regular spiking-bursting activity in each of their member neurons. Thus, both theoretical and experimental studies on CPGs typically consider regular spiking-bursting regimes.

In this study, we aim to understand the fast rhythm negotiation of CPG neurons by means of experimental and theoretical analyses of the pyloric CPG activity in situations where irregular yet coordinated rhythms are produced. In particular, we focus our study in the context of two sources of rhythm irregularity: intrinsic damage in the preparation, and irregularity induced by ethanol. Our departing hypothesis is that the analysis of non-periodic regimes can unveil important properties of the robust dynamics controlling rhythm coordination in this system.

Membrane potential was recorded from the LP and PD neurons, which form a half-center oscillator in the pyloric CPG of *Carcinus maenas*. The level of irregularity and coordination of the neurons' activity were analyzed using measures characterizing the cells' instantaneous waveform, period, duty cycle, hyperpolarization, temporal structure of the spiking activity, and measures describing instantaneous phases among them in the irregular rhythms and their variability.

Different sources of irregularity unveil distinct aspects of the flexibility and coordination of the CPG rhythm, particularly affecting the burst and hyperpolarization waveforms and their durations. Our results illustrate the strong robustness of the circuit to keep LP/PD anti-phase relationships under all conditions analyzed. In spite of being electrically coupled to the pacemaker cell of the circuit, the PD neurons showed a wider flexibility to participate with longer burst durations and larger increase in variability in the CPG rhythm. A conductance-based model of a half-center oscillator was used to assess the role of asymmetry to shape the irregular but coordinated activity observed experimentally.

The experimental and modeling results from the analysis of irregular CPG rhythms presented in this work illustrate that the rich dynamics of neurons and connections in the pyloric circuit

contribute to balance flexibility and coordination to readily negotiate their rhythms. We also discuss the presence of preserved relationships in the non-periodic but coordinated bursting activity of the pyloric CPG, and their role in the fast rhythm negotiating properties of this circuit.

Title: Temperature-sensitive and temperature-stable modules in spinal locomotor networks activity

Authors: J. BENEDICT[1], *A. E. TALPALAR[2];
[1]Dept. Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Dept. Neuroscience, Karolinska Institutet, Stockholm, Sweden

Abstract: Adult homeotherms experience reduced motor performance and fatigue from body temperature changes due to external conditions, fever, torpor or hibernation. In contrast, perinatal mammals display motor activity in a larger range of body temperatures, with rhythm enhanced at low temperatures in some species while suppressed in others. To understand how spinal networks produce these phenomena we studied temperature effects on motor activity. The perinatal murine in vitro spinal cord, when exposed to neuro-active drugs or afferent fiber stimulation, elicits ventral root activity with rhythm and pattern that resemble locomotion. Stimulation of descending fibers in this preparation elicits locomotor-like activity with flexor-extensor and left-right alternating pattern at a frequency of about 0.5 Hz at 23-24^{o}, and the frequency increases to about 1 Hz at 27^{o} C (n=4). Higher temperatures did not further accelerate the rhythm, but tended to disrupt activity. Bath application of NMDA and 5HT produces locomotor activity whose frequencies vary from 0.2 Hz to 1.6 Hz at temperatures 21^{o} to 35^{o} C (n=9). Plotting frequency as function of temperature showed a linear increase in frequency with a Q_{10} of 2.59±1.04 (n=9). Within this range, locomotor-activity showed highly conserved flexor-extensor and left-right alternation (n=9). Increasing temperature from 31^{o} to 35^{o} C resulted either in further increase in the frequency (50 %) or collapse of locomotor-activity (50 % crashes) with disruption of the flexor/extensor and left/right alternating pattern, or severe frequency reduction. Analysis of locomotor activity showed that burst amplitude displays an inverse U-shaped curve in response to temperature with the highest amplitude at 27^{o} C (n=9). Raising the Ringer's flow

from 14 to 20 ml/min succeeded in consistently improving locomotor-activity and avoiding temperature-crashes. Recordings of descending axons showed that conduction velocity was temperature dependent with a Q_{10}=1.39±.10 (n=4), and that action potential duration had a Q_{10}= 0.61±0.14 (n=4) for the range of 24-34^{o} C. This study shows that locomotor rhythm is highly temperature-dependent, but that pattern and other locomotor features have great stability in a large temperature range, suggesting they rely on a robustly hardwired networks. Axonal conduction velocity and action potential duration may contribute to locomotor effects, but the larger Q_{10} for locomotor frequency suggests participation of additional factors. Temperature effects are associated with diverse metabolic states, which may determine different operational modes of neural networks for adaptation to changes in ambient temperature.

Abstract: The sequential activation of neurons has been observed during a range of behaviors and cognitive states and is central to many models of neural circuit function, but the synaptic

connections enabling such dynamics are poorly understood. Song production in the zebra finch depends on a cortical region called HVC, which contains a major class of excitatory ($HVC_{(RA)}$) neurons that fire action potential bursts in a fixed, sequential pattern during singing. These neurons not only project to downstream motor centers but also make numerous connections within HVC and could, therefore, form a sequence-generating synaptic chain. Evidence for this network architecture has, however, been either indirect or inconclusive. Here we employ light and transsynaptic electron microscopy to explore the synaptic connectivity of $HVC_{(RA)}$ neurons. We find that $HVC_{(RA)}$ cells receive the vast majority of their excitatory connections from distal sites on the axons of other $HVC_{(RA)}$ cells; proximal axonal sites, on the other hand, nearly always target inhibitory interneurons. Overall, this connectivity pattern provides evidence for a distributed excitatory synaptic chain supported by local inhibition, characteristic of coupled winner-take-all architectures.

Title: Synapse distribution on leech neurons reconstructed via electron microscopy

Authors: *J. PIPKIN[1], M. H. ELLISMAN[2], W. B. KRISTAN, Jr.[2];
[1]Brandeis Univ., Waltham, MA; [2]Univ. of California at San Diego, La Jolla, CA

Abstract: The anatomical distribution of synaptic inputs and outputs within a neuron's arbor constrains that neuron's behavior. In many invertebrate systems, neurons assemble into circuits by extending their arbors into regions of neuropil, where they form appropriate synapses despite dense intermingling with many possible synaptic partners. We describe the patterns and distribution of synaptic contacts among arbors of neurons from the segmental ganglia of the

medicinal leech, *Hirudo verbana.* To locate sites of synaptic input and output, we reconstructed individual neurons from within a large volume of images spanning an entire juvenile leech ganglion generated via serial blockface scanning electron microscopy. We find three basic patterns governing the distribution of synaptic inputs and outputs. In some neurons, inputs and outputs are evenly distributed throughout all branches of the arbor. In others, the ipsilateral half of the arbor contains only inputs while the contralateral half contains both inputs and outputs. Finally, some cells contained only synaptic inputs or very few outputs at least within the ganglion-contained neuropil. We also analyzed specific pairs of synaptically-linked neurons and found that their synapses were broadly distributed over the region of overlap between the output-containing portion of the presynaptic neuron's arbor and any portion of the postsynaptic neuron's arbor. These results have implications for both functional and developmental models of circuit function in neuropilar systems.

[1]Dept. of Connectomics, Max Planck Inst. For Brain Res., Frankfurt, Germany; [2]Dept. of Connectomics, Max Planck Inst. for Brain Res., Frankfurt, Germany

Abstract: Long range projecting neurons in the deeper cortical layers 5 and 6 of primary motor cortex are one of the principal inputs to the cortico-striatal pathways. Here we used 3D EM microscopy and circuit reconstruction to analyze the local circuit in Layer 6 of mouse primary motor cortex. A volume of 93 × 74 × 108 μm^3 was imaged using serial block face scanning electron microscopy (SBEM) with a resolution of 12 x 12 x 28 nm^3 and analyzed using semi-automated segmentation (SegEM, Berning et al., 2015) . We are currently quantifying the degree of specificity of axonal wiring with respect to the different types of postsynaptic targets present, a first step to establish a baseline of healthy L6 connectomes. This may open the path to analyse specific wiring changes in mutant mouse models of psychiatric diseases.

Abstract: Cockroaches are known for their rapid and stable locomotion. The walking and running motor pattern is a product of the intricate interplay between central-pattern-generator (CPG) networks and sensory feedback that shapes their rhythmic motor output. The cockroach is a leading model in studies of motor pattern generation and a useful inspiration for technological innovations. This study was aimed at characterizing the basic-endogenous rhythmic activity generated by isolated cockroach thoracic pattern-generating circuits, to fill current gaps in our knowledge, re-examine previous findings, and establish general rules for the system connectivity. We monitored pilocarpine-induced simultaneous rhythmic motor output of levator and depressor motorneurons (MNs) in the meso- and meta-thoracic segments of brainless and deafferented cockroach preparations. Data analyses included measures of coupling strength among the network units, phase relations, latencies between and overlaps of rhythmic bursts of activity, spike frequencies within bursts, and the dependence of these parameters on burst frequency. Our findings reveal an endogenous front-to-back activation sequence typical of double-tripod locomotion. Differences in the activity of homologue units in the different segmental ganglia were observed, as well as asymmetries in connectivity among the different components. The data suggest differences in the functional role of network units and unit interactions in the overall rhythm generation. Many of the observed characteristics were similar to those exhibited by intact animals, suggesting a dominant role for feedforward control in cockroach locomotion, while differences provide better understanding of the role of sensory feedback in locomotive behavior. Based on our data we posit an explanatory connectivity scheme within the hemisegmental levator-depressor CPG's components and among neighboring homologue CPGs. We combine our experimental data with results and assumptions drawn from earlier studies in order to present a more complete connectivity scheme, which includes the

subesophageal ganglion and the prothoracic hemiganglia. The proposed parsimonious model can explain our data without compromising the system's ability to generate different locomotion-related behaviors, and provides a useful tool for further discussion of our current findings, as well as guiding future work. Our data also enable more comprehensive comparisons with data obtained from other insects that, while sharing their basic thoracic neural architecture with the cockroach, produce very different locomotion patterns under similar experimental conditions.

Title: Glutamate, CNQX or WAY-10063 produce fictive locomotion in thalamic cats

Authors: *S. H. DUENAS JIMENEZ[1], L. LOPEZ VALENZUELA[2], I. JIMENEZ ESTRADA[4], M. E. MENDOZA GARRIDO[4], B. DE LA TORRE VALDOVINOS[3], L. CASTILLO HERNANDEZ[5], J. M. DUEÑAS JIMENEZ[2], N. E. FRANCO RODRIGUEZ[6]; [1]Univ. De Guadalajara, Zapopan, Mexico; [2]Physiol., [3]Computat. Sciences, CUCEI, Univ. de Guadalajara, Guadalajara, Mexico; [4]Physiology, Biophysics and Neurosci., CINVESTAV-IPN, Mexico City, Mexico; [5]Physiol. and Pharmacol., Univ. de Aguascalientes, Aguascalientes, Mexico; [6]Computat. Sci., Univ. of Guadalajara, Guadalajara, Mexico

Abstract: In thalamic and subsequently spinalized cats we analyzed whether glutamate (GLU), CNQX (an AMPA/Kainate glutamate inhibitor drug), serotonine (SER), or WAY-10063 a serotonin 1A receptor inhibitor drug injected: intra brain stem (BS, 1 mm down the obex) or in spinal cord (ISC) interfered with fictive locomotion (FL) or fictive scratching (FS) produced by pinna stimulation. In twelve cats, brain cortex was ablated under brevital anesthesia, we named these cats: thalamic cats (TC). Two hours later, the same animals were spinalized cutting the spinal cord at C1-C2 segment; spinalized cats (SC). In these cats once tubocurarine (0.25-01mM) was topically applied in C1-C2 segments, pinna stimulation induces fictive locomotion (n=3) or FS (n=6). Glutamate in BS or ISC induces the FS-FL phenomena. It also increase the electroneurogram (ENG) extensor burst duration during spontaneous fictive locomotion (n=2). In three TC, CNQX was injected (5nM/min) in BS or ISC at L3-L4 segments. CNQX in BS induced FL. In TC, SER injected in BS or ISC increase the scratching episodes duration and the

extensor ENG amplitude during FL. In other three different cats, which pinna mechanical stimulation did not elicited FS or the FS-FL phenomena, WAY-10063 (0.2-3.5 nM/min,) in the BS or injected i.v. (0.25 mg/kg (n=2) induces FL. In spinal cats, glutamate (n=3), CNQX (n=3), SER (n=3) and GLU (n=3) favored pinna stimulation to generate FS. Activation of BS neurons with NMDA receptors could form a pathway activating the spinal cord locomotion generator. These neurons localized between obex and C1 spinal cord segment are also activated by d-tubocurarine and pinna stimulation and could be inhibited by serotonin since WAY-10063 a SER 1A receptor inhibitor injected i.v. or in BS favored pinna stimulation to generate FL.

Title: Functional diversity of excitatory V0 interneurons in the adult zebrafish

Authors: R. BJÖRNFORS, *A. EL MANIRA;
Karolinska Inst., Stockholm, Sweden

Abstract: Flexibility in the bilateral coordination of muscle contraction underpins variable locomotor movements or gates. The left-right coordination during locomotion can vary in a context-dependent manner to produce alternation through the activity of commissural interneurons connecting local interacting circuits on the two sides of the spinal cord. The V0 interneurons represent a major commissural neuronal population comprising dorsal excitatory (V0v) and ventral inhibitory (V0d) classes. The current view of V0 function derives from studies in immature motor systems (larval zebrafish and newborn mouse), but the activity patterns of V0d and V0v classes is unknown. Here we examined how the activity of the V0v interneurons varies with the speed of locomotion in adult zebrafish. Our results show that although V0v interneurons express a defined transcription factor and transmitter phenotype, their activity

patterns during locomotion are heterogeneous. V0v interneurons could be segregated into two distinct types based on whether or not they display rhythmic activity during locomotion. The rhythmically active V0v interneurons could be further subdivided into three main sub-classes engaged sequentially during swimming, first at slow then intermediate and finally fast locomotor speeds. The order of recruitment of the three sub-classes of V0v interneurons is defined by a combined computation of their synaptic drive and intrinsic properties. The extent of the rhythmic excitation is the result of a scaling of the synaptic current with the input resistance of the different V0v interneurons. This study thus uncovers, for the first time in an adult vertebrate, an important organizational principle for a key class of commissural interneurons and the underlying cellular and synaptic mechanisms defining their pattern of recruitment as a function of locomotor speed.

Title: Wiring-specificity in a larval zebrafish premotor network

Authors: ***F. SVARA**[1], J. KORNFELD[2], W. DENK[2], J. BOLLMANN[3];
[2]electrons - photons - neurons, [1]Max Planck Inst. of Neurobio., Martinsried, Germany; [3]Dept. of Biomed. Optics, Max Planck Inst. for Med. Res., Heidelberg, Germany

Abstract: Larval zebrafish produce a range of different motor patterns, appropriate to the range of different situations they face. Noxious stimuli induce vigorous and fast tail bending, followed by a period of high-frequency tail beating, to allow a quick escape. On the other hand, the fish produces precise, low-amplitude, low-frequency swim patterns when it pursues its prey. Central pattern generator circuits (CPGs) in the spinal cord underlie the generation of these movements. A segmentally repeating pool of motoneurons (MNs) is recruited in an orderly fashion, with the smaller, more ventral MNs engaged during the weaker swims and large, dorsal MNs being added only during the strongest movements.
How the spinal CPG interneurons produce this graded activation of MNs is not well understood, but it is known that ipsilateral descending interneurons (CiDs) provide rhythmic excitation to MNs and commissural inhibitory interneurons ensure left-right alternation. These inputs interact

with the intrinsic excitabilities of the MNs, with larger MNs being less excitable.
In a stochastic connectivity model, the recruitment of MNs would be governed mainly by their input resistance. Alternatively, in a wiring-based recruitment model, subtypes of premotor interneurons would precisely select their postsynaptic partners from the pool of MNs.
To distinguish between these models, we reconstructed the MN pool in one segment of a 6 day old larval zebrafish from a Serial Block-Face Electron Microscopy dataset containing 2.5 segments of spinal cord, allowing us to comprehensively elucidate the distribution of MN subtypes. We then traced from synaptic terminals on selected MNs of different types back into their presynaptic partners, identifying the CPG elements that activate and inhibit them, including the CiD and CoBL interneurons.
We find that a large subset of the CiDs is highly specific to the type of MN it contacts and that the somata of CiD subtypes with different specificity are dorso-ventrally segregated.

Title: Convergence rules and synaptic fidelity dictate the recruitment of motor neurons in adult zebrafish

Authors: *J. SONG, A. EL MANIRA;
Karolinska Inst., Stockholm, Sweden

Abstract: Locomotor movements are generated by spinal locomotor networks and require the coordinated recruitment of motor neuron pools to drive muscle contractions in an appropriate sequence. Different motor units need to be engaged successively from slow to intermediate and fast to increase the locomotor speed. Presumably, specific rules of convergence of synaptic drive from premotor excitatory interneurons are needed to dictate the sequence of activation of motor neurons. However, the nature of the convergence and the dynamics of the excitatory inputs to identified motor neurons are still unclear. We have addressed these issues in the adult zebrafish

in which the locomotor circuit is organized in three sub-circuit modules with sub-classes of the excitatory V2a interneurons connecting selectively to slow, intermediate or fast motor neurons. We sought to determine the rules of convergence of V2a interneurons that reliably control the recruitment of motor neurons of the slow, intermediate and fast sub-circuits. Our results show that the convergence rules varied among the three sub-circuits. In addition, there were differences within each sub-circuit depending on the firing properties of the presynaptic V2a interneurons. Indeed, V2a interneurons either displayed intrinsic burst or tonic firing. The bursting V2a interneurons target the motor neuron dendrites to elicit large EPSPs, while the tonically firing ones have bifurcating axons targeting the soma to produce relatively smaller EPSPs. During each V2a interneuron burst there was super linear EPSP summation that was highest in the slow sub-circuit module and lowest in the fast module and required activation of NMDA receptors. These properties ensured the fidelity and strength of the transfer of excitatory drive within each sub-circuit module and hence a module-specific convergence rule. In the slow module the convergence of only two V2a interneurons was required to engage the corresponding motor neurons. The intermediate module required the convergence of 6 V2a interneurons, while the fast module necessitated more than 40 interneurons to ensure motor neurons recruitment. Thus, this study reveals the rules of convergence that in combination with the NMDA-induced super linear synaptic dynamics ensure the sequential activation of motor neurons of three sub-circuit modules to increase the locomotor speed.

Title: Brainstem functions assessment in a cohort of very preterm babies born at less than 28 weeks

Authors: *J.-C. VIEMARI, A. SAMONINI, B. BELLOT;
CNRS-INSTITUT DE NEUROSCIENCES DE LA TIMONE, Marseille, France

Abstract: Although significant advances in neonatal care have increased survival rates of preterm infants born before 28 weeks gestation, a concomitant decrease in neuro developmental disorders has not been achieved. Cerebral injuries, well documented during the previous years, in preterm babies are particularly deleterious since they occur in a developing brain. They affect both white and grey matter by complex mechanisms and the principal targets are the developing oligodendrocytes and neurons of the subplate. All these criteria define the encephalopathy of prematurity. Nevertheless, the consequences of prematurity at the level of the brainstem are not very well known and may explain neuro-developmental disorders with normal RMI.
The assessment of the motor repertoire is complementary to the neurological examination and may represent a diagnostic tool for cerebral palsy, mild motor deficits and delayed acquisition in children. The newborn have a rich motor repertoire. GMs play a key role in the development due to the feedback that they send to cortical neurons and reflect the maturational stage of the CNS. Lesions of the brainstem caused by prematurity may induce alterations of the motor repertoire. Dysautonomic disorders, such as bradycardia, apneas, feeding problems that occur frequently in very preterm babies may reflect brainstem abnormalities. These symptoms are also described in other pathologies such as in Rett syndrome, in ASD and SIDS. In these pathologies, deficits of the 5-HT system have been described and associated with dysautonomia. It would then be interesting to evaluate 5-HT levels in very preterm babies.
The serotonergic system develops very early during gestation and is one of the first neurotransmitter to appear in the developing brain. The main 5-HT nuclei are located within the brainstem. 5-HT plays an important role in the homeostasis and the modulation of the respiratory network. Moreover, previous studies have shown that 5-HT projections to the spinal cord are involved in posture and in the coordination. It is tempting to think that 5-HT deficits may have some repercussions on the development of the CNS, changing activity dependent processes, such as spontaneous activity recorded at the spinal level in rodents.
Here we compared 5-HT platelets level in preterm infants born before 28 weeks with newborn infants. We would like to correlate 5-HT levels with MRI of the posterior fossa, the GMs and different parameters of dysautonomia such as cardiac variability, succion-swallowing and respiratory patterns.

Title: Postnatal development of spinal circuits in the presence and absence of descending systems

Authors: *C. C. SMITH[1], J. F. R. PATON[2], S. CHAKRABARTY[1], R. M. ICHIYAMA[1]; [1]Univ. of Leeds, Leeds, United Kingdom; [2]Univ. of Bristol, Bristol, United Kingdom

Abstract: Interestingly, neonatally spinalised (TX) rats display enhanced prospects of locomotor recovery compared to adults. Both these models must learn to produce hindlimb stepping with only sensory input, suggesting a fundamental difference in the ability of the neonatally TX spinal cord to utilise this information. This difference is likely induced by distinct developmental activity patterns which alter the organisation of crucial spinal circuits. However, the postnatal (PN) development of the sensory-motor circuitry isolated from descending influences is not well understood. This study assessed the development of lumbar spinal circuits and sensory systems of normal and neonatally (PN5) TX rats. All assessments were performed at PN10, 14 and 21. For the transection group, PN5 rats were anaesthetised (Isoflurane) and spinally transected (mid-thoracic), after which they were allowed to recover for 5 (PN10), 9 (PN14) or 16 (PN21) days. Immunohistochemistry was used to assess PN development of proprioceptive afferents (PA) and their presynaptic innervation by GABApre neurons (P boutons). PA were quantified with respect to inputs to motoneurones (MNs), Renshaw cells and their laminae distribution. Electrophysiological (H-reflex) assessments were used to physiologically corroborate the anatomical findings. Finally, excitatory and inhibitory premotor inputs to MNs were quantified to assess the impact of PN5 TX on development of the intraspinal circuitry. Results show that during normal development, proprioceptive afferents are retracted from the lumbar spinal cord, whilst GABApre (P bouton) innervation of PA afferents increased with development. Premotor projections were retracted. PN5 transection abolished afferent retraction and severely attenuated P bouton proliferation on PA terminals. H-reflex data showing increased excitability and reduced modulation of the monosynaptic reflex affirmed the anatomical data. Importantly, normal development of premotor projections was utterly resilient to PN5 transection. This study shows that PN retraction of PA is abolished following neonatal TX, leading to both disruption and maintenance of the formation of key spinal circuits in the absence of descending systems. These changes may represent crucial differences between neonatal and adult spinal cord injuries which afford enhanced recovery to the former. Understanding how spinal circuits compensate for developmental loss of supraspinal control is vital to directing questions regarding future and current treatments for conditions such as cerebral palsy and spinal cord injury.

Abstract: We have shown previously that the medicinal leech (Hirudo verbana) exhibits a remarkable ability to recover its crawling after coordinating signals from the brain are removed. Such descending information is vital for the initiation and coordination of body segments during crawling in uninjured control animals. The aim now is to determine what changes occur after injury that facilitates the recovery of coordinated crawling in the absence of descending information. To investigate how crawling becomes reinstated, we examined the neuroanatomical, electrophysiological and cell-molecular features of the anterior-most ganglion below the transection, as well as the rest of the nerve cord in recovered animals. We determined that recovery does not involve the reconnection of axons from anterior neuronal projections. Furthermore, major morphological alterations of motoneurons were deemed not to contribute substantially to recovery. One hypothesis we tested was whether the dopamine (DA)-sensitive crawl neural networks in the lead ganglion of recovered leeches were newly capable of providing both crawl drive and coordination to neighboring crawl oscillators. Although DA administered only to the lead ganglion was found to be effective in generating crawl-bursting within neighboring segmental oscillators, the phase relationships were aberrant and lacked the metachrony specific to crawling. In recovered nerve cords in which all the ganglia were bathed in DA, a spectrum of crawl-bursting profiles emerged. Even though some of the nerve cords from crawl-recovered animals showed a few episodes of crawl-specific phase relationships, none of the 12 preparations tested displayed continuous bouts of crawl-specific coordination similar to that seen in isolated nerve cords with their brains connected. Thus, fictive crawling with appropriate segmental phase relationships appears to depend on the presence of the body and its ability to provide sensory input, in contrast to controls. Thus, our next steps are focusing on the role of proprioceptive feedback arising from body-wall stretch receptors. Neurobiotin fills of stretch receptors in recovered and control leeches reveal some differences in the dye-coupling of

these cells. Semi-intact preparations will be used next to test whether crawl-specific coordination can be established when the stretch receptors are activated during uncoordinated crawling in recovered animals. Lastly, we have begun to investigate changes in gene transcript levels in response to injury by collecting, sequencing and quantifying levels of RNA from entire ganglia of recovered and control leeches.

Title: Functional contribution of glutamatergic neurons of the medullary reticular formation to the motor control in mice

Authors: *M. LEMIEUX, F. BRETZNER;
Univ. Laval, CRCHU De Québec - CHUL, Quebec, QC, Canada

Abstract: The motor activity of limbs is generated within the spinal cord network but is initiated and modulated by supraspinal centers. Due to its intermediate position between the mesencephalic locomotor region (MLR) and the spinal interneuronal circuit, the medullary reticular formation (MRF) is bound to play a crucial role in the locomotor control. However, the identity of MRF neurons involved in motor control is still unclear. Using optogenetic tools accessible in the mouse, our goal was to study the functional contribution of MRF glutamatergic neurons to motor and locomotor control. Optical probes were inserted chronically into one side of the MRF of VGluT2-cre mice expressing Channelrhodopsin-2, a photo-activated cationic channel. The EMG activity was recorded from both flexors (Tibialis anterior, TA) and extensors (Gastrocnemius lateralis, GL) of the ankle at rest and during locomotion upon a 10 or 80 ms photo-stimulation . At rest, a 10 ms photostimulation evoked excitatory responses in TA and GL on both sides. As the intensity of photostimulation increased, the failure rate and the latency decreased, whereas the duration and amplitude of the EMG responses increased. Responses were evoked at the lowest threshold and the shortest latency in the ipsilateral TA. During locomotion, a 10 ms photostimulation evoked excitatory responses in TA and inhibitory ones in GL during the stance phase, while it evoked excitatory responses in the GL and either excitatory or no

responses in the ipsilateral TA during the swing phase. Inhibitory responses were sometime observed in the contralateral TA. An 80 ms photostimulations increased the duration of the ongoing step cycle, but without influencing the subsequent step cycles. We conclude that glutamatergic neurons from the MRF act on flexor and extensor muscles at rest, influence the locomotor pattern but not the rhythm.

Title: Variable delays in the decision to move: neurons coordinating the sensory initiation of locomotion

Authors: *S. KOUTSIKOU[1], E. BUHL[1], R. MERRISON-HORT[2], R. BORISYUK[2], S. SOFFE[1], A. ROBERTS[1];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Univ. of Plymouth, Plymouth, United Kingdom

Abstract: Sensory stimuli can lead to coordinated movements like eye saccades or locomotion where reaction times are long (>100ms) and variable. The current hypothesis is that decisions to act involve the noisy build-up of excitation to a threshold as sensory information is 'integrated' (Gold & Shadlen 2007 *Ann Rev Neurosci* 30:535). Where and how this happens remains unknown. Mammal nervous systems are very complex but all animals must decide whether to respond. We study hatchling *Xenopus laevis* tadpoles where most neurons in the pathway from skin touch to swimming are known. Delays to swimming are long and variable in behaving tadpoles (45-250ms) and in motor nerve recordings from immobilised tadpoles (20-140ms). Whole-cell recordings show synaptic input and spiking in neurons of the swim initiation pathway and the reticulospinal neurons (RS) that drive swimming (Li et al. 2010 *JNeurosci* 30:16609). After a brief skin stimulus, EPSPs build up slowly and noisily in RSs on both sides. The first side to reach threshold fires after 20-60ms and swimming follows. The known sensory (S) and sensory pathway (Sp) neurons fire once at 5-15ms so cannot explain the slow EPSP build-up. We record from hindbrain 'extension' neurons (xINs) which are excited at short latencies (5-16ms) by skin stimuli. They start spiking at 8-30ms but unlike Sps fire repetitively to extend excitation and introduce variability. A network model of 30 xINs with mutual excitation can also extend firing

to brief stimulus. The pathway from sensory stimulus to swimming therefore has 5 functional layers: (1) sensory neurons (S); (2) sensory pathway neurons (Sp); (3) extension neurons (xINs) prolong firing and introduce variability, (4) reticulospinal neurons (RS) make the decision to swim when xIN excitation sums to threshold and recruits the whole electrically-coupled RS population; RSs excite (5) motoneurons (mn) which excite the muscles. We conclude that the long and variable delays to swimming, as widely observed in decisions to act, result from the noisy slow-rising excitation in RSs which is a consequence of the newly discovered xIN layer.

Title: Short-interval intracortical inhibition projecting to the biceps brachii during arm cycling

Authors: ***L. R. ALCOCK**[1], E. J. LOCKYER[1], A.-J. SPENCE[1], K. E. POWER[2,3];
[2]Human Kinetics and Recreation, [1]Mem. Univ. of Newfoundland, St Johns, NL, Canada; [3]Fac. of Med., St. John's, NL, Canada

Abstract: The motor cortex has been previously shown to play a role during spinally-mediated rhythmic and alternating locomotor outputs. Recent studies likewise suggest that evidence of enhanced corticospinal excitability in the absence of increased spinal excitability during arm cycling indicates that excitatory output is mediated via changes at the supraspinal level. Short-interval intracortical inhibition (SICI) is a type of cortical inhibition which is elicited through a paired-pulse transcranial magnetic stimulation (TMS) paradigm and is considered to be represented by a reduction in test motor-evoked potential (MEP) amplitude. The present study sought to explore the possible involvement of SICI projecting to arm muscles during arm cycling. Ten volunteers (eight male, two female) participated in this study. Subjects completed the protocol using a SCIFIT arm cycle ergometer during which muscle responses were recorded via surface electrodes placed on the biceps brachii. SICI was assessed using a subthreshold conditioning stimulus (CS) and a suprathreshold test stimulus (TS) made relative to active motor threshold (AMT) at an interstimulus interval (ISI) of 1.5ms applied over the dominant motor cortex. Responses were elicited using conditioning stimuli of 70% and 90% of AMT during arm cycling at a constant workload of 25W and 60RPM. We have previously reported enhanced MEP responses due to supraspinal factors during the flexion phase of cycling, therefore subjects received stimulation at this phase throughout the study. SICI was effectively elicited in all subjects; test MEP amplitudes were significantly reduced by 72.5% ($p = 0.003$) and 66.9% ($p = 0.004$) following conditioning stimuli of 70% and 90% AMT, respectively. Background EMG recordings show no significant variance between test and conditioned trials, indicating similar intensity of muscle activation was used throughout the experiment. This data represents the novel finding that SICI is present during arm cycling, which suggests that activation of inhibitory intracortical interneurons may modify the descending supraspinal drive to muscles during arm cycling.

Title: Workload-dependent changes in corticospinal excitability to the elbow extensors during arm cycling

Authors: *E. J. LOCKYER[1], D. A. FORMAN[1], D. T. G. PHILPOTT[1], D. C. BUTTON[1,2], K. E. POWER[1,2];
[1]Sch. of Human Kinetics and Recreation, Mem. Univ. of Newfoundland, St John's, NL, Canada; [2]Fac. of Med., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: The purpose of the present study was to investigate the influence of different external workloads on the modulation of supraspinal and spinal excitability to the triceps brachii during arm cycling. Ten male participants (age, 24.3 ± 5.3 years; weight, 81.7 ± 7.3 kg) participated in this study. Supraspinal and spinal excitability were assessed using transcranial magnetic stimulation (TMS) of the motor cortex and transmastoid electrical stimulation (TMES) of the corticospinal tract, respectively. Motor evoked potentials (MEPs) elicited by TMS and cervicomedullary-evoked potentials (CMEPs) elicited by TMES were measured from the triceps brachii at two different positions corresponding to mid-elbow flexion and mid-elbow extension (6 and 12 o'clock made relative to a clock face, respectively) while arm cycling at 10, 20, 30, and 40 W and a set cadence of 60 rpm. Electromyographic (EMG) recordings were made from the dominant arm triceps brachii. MEP amplitudes (n = 10) were not statistically different as cycling workload increased during either flexion (P = .266) or extension (P = .366). Similarly, CMEP amplitudes (n = 5) were not statistically different as cycling workload increased during either flexion (P = .489) or extension (P = .783). In addition, MEP amplitudes were not different between flexion and extension (P = .435). However, CMEP amplitudes were larger (P = .016) during flexion (10W, 18.7% ± 5.05%; 20W, 18.9% ± 5.97%; 30W, 24.1% ± 5.96%; 40W, 21.58% ± 4.69% of triceps brachii M_{max}) than during extension (10W, 10.0% ± 4.45%; 20W, 7.67% ± 3.34%; 30W, 9.7% ± 4.03%; 40W, 10.3% ± 3.65% of triceps brachii M_{max}). The data indicate that corticospinal excitability projecting to the triceps brachii did not increase during arm cycling with increased workload at either position. However, spinal excitability as workload increased demonstrated phase-dependent modulation (i.e., increased during elbow flexion and decreased during elbow extension).

Title: Corticospinal excitability to the biceps brachii is elevated during arm cycling with a neutral versus pronated forearm position

Authors: *D. FORMAN[1], G. N. FORMAN[2], M. RICHARDS[3], M. W. R. HOLMES[2], K. E. POWER[3,4];
[1]Fac. of Sci., Univ. of Ontario Inst. of Technol., Whitby, ON, Canada; [2]Fac. of Hlth. Sci., Univ. of Ontario Inst. of Technol., Oshawa, ON, Canada; [3]Sch. of Human Kinetics and Recreation, [4]Fac. of Med., Mem. Univ., St. John's, NL, Canada

Abstract: The influence of forearm position on corticospinal excitability (CSE) to the biceps brachii has previously been assessed during static, resting conditions. However, the relationship between forearm position and CSE has not been examined during a rhythmic motor output. Therefore, the purpose of this study was to examine the influence of neutral and pronated forearm positions on CSE to the biceps brachii during arm cycling. Corticospinal and spinal excitability were measured using motor evoked potentials (MEPs) elicited via transcranial magnetic stimulation (TMS) and cervicomedullary-evoked potentials (CMEPs) elicited via transmastoid electrical stimulation (TMES), respectively. Recordings were taken from the biceps brachii during mid-elbow flexion and extension (6 and 12 o'clock positions relative to a clock face) while arm cycling with two different forearm positions; neutral and pronated. Arm cycling was kept at a constant cadence of 60 rpm and a fixed workload of 5% of the individual's cycling peak power. Recordings were also taken during tonic elbow flexion of similar muscle activity in order to differentiate any findings as either dependent on forearm position or task. Peak-to-peak amplitudes were significantly larger at the 6 o'clock position while arm cycling with a neutral forearm position compared to pronated for both MEPs (Neutral: 55.6 ± 20.2% of M_{max}, Pronated: 38.2 ± 21.7% of M_{max}, $P < .01$) and CMEPs (Neutral: 31.3 ± 11.9% of M_{max}, Pronated: 24.1 ± 11.4% of M_{max}, $P < .005$). There were no differences in amplitude at the 12 o'clock position between forearm positions for MEPs ($P = .09$) or CMEPs ($P = .54$). For the tonic contractions, MEPs were significantly larger with a neutral versus pronated forearm position (Neutral: 40.1 ± 14.8% of M_{max}, Pronated: 30.4 ± 11.2% of M_{max}, $P < .05$) while there were no difference in CMEPs ($P = .38$). CSE was higher with a neutral forearm position for both arm cycling and tonic elbow flexion. While spinal excitability was also higher with a neutral forearm position during arm cycling, no difference was found during tonic elbow flexion. This suggests that the influence of forearm position on spinal excitability is not universal across motor outputs and may be specific to arm cycling (ie. task dependent).

Title: The role of central drive and afferent feedback on corticospinal excitability during arm cycling

Authors: ***N. SORAN**[1], L. R. ALCOCK[1], E. J. LOCKYER[1], A.-J. SPENCE[1], C. P. CHAYTOR[1], D. C. BUTTON[1,2], K. E. POWER[1,3];
[1]Human kinetics and Recreation, Mem. Univ. of Newfoundland, St Johns, NL, Canada; [2]Fac. of Med., Mem. Univ. of Newfoundland, Memorial University of Newfoundland, NL, Canada; [3]Fac. of Med., Mem. Univ. of Newfoundland, St John's, NL, Canada

Abstract: We recently demonstrated that supraspinal excitability to the biceps brachii, an elbow flexor, was enhanced during the extension phase of arm cycling as cadence increased from 60 to 90 rpm. The purpose of the present study was to determine if the increase in surpaspinal excitability was due to the modulation of supraspinal drive and/or afferent feedback. Corticospinal excitability was measured using motor evoked potentials (MEPs) elicited via transcranial magnetic stimulation (TMS). Recordings were made from the biceps brachii of the dominant arm during mid-elbow extension (12 o'clock relative to a clock face) while arm cycling using three experimental tasks and two cadences (i.e. 60 and 90 rpm). The three tasks were: 1) bilateral arm cycling (BL; supraspinal drive and afferent feedback present); 2) unilateral, non-dominant arm cycling with the dominant arm moving passively (P; no supraspinal drive with afferent feedback present); and 3) unilateral, non-dominant arm cycling with the dominant arm at rest (R; no supraspinal drive or afferent feedback present). MEPs were normalised to M_{max} and were expressed as a percentage. Preliminary data analysis demonstrates significant main effects for cadence ($p = .017$) and tasks ($p = .007$). As expected, the peak-to-peak amplitudes were significantly larger during cycling at 90 vs 60 rpm (60 rpm: $9.7 \pm 3.2\%$ of M_{max}; 90 rpm: $16.1 \pm 4.6\%$ of M_{max}, $p=.017$). During non-dominant arm cycling at 90 rpm, corticospinal excitability to the biceps brachii of the dominant arm was highest when at rest (R: $26.45 \pm 23.3\%$ of M_{max}) followed by passive arm cycling (P: 15.0 ± 11.4 % of M_{max}) and finally during bilateral arm cycling (BL: $7.0 \pm 7.3\%$ of M_{max}). Changes in interhemispheric inhibition (IHI) may partially explain the current findings. Enhanced corticospinal excitability in the higher cadence may result from cross facilitation and/or reduced IHI between motor cortices as the limbs attempt to cycle synchronously. Reduced IHI may also contribute to the increase in

corticospinal excitability with the higher cadence in dominant arm as it becomes less active as the need to inhibit an inactive hemisphere may not be required.

Title: Behaviors formed by the coordination of ingestive motor actions with breathing

Authors: ***S.-M. LIAO**, D. KLEINFELD;
Physics, UCSD, La Jolla, CA

Abstract: Ingestive behaviors, which include chewing, licking and swallowing, require a precise temporal coordination among the participating muscles. They further require coordination with the respiratory rhythm to avoid interference with the upper airway. Here we electrophysiologically record from selected muscles involved in ingestive behaviors of the rat and study how the rhythmic pattern of orofacial movements relates to the inspiratory rhythm, generated by the preBötzinger complex (Smith 1991 Science), and to the chewing rhythms, generated in a more dorsal-medially located nucleus nearby reticular formation (Nozaki et al 1986 J Neurphysiol; Chandler & Tal 1985 J Neurosci). Licking occurs at 6 to 7 Hz (Travers et al. 1997 Neurosci Biobehav Rev). The concurrent respiration is primarily composed of basal breathing, at frequencies < 3 Hz, with relatively few sniffing cycles, which occur at frequencies > 5 Hz. We observe that protrusion of the tongue movement never phase-locks with basal breathing although it will phase lock with sniffing. This implies that the coupling between the preBötzinger complex and the premotor circuitry that controls rhythmic tongue movements is strongly nonlinear. In contrast to breathing, rhythmic motion of the masseter muscle that drives chewing is strongly phase-locked with motion of the tongue at all frequencies. This later finding is consistent with common premotor projections to both the hypoglossal motor nucleus and the trigeminal motor nucleus (Stanek et al. 2014 eLife).

Title: Brainstem control of exploratory nose motion in rodents

Authors: *A. KURNIKOVA[1], M. DESCHÊNES[3], D. KLEINFELD[2];
[1]Neurosciences, [2]Physics, UC San Diego, La Jolla, CA; [3]Univ. Laval, Québec, QC, Canada

Abstract: Rodents shift their nose from side to side while they actively explore their surroundings. This motor action is used to sample and presumably lateralize odors in order to guide navigation. Here we find that nose motion occurs both spontaneously during sniffing and in response to presentation of an odorant. Lateral motion of the nose is phase-locked to rhythmic breathing (Deschênes et al. 2014 Anatomical Record), such that the peak displacement of the nose occurs during inspiration. A second component of this motion is a slowly varying bias, which changes on a time-scale of 0.5 seconds. The bias is strongly driven by odorant presentation and furthermore, the nose will not deflect to a side if the corresponding nostril is blocked. We study premotor control of nose motion to further understand the generation of orofacial exploratory behaviors in synergy with the respiratory drive. Premotor nuclei provide input to motor neurons that are located in the dorsal lateral division of the facial motor nucleus (Deschênes et al. 2016 Neuron) that in turn contact the deflector nasi muscle (Deschênes et al. 2014; Haidarliu et al. 2015 Anatomical Record) to drive deflection of the nose. As a means to localize putative premotor nuclei, we use replication competent rabies virus to transsynaptically label secondary inputs to the deflector nasi muscle. In preliminary data, we identified multiple clusters of secondary labeled cells, including a group in the reticular formation caudal to the facial motor nucleus, i.e., the retrofacial area. Activation of cells in this group with glutamate microstimulation deflects the nose and activates the deflector nasi muscle. Further, a complete transsection of this area completely abolishes nose motion to the affected side. Cells in the retrofacial area send primarily glutamatergic projections to the facial motor nucleus (Deshenes et. al. in press). We thus use AAV-FLEX-ReaChR, which drives expression of a red shifted

channelrodopsin, to target the glutamatergic cells in the retrofacial area and determine the effect of their activation on nose motion. These ongoing studies will delineate the contribution of neurons cells in the retrofacial region to lateral motion of the nose and in relation to the respiratory drive and other orofacial motor actions.

Title: Effects of different motor patterns on the stability of isochronous serial interval production

Authors: ***W. QI**[1], A. MIURA[2], K. KANOSUE[3];
[1]Sports Sci., Waseda Univ., Tokorozawa-Shi, Japan; [2]Sports Sci., [3]Waseda Univ., Saitama, Japan

Abstract: Isochronous serial interval production (ISIP) inevitably accompanies with variability, which plays a crucial role in sports and music performances. However, the question where and how variability occurs still remains unknown. The purpose of this study is to elucidate variability of different ISIP motor patterns (tapping and pressing) and delineate the dominant factor of variability categorized in Collier & Ogden's model (2004). Eleven males and nine females in healthy condition participated in this experiment (20-30 years old, right-handed). Subjects sit at a table upon which one force plate was placed and did tasks of tapping or pressing 21 times (20 intervals) at one of nine time intervals (500ms, 750ms, 1000ms, 1250ms, 1500ms, 1750ms, 2000ms, 2500ms and 3000ms). The time and force of taps and presses were recorded with the force plate. Before each task, subjects were required to listen to the target inter-tap (press) intervals supplied with a metronome until they memorized it. Each task was tested twice and the order of tasks was randomized across subjects. Average inter-tap (press) intervals, their standard deviations and their coefficient of variations were calculated. Coefficient of variation increased with the increase in length of inter-tap (press) interval but the trends of increasing were significantly different between tapping and pressing tasks (Interaction: $P<0.05$). The coefficient of variation in tapping tasks at inter-tap intervals above 2000ms was larger than that at 500ms, while there was no difference among intervals for pressing tasks ($P<0.05$). Therefore, different motor patterns would influence the stability of ISIP only at relatively fast pace. Furthermore, standard deviations of timekeeping process, motor delay and drift were estimated according to Collier & Ogden's model. Standard deviation of timekeeping process shows significant difference at 500ms, 750ms, 1000ms and 1500ms inter-tap (press) intervals between tapping

tasks and pressing tasks ($P<0.05$), while no significance was found in standard deviation of motor delay and drift between two kinds of tasks ($P>0.05$). From these facts, we suggest that motor patterns influence the stability of short interval ISIP movement. Furthermore, the variability in short interval ISIP movement occurred in timekeeping process rather than those of motor delay and drift.

Title: Organization of medullary reticulospinal inputs to thoracic descending commissural interneurons

Authors: *B. K. LAPALLO, M.-C. PERREAULT;
Emory Univ., Atlanta, GA

Abstract: We have previously described new organizational principles of the medullary reticular formation (MRF) whereby reticulospinal (RS) neurons in medial and lateral MRF preferentially activate hindlimb and axial motoneurons, respectively (Szokol et al. 2008, Szokol and Perreault 2009). We have also shown that, in the L2 segment, the differential control by mMRF and lMRF is mediated in part via specific connections to descending commissural interneurons (dCINs; Szokol et al. 2011). The goal of the present work is to investigate the rules that may underlie the specificity of the RS-dCINs connections. One possibility is that the recruitment of dCINs by mMRF and lMRF is segment-specific. If so this could be coded by differences in relative proportions of dCINs recruited. Here we are assessing the recruitment patterns of dCINs in the T7 segment because of the difference in motoneuron composition (axial only) compared to the L2 segment (axial and hindlimb). We combined electrical stimulation of the mMRF and lMRF and single-cell calcium imaging in the isolated brainstem-spinal cord neonatal (P0-P6) mouse preparation. The response patterns to mMRF and lMRF stimulation were assessed for 78 dCINs (n= 7). We found that 7% responded to mMRF stimulation only, 14 % responded to lMRF only, 75% responded to both mMRF and lMRF and 4% did not respond to either. Of the group that responded to both MRF regions, the majority (63%) were preferentially activated by lMRF stimulation (lMRF>mMRF). These proportions are comparable to the proportions reported

earlier for L2 dCINs (8%, 26%, 36% and 30%, respectively) particularly if we consider that our limit for response detection was lowered slightly compared to past studies. Altogether the present findings do not appear to support a segment-specific recruitment of dCINs by RS inputs. However, our experiments have not so far distinguished between dCINs of different transmitter phenotypes. Current experiments are addressing the issue by determining the relative proportions of $vGluT2^+$ vs $vGluT2^-$ (excitatory vs inhibitory) dCINs that respond to mMRF and lMRF stimulation in both T7 and L2 segments.

Title: In search for the interneurons implicated in the resetting of the locomotor rhythm by extensor group I afferents

Authors: L. E. DOMÍNGUEZ-RODRÍGUEZ[1], K. STECINA[2], D. L. GARCÍA-RAMÍREZ[1], E. MENA-AVILA[1], J. J. MILLA-CRUZ[1], L. MARTÍNEZ-SILVA[1], H. HULTBORN[3], *J. N. QUEVEDO[1];
[1]CINVESTAV del IPN, Mexico City, Mexico; [2]Physiol., Univ. of Manitoba, Winnipeg, MB, Canada; [3]Neurosci. and Pharmacol., Univ. of Copenhaguen, Copenhaguen, Denmark

Abstract: Sensory information arising from limb movements is able to control the spinal locomotor circuitry for locomotion to adapt the motor pattern to demands of the environment. Stimulation of extensor group I afferents during the flexion phase of fictive locomotion produces a suppression of the ongoing flexion and initiation of the subsequent extension (resetting to extension; Conway et al Exp Brain Res 1987, 68: 643-56; Hultborn et al Ann N Y Acad Sci 1998; 860:70-82). During fictive locomotion, instead of the classical Ib non-reciprocal inhibition, stimulation of extensor group I afferents produced an oligosynaptic excitation in extensor motoneurons with latencies (~3 ms) compatible with 3 interneurons interposed (see Gossard et al, Exp Brain Res 1994, 98:213-28). We assume that some interneurons in this pathway actually belong to the rhythm-generating layer of the Central Pattern Generator (CPG), since it causes a

resetting of the rhythm.
The present work was aimed to identify the interneurons causing the resetting to extension and mediating the polysynaptic group I excitation during L-DOPA-induced fictive locomotion in the cat (and was a continuation of previous work; Stecina et al 2007, SfN poster 78.11).
Peripheral nerve dissection, laminectomy and decerebration were made under isofluorane anesthesia. Subsequently spinalization at C1 was performed. Fictive locomotion was induced by the injection of Nialamide (50 mg/kg) followed by L-DOPA (100 mg/kg). Ankle extensor motoneurons were recorded with K^+-acetate-filled micropipettes. Orthodromic extracellular field potentials (EFPs) and interneuron spikes were recorded in the intermediate nucleus and the ventral horn with Na^+-glutamate-filled micropipettes (to be able to cause tonic firing of interneurons).
We recorded candidate interneurons to mediate the resetting to extension based on the following criteria: i) rhythmic activation during the extension phase, ii) mono-, di-, or trisynaptic activation by extensor group I afferents, iv) polysynaptic activation by stimulation of contralateral flexor reflex afferents. Some interneurons were antidromically activated from an extensor motor nucleus and their spikes associated to negative EFPs in the same motor nucleus, suggesting they were last-order excitatory interneurons.
We conclude that interneurons recorded fulfill the characteristics to belong to the neuronal pathway activated by extensor group I afferents during locomotion. As the activity of interneurons exhibit the same pattern as the 'resetting to extension', they may belong to the rhythm generating layer of the CPG for locomotion.

Title: Computational modeling of effects of dorsal root stimulation on locomotor CPG

Authors: *N. A. SHEVTSOVA[1], S. B. DIETZ[2], J. AUSBORN[1], R. M. HARRIS-WARRICK[2], I. A. RYBAK[1];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: We studied the effects of sensory nerve stimulation on fictive locomotor activity to understand afferent control of the central pattern generator (CPG) in the isolated neonatal mouse spinal cord. In our experiments, fictive locomotor activity was evoked by bath application of N-Methyl-D-aspartate (NMDA), dopamine (DA) and serotonin. The lumbar dorsal roots (dL5) were stimulated while monitoring activity of flexor-related ventral roots, ipsi- (iL2) and contralateral (cL2), as well as the ipsilateral extensor-related ventral root (iL5). We found that low intensity stimuli delivered in an appropriate phase of locomotor activity triggered a phase advance activity in the ipsilateral ventral L2 root while high intensity stimulation induced a complex bilateral speeding effect lasting for seconds. This effect was characterized by an increase in burst frequency in all ventral roots with correct flexor-extensor and left-right alternation. The speeding effect was less pronounced as NMDA or DA concentrations were increased and could be abolished by bath application of the 2-methyl-6-(phenylethynyl)-pyridine (MPEP), antagonist of metabotropic glutamate receptor of subtype 5 (mGluR5), suggesting the critical role of mGluR5 for this speeding effect.
To reproduce and explain the experimental results of the dorsal root stimulation, we extended our earlier computational bilateral model of the locomotor CPG by incorporating sensory inputs. In the model, the rhythm generator (RG) on each side consists of flexor and extensor half-centers mutually inhibiting each other. Coordination between the left and right RGs is provided by excitatory and inhibitory commissural pathways. Sensory inputs drive two types of dorsal horn relay neurons, with low and high activation thresholds, which affect the CPG. High-threshold relay neurons incorporate mGluR5 receptors. Activation of mGluR5 by high-intensity afferent stimulation provides a long-lasting depolarizing effect on the RG, inducing speeding. Our model suggests that higher DA or NMDA concentrations presynaptically block glutamate release from sensory afferents to the relay neurons, or occlude the glutamate effect, thus reducing the speeding effect. Simulating MPEP application in the model by blockade of the mGluR5 receptors prevents speeding.
Our model proposes mechanistic explanations for the experimentally observed effects of afferent stimulation and provides novel insights into the organization of the locomotor central pattern generator.

Title: Effects of thermal stimulation of the face on limb movements in *In vitro* preparations of newborn opossums, Monodelphis domestica

Authors: *E. CORRIVEAU-PARENTEAU, T. CABANA, J.-F. PFLIEGER;
Sci. biologiques, Univ. de Montreal, Montreal, QC, Canada

Abstract: Marsupials are born very immature and must attach to the mother's nipples in order to continue their development. The newborn grey short-tailed opossum crawls on the mother's belly, unaided by her, using alternate rhythmic movements of the forelimbs (FLs). These movements are generated by the spinal cord but cephalic sensory systems are needed to sustain crawling, to guide the newborn to the nipple and to induce the attachment to it. In this species, we have shown that electrical stimulation of the trigeminal ganglion, which is the main source of sensory innervation of the snout skin, readily induces FL movements in *in vitro* preparations of newborn. We have further shown that mechanical pressures on the snout skin induce FL movements. To determine if sensory modalities other than touch could influence FL movements of newborn opossums, we tested the effect of temperature on facial skin. 11 newborns were deeply anesthetized before being eviscerated. Each specimen was placed in a petri dish filled with oxygenated physiological solution. Following craniotomy and laminectomy, decerebration was done by sectioning rostral to the midbrain. The limbs and tail were left attached to the carcass. Under a microscope 0.3 cc of solution at variable temperature was ejected from a needle directed towards the face skin. 10 ejections at each 3 temperature ranges: cold (4-8°C), warm (room temperature, 21-25°C), or hot (35-45°C), were made on each specimen, with a minimum interval of 3 min. between ejections. The FL responses were observed visually and described as non-locomotor-like: extensions of one FL or of both FLs without obvious interlimb coordination, or locomotor-like: alternate extensions of the left and right FLs. Ejections of the cold solution always induced FL movements (100%), whereas ejections of warm or hot solution induced movements 17% and 26% of the times, respectively. Locomotor-like responses accounted for 57% of the responses to cold, but of only 5% of the responses to the warm or hot temperature stimulations. After complete section of the spinal cord at the obex, only non-locomotor-like responses were obtained after cold stimulation, and in only 59% of the tests. The latter may be explained if the puff ejections of the liquid reached the neck or FL skin. Warm and hot temperatures were not tested in spinalized animals. These results show that temperature can

influence motor behaviors of newborn opossums and that cold is far more potent than warm and hot. We propose that exposure to colder temperature after birth may induce or sustain locomotion of the newborn until it reaches a nipple, thereafter other stimuli may inhibit this behavior.

Title: Investigation of neural circuits in the zebrafish hindbrain during active locomotion

Authors: *K. E. SEVERI, U. L. BOEHM, M. CHAVEZ, C. WYART;
Inst. du Cerveau et de la Moelle Épinière (ICM), Paris, France

Abstract: Locomotion is a complex process relying on motor circuits in the spinal cord that integrate dynamic sensory feedback as well as descending commands from the brain. The hindbrain is a major control center to drive locomotor central pattern generators and perform sensory integration across modalities. In the larval zebrafish, activity patterns in the hindbrain apart from the reticulospinal neurons have been vastly underexplored. To characterize the hindbrain population driving motor output and integrating sensory signals, we perform *in vivo* two-photon calcium imaging in both paralyzed and actively swimming larval zebrafish expressing genetically-encoded calcium indicators under panneuronal drivers. By inducing locomotion with whole-field visual motion and simultaneously recording high-speed video of the moving tail during calcium imaging, we can link tail kinematics to neural signals. We used automated selection algorithms and registered active regions across individuals. To characterize the neural circuitry, we estimated the Granger causality between time series recorded from cells of interest. We also use specific markers to label subsets of the population and ask what role these neurons play during locomotion. These experiments contribute to a functional map of the hindbrain and by comparing active and paralyzed conditions, to explore activity associated with either locomotor drive or mechanosensory feedback mechanisms.

Title: Motor activity in the three major leg joints of the turning stick insect is modified in a joint- and context-specific way

Authors: *E. I. HAMMEL, A. BÜSCHGES, M. GRUHN;
AG Bueschges, Univ. of Cologne, Koeln, Germany

Abstract: Locomotion depends on neuronal activity, muscle contractions, and sensory feedback. The generation of straight walking has already been well studied and much is known about the neural activity underlying basic locomotor patterns in the single leg (Büschges 2005). However, we only begin to understand the neuronal mechanisms underlying behavioral flexibility, and the knowledge on local segmental activity during adaptive locomotion and the role of descending influences on it is scarce (Hellekes et al. 2012; Martin et al. 2015; Gruhn et al. 2016).
Here we investigate the neural mechanisms underlying curve walking in the stick insect (Carausius morosus). Turning of the tethered animals on the slippery surface was induced using an optical stimulus, and walking sequences were monitored by video and by EMG recordings of the *Flexor tibiae* muscle in both front legs. We studied the influence of optomotor induced turning on motor activity in all three major leg joints by recording extracellularly from leg nerves nl2 (containing protractor motoneurons (MNs)), nl5 (retractor MNs), C1 (levator MNs), C2 (depressor MNs), nl3 (extensor MNs), and branches of the nervus cruris (flexor MNs) of the deafferented meso- and metathoracic ganglia in a reduced preparation with all legs cut off except for the two front legs.
The motor activity of the three joints showed three types of responses: 1) a context-dependent change in activity in the subcoxal joint: meso- and metathoracic protractor MNs showed an increased activity during inside over outside turns (mesothorax (Ms) N = 4, metathorax (Mt) N = 12), while retractor MNs showed an increased activity during outside vs. inside turns (Ms N = 4, Mt N = 8). 2) a context-independent activity: the meso- and metathoracic levator and depressor MNs mostly did not show changes depending on the turning direction. The levator MN activity increased as soon as the front legs started stepping in either direction (Ms N = 8, Mt N = 6), whereas depressor MN activity ceased (Ms N =4, Mt N = 6). 3) no characteristic pattern for either inside or outside turns: extensor (Ms N = 8, Mt N = 9) and flexor (Ms N = 13, Mt N = 12) MNs showed either increase or decrease in activity upon inside or outside turning with high

variability in neuronal activity, without an obvious context-dependent pattern.
Our results indicate that changes in meso- and metathoracic motor activity during curve walking of the front legs are not thorax-segment specific but occur on the level of each leg joint. Further studies will clarify in how far the activity of meso- and metathoracic central pattern generators are affected by descending influence from curve walking front legs.

Title: Role of capsaicin sensitive nerves in initiation of swallows evoked by carbonated water stimulation in rats

Authors: ***K. TSUJI**, T. SUZUKI, S. SAKAI, J. MAGARA, T. TSUJIMURA, M. INOUE; Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata City, Japan

Abstract: Purpose: Capsaicin is known as a therapeutic drug which improves swallowing function and prevents aspiration pneumonia. However, a role of capsaicin-sensitive receptors/fibers on naturally evoked swallows has not yet been clarified precisely. The aim of the present study was to investigate effects of capsaicin-sensitive laryngeal nerves on swallowing evoked by mechanical and chemical stimulation. Materials and Methods: Urethane-anesthetized male Sprague Dawley rats were used. Swallowing reflex was identified by the electromyographic burst of suprahyoid and thyrohyoid muscles. Following topical application of capsaicin alone or together with QX-314 (QX-314/capsaicin) to the vocal folds, the number of swallows by capsaicin application to the vocal folds was measured at 5, 30 and 60 min after initial procedure. Effect of topical application of QX-314/capsaicin on the following swallows evoked by carbonated water stimulation and von Frey mechanical stimulation was also evaluated at 5 min. Results: While swallow initiation did not significantly change among the time points in capsaicin alone model, it was significantly suppressed in QX-314/capsaicin model at 5 min and was back in a time dependent manner. Topical application of QX-314/capsaicin inhibited swallows evoked by carbonated water stimulation. This was not the case of those evoked by

mechanical stimulation. Conclusion: Capsaicin sensitive nerves play an important role in initiation of swallows evoked by carbonated water stimulation.

Title: Spinal changes after one session of isometric training of the elbow flexors are influenced by forearm posture

Authors: *J. NUZZO[1], B. BARRY[2], S. GANDEVIA[1], J. TAYLOR[1];
[1]Neurosci. Res. Australia, Randwick, Australia; [2]Sch. of Med. Sci., Univ. of New South Wales, Kensington, Australia

Abstract: Strength training is motor training that involves repetitive high-force muscle contractions. After one session of isometric strength training of the elbow flexors, cervicomedullary motor evoked potentials (CMEPs) in biceps brachii increase in size for up to 25 minutes (Nuzzo et al. Med Sci Sports Exerc 2016). Thus, acute strength training can increase corticospinal excitability at a subcortical level. In *Experiment 1*, we examined if these spinal changes also occur with isometric training at low forces. Ten subjects completed low-force training (12 sets of 8 isometric contractions, 15% peak force) of the right elbow flexors in one session, and high-force training (12 sets of 8 isometric contractions, 75% peak force) in another. Training was performed with the forearm supinated and vertical, and the elbow and shoulder flexed to 90 degrees. Before and after training, electrical stimulation of corticospinal tract axons at the cervicomedullary junction elicited CMEPs in biceps brachii. Unexpectedly, biceps CMEPs were unchanged after both low- and high-force training. To determine if the lack of change in CMEPs after high-force training was due to the posture of the forearm during training, a second experiment was conducted. In *Experiment 2*, 14 subjects completed one session of high-force training with the forearm pronated rather than supinated. All other aspects of posture and the

training were unchanged. Biceps CMEPs were facilitated for up to 25 minutes after training. The increase in biceps CMEPs after high-force training in *Experiment 2* (51 ± 54.7%; mean ± SD) was greater than in *Experiment 1* (-0.5 ± 35.4%, $t = 2.603$, $p = 0.016$). Thus, spinal level changes (i.e., increased motoneuron excitability and/or increased efficacy of corticospinal-motoneuronal synapses) occur after one session of isometric strength training of the elbow flexors. However, these effects depend on the posture of the forearm during training. The mechanisms are unknown, but could include modifications in reflex paths and corticospinal transmission.

Title: Transforming growth factor growth-supportive effect on delayed nerve repair is mediated via a non-SMAD signaling pathway

Authors: *D. NGUYEN[1], M. BEAVERS[2], L. ALLULLI[2], I. IWUCHUKWU[3], W. SULAIMAN[4];
[1]Neurosurg., Ochsner Hlth. Syst., New Orleans, LA; [3]Neurol., [4]Neurosurg., [2]Ochsner Med. Ctr., New Orleans, LA

Abstract: Background and Objective: Our previous works have demonstrated the mitogenic effects of transforming growth factor -beta (TGF-β1) and forskolin on Schwann cells reactivation and axonal regeneration in delayed repair nerve. In this study we examine the components of the TGF-β/Smad signaling pathway involved in modulating the mitogenic effects. **Methods**: Adult female SD rats were used for chronic tibial nerve injury and delayed repair. After 2 months, the transected nerve was repaired and treated with forskolin (0.5 uM), TGF-β1 (1ng/mL) plus forskolin, or saline-treated. After 6 weeks, the proximal, site of injury-repair, and distal nerve stump were harvested and frozen. Total RNA was prepared for real-time RT-PCR using custom TGF-β signaling PrimePCR arrays. The expression of Smad2, Smad3, Smad4, Smad7, transforming factor beta receptor type 1 (TBRI) and type 2 (TBRII) were analyzed. A cycle

threshold (Ct) of less than 34 was used as a cut-off for reliability. Data were normalized to GAPDH and fold change relative to forskolin- treated were determined. **Results**: All SMADs were detectable in all groups except for SMAD-3 and SMAD-7 but those detected were at very low levels. In the TGF-β1 /forskolin-treated group, expression of Smad2 and Smad 4 were decreased in both repair sites and distal nerve stumps but more so at the site of repair. In the forskolin-treated group, Smad2 was expressed at both locations and at 15-fold higher than the corresponding TGF-β1 /forskolin-treated nerves.The TBRI was expressed in both treatment groups, and decreased 7.3-fold and 4.3-fold i*n* the distal and site of repair of TGF-β1 /forskolin-treated nerves, respectively. The TBRII was expressed only at the site of repair and decreased 21-fold in TGF-β1 /forskolin-treated nerve stumps. Expression of TGF- β1 decreased 67-fold and 26-fold in the distal and site of repair respectively. **Conclusion**: TGF-β1/Smad signaling components were downregulated with TGF-β1 /forskolin treatment suggesting alternative pathways are involved in maintaining Schwann cells in a reactivated state necessary for axonal regeneration.

Title: Hip joint movement modulates the neural plasticity in reciprocal Ia inhibition induced with patterned electrical stimulation

Authors: *Y. UENO[1], J. USHIYAMA[2,3];
[1]Grad. Sch. of Media and Governance, [2]Fac. of Envrn. and Information Studies, Keio Univ., Kanagawa, Japan; [3]Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: BACKGROUND: Stroke patients often lose the function of Reciprocal Ia Inhibition (RI) from the tibialis anterior to the soleus, which is a key factor for smooth heel contact in walking. It was previously reported that Patterned Electrical Stimulation (PES) to the common peroneal nerve for 20-30 min temporarily enhanced the RI. In this study, we investigated whether PES combined with passive flexion/extension movement of the hip joint modulates RI. METHODS: Seven healthy young individuals voluntarily participated in this study. Three

stimulation protocols were assessed as follows: 1) PES (10 pulses at 100 Hz every 1.5sec: 900-1000 trains) was applied during non-weight standing (CON); 2) PES was applied at the phase of hip flexion during passive hip movements with no loads (FLX); 3) PES was applied at the phase of hip extension during passive hip movements with no loads (EXT). Passive hip movements were reciprocally induced, by examiners manually moving the handles of a rehabilitation device (EasyStand Glider^{TM}, Altimate Medical Inc., Minnesota, USA). The strength of RI was measured by using conditioning-test paradigms of soleus H-reflex. As for all participants, RI assessments were performed at before, 0 min, and 25 min after the three PES interventions mentioned above. RESULTS: The strength of RI was significantly increased in EXT (before, 5.17 ± 2.60%; after, 17.83 ± 4.15%; $p < 0.01$). In CON, RI was increased to some extent, but the effect was no significant (before, 6.97 ± 5.81%; after, 11.53 ± 7.45; $p = 0.49$).On the other hand, no change of RI was observed in FLX (before, 8.79 ± 6.76%; after, 8.89 ± 13.58%; $p = 1.00$). Additionally, from assessment at 25 min in all paradigms, we confirmed the strength of RI dropping back to the initial level. CONCLUSION: These results indicate that the effect of PES on RI can be enhanced by adding passive hip joint movements which induce Ia afferent activity of hip flexors. Such combination of nerve stimulation and movement may help future development of new rehabilitation methods for post-stroke patients.

Title: Stimulation of a denervated laryngeal muscle with low frequency promotes selective reinnervation and restores function

Authors: *Y. LI, S. HUANG, D. ZEALEAR;
Hearing and Speech Sci., Vanderbilt Univ. Med. Center/Oto, Nashville, TN

Abstract: Previously, electrical stimulation of a denervated canine laryngeal muscle was shown to promote reinnervation by original over foreign motoneurons. An implantable nerve stimulation-EMG system was used to index the appropriateness of reinnervation of the vocal fold abductor (posterior cricoarytenoid, PCA) muscle by inspiratory versus foreign reflex glottis closure (RGC) motoneurons following recurrent laryngeal nerve section and repair. In the

present study in 11 canines, a clinical model was used, where both nerves were sectioned and ventilation compromised due to loss of abduction. The EMG system and a pulse generator were implanted, the latter for electrical conditioning of PCA muscles. After nerve section, animals were randomly assigned to four groups to assess the effect of different muscle stimulus paradigms on reinnervation quality and degree of functional recovery: 1)40 pps train, 2)20 pps train 3)10 pps train and 4)control-no stimulation. One msec pulses were applied with 4 sec on/4 sec off duty cycle during the post neurorrhaphy regeneration period. In bimonthly sessions, spontaneous vocal fold movement was measured endoscopically during induced hypercapnea in the anesthetized animal. Rectified integrated EMG potentials were recorded from abductor muscles and adductor (thyroarytenoid, TA) muscles. Recordings were obtained during hypercapnic respiration to index reinnervation by inspiratory motoneurons, and during superior laryngeal nerve stimulation to index reinnervation by RGC motoneurons. Exercise tolerance was measured on a treadmill in the awake animal using pulse oximetry. Results demonstrated that all stimulated groups tended to have better results (i.e. higher rank order) in all outcome measures compared to the non-stimulated control group. The rank order stayed fairly consistent across all outcome measures: 10Hz > 20Hz > 40Hz > non-stimulated. It would appear that electrical stimulation of the denervated PCA muscle inhibited synkinetic reinnervation by RGC motoneurons and promoted selective reinnervation by its original inspiratory motoneurons. In addition, stimulation with low frequency, characteristic of the intrinsic activity of PCA inspiratory motoneurons, was more effective than high frequency in inducing correct reinnervation and improving functional recovery.

Title: Intermuscular coherence is altered in adolescent scoliosis patients

Authors: *M. SIMONEAU[1], C. BLUTEAU[1], J.-P. PIALASSE[1], J.-S. BLOUIN[2];
[1]Laval Univ., Quebec, QC, Canada; [2]Sch. of kinesiology, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Adolescent idiopathic scoliosis (AIS) is a three dimensional deformation of the spine. AIS is often associated with vestibulomotor deficits and it has been proposed that an asymmetric descending vestibulospinal activity would cause an asymmetric motor drive to the torso muscles. Such asymmetrical muscles activity, during bone development, may lead to a spine deformation (Lambert et al., 2012). Although this hypothesis is attractive, a dysfunction of other descending pathways could also induce asymmetric motor drive to the torso muscles. The aim of this study was to compare the function of the descending corticospinal pathway between AIS patients (n=13, 11 girls, mean age = 13.8 ± 1.8 years) and healthy adolescents (n=12, 11 girls, mean age = 13.7 ± 2.0 years). The function of the corticospinal tract was assessed through intermuscular coherence between paraspinal muscles while participants performed isometric back extension at two different force levels (i.e., 15% or 30% of maximal strength). Each trial lasted 16 s and there were 15 trials per condition. Back extension strength was measured using a load cell located 0.1 m below the 7^{th} cervical vertebra. Right and left paraspinal muscle activity was recorded using surface electromyography at a sampling frequency of 1000 Hz. For each condition, coherence was estimated with concatenated data for each trial within each participant and concatenated pooled data for each trial across all participants. Significant differences between groups for the pooled coherence were determined with the difference of coherence test. Significant coherence between 8 and 12 Hz and 15 and 50 Hz was observed at both isometric force amplitudes. For the control group, 11 out of 12 participants demonstrated significant coherence for both frequency bands. For the AIS group, 8 out 13 participants exhibited significant coherence for the 15 to 35 Hz frequency band while only 2 participants showed significant coherence for the 8 to 12 Hz frequency brand. Results of the difference of coherence test revealed that regardless of the isometric force amplitude, AIS patients showed less coherence between the 8 to 12 Hz and 15 to 35 Hz frequency bands compared to controls. These results suggest a dysfunction of the descending corticospinal tract or the sensorimotor network involved in torso muscle activation in AIS patients.

Title: b - Learning of mindfulness, studying body and brain unifying science through conscious trunk regulation using tactile information

Authors: *Y. ATOMI[1], R. TUZUKI[1], T. ATOMI[2], K. TANAKA[2], A. ATOMI[1], M. SHIMIZU[1], E. FUJITA[1], K. HASEGAWA[3];
[1]Dept of Material Hlth. Science, Fac. and Grad. Sch. of Engin., Tokyo Univ. of Agr. and Technol., Tokyo, Japan; [2]Teikyo Sci. Univ., Yamanashi,, Japan; [3]Japan Aerospace Exploration Agency, Sagamihara Kanagawa, Japan

Abstract: We propose b-leaning, which connects body and brain to recreate human system. We have been presented in this meeting about dual instability of adhesive cells consisting of multicellular organism and human body bipedalism connecting by extracellular matrix (ECM) associating with voluntary movement and passive tension development under the gravity. We need integrating body-mind bi-directionality to control posture, especially slow voluntary movement like Noh and Tai-chi-chuan, which have been developed in Asia. Previously we reported that using analysis of ultrasonic images of abdomen muscles contractions during special standing performed in Tai-chi-chan using video images. Investigation of the neural substrate underlying whole body instability, based on the self-recognition paradigm revealed significant activity in the regions of the right parieto-insular vestibular cortex, inferior frontal junction, posterior insula and parabrachial nucleus (Atomi T et al., 2014). On the other hand, we have also reported the importance of tactile information using special wear to balance and normalize posture during standing, sitting and walking using 3D-motion analysis system (2015SfN). In the present study, we report the usefulness of one-week practices of voluntary conscious trunk exercises performed with touching by own hands, feeling the tactile information, and developing tension of own abdominal muscles at “the” area performed under recumbent position and scanning over whole ventral side of the body for 1~5 minutes per day. The effects were measured by physical performances like sit-up and jumping side to side, standing posture by photograph and questionnaire. Especially sit-up performance, standing posture and motivation to do active life significantly improved after one-week practice. Sit-up exercise is a special index showing good connection of whole body and brain according to Murata et al. (2010). It is very important for us to understand dual knowledge about not only own real human life system consisting of cells and ECM that are secreted by the cells, and responds well to mechanical stresses to increase during own physical exercise, and that works with activity-dependent survival rule, but also conscious movement bridging body and mind to control instable own body and conscious mind. Tactile information is essential for accepting own real system of body and imaginary brain systems creating human mind. Craig reviewed the neuroanatomical evidence for a progression of integrative representations of affective feelings from the body in the bilateral anterior insular cortex, or “the sentient self.”

Title: Protective role of monoamine oxidase B inhibitor on degenerating spinal neurons and its effects on nerve regeneration and functional recovery in sciatic nerve crush injury model

Authors: *H. M. ALSHIMALI[1], N. M. KAYALI[2], A. ALSALEM[2], W. M. RENNO[2], M. S. RAO[2], K. M. KHAN[2];
[1]Kuwait Univ., Safat, Kuwait; [2]Kuwait Univ., Kuwait City, Kuwait

Abstract: Monoamine oxidase (MAO) is a flavin adenine dinucleotide (FAD) containing an enzyme which catalyzes the oxidation of amines. MAO-B is proposed to play an important role in the pathogenesis of neurodegeneration through the production of reactive oxygen species (ROS) and neurotoxins. The present study was designed to outline the effects of the MAO-B inhibitor on sciatic nerve regeneration, neuroprotection of spinal neurons and sensory-motor functional recovery in the sciatic nerve crush injury model. Male Wistar rats (4-month-old) were assigned to i) Naïve (N), ii) Sham (S), iii) Sciatic nerve injured and treated with saline (I+saline) and iv) Sciatic nerve injured and treated with MAO-B inhibitor (I+MAO-B-I) groups (n=10/ group). In group iii and iv, the injury was produced by crushing the sciatic nerve followed by treatment with saline or MAO-B-I (2.5 mg/kg) for 10 days. Behavioral tests were conducted from week 1 to week 7. At the end of the study sciatic nerve and lumbar spinal cord were studied by immunohistochemistry, light and electron microscopy. Data were analyzed with one-way ANOVA followed by Bonferroni's multiple comparison tests. I+MAO-B-I treatment showed significant improvement in sensory and motor tests (Hoping reflex, hot plate test, tail flick test, extensor postural thrust, foot position, toe spread test, mechanical hyperalgesia test) compared to I+saline group ($p<0.05$ - 0.001). The morphological study showed a significantly increased number of nerve fibers in sciatic nerve ($p<0.05$), with better myelination pattern in I+MAO-B-I treated group compared to I+saline group. Spinal cord ventral horn showed a significant increase in the number of NeuN-immunoreactive neurons in the I+MAO-B-I treated group compared to I+saline group ($p<0.01$). These results show that MAO-B-I has a significant potential for protecting the degenerating spinal cord neurons and enhancing the regeneration of injured sciatic nerve following crush injury.

Title: Quantification of a single score (1+) in the modified ashworth scale (MAS), a clinical assessment of spasticity quantification of the modified ashworth score, a clinical assessment of spasticity <!--[endif]-->

Authors: *N. L. SURESH[1], J. EWOLDT[2], E. ROTH[1];
[1]Sensory Motor Perf Prgm, Rehabil. of Chicago, Chicago, IL; [2]Johns Hopkins, Baltimore, MD

Abstract: The Modified Ashworth Scale (MAS) is an assessment that is often used by clinicians to grade spasticity in the affected limbs of stroke survivors. The MAS scale is a function of whether the clinician perceives a resistance to stretch and/or a 'catch' during a passive joint rotation. The qualitative nature of the assessment in combination with the low resolution of the scale could result in varied grouping of spastic patients, even for a single score. The objective of this pilot study was to develop a method for the quantification of the MAS, which could provide greater resolution and could eventually guide better informed therapeutic interventions. The MAS assessment for four stroke survivors with the same clinical MAS score of 1+ was performed by a clinician and quantified using signals from surface electromyography (EMG) and an electrogoniometer during passive joint rotation of the affected and contralateral upper limbs of stroke survivors. The findings from this study show a varied set of signals across four stroke survivors, all graded at 1+. The quantification provides insight as to the mechanisms underlying the passive resistance.

Title: A new method for assessing human upper limb Ib function in health and disease

Authors: *S. A. AGUIAR[1], S. CHOUDHURY[2], H. KUMAR[2], M. A. PEREZ[3], S. N. BAKER[1]; [1]Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Inst. of Neurosciences, Kolkata, Kolkata, India; [3]Dept. of Neurolog. Surgery - The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Non-invasive assessment of spinal circuitry in human upper limb is important experimentally and clinically; however, methods are limited. We propose a new protocol in which we conditioned the flexor carpi radialis (FCR) H-reflex, evoked by median nerve stimulation, by previous extensor carpi radialis (ECR) stimulation - three times motor threshold (MT) -, at 18 inter-stimulus intervals (ISIs). Results showed significant facilitation at 30ms ISI and inhibition at 70ms ISI. We hypothesized the facilitation was caused by the action of Ib afferents from Golgi tendon organs in ECR, activated by the twitch that follows stimulation at such intensity. Our aim was to test this hypothesis and investigate this effect in disease. Several human experiments were carried out, which showed that: (i) the first peak in force production after the ECR shock starts in less than 30ms, meaning that the timing of ECR Ib activation was consistent with the hypothesis; (ii) stimulation given to ECR at MT did not cause facilitation, showing that the ECR twitch was necessary for the effect to occur; (iii) taps applied to ECR tendon instead of electrical stimulation produced a similar curve with the facilitation shifted around 15ms earlier; and the facilitation seemed to remain both (iv) when the protocol was applied with the wrist held in a flexed position, excluding the possibility that the effect was caused by afferents from FCR which was disengaged in this position, (v) as well as after vibration of ECR tendon for 25 minutes, which increases the threshold for electrical activation of Ia afferents but does not change the threshold for Ib activation. The main protocol was also tested in three anesthetized rhesus monkeys, with ECR dissected. Results showed a similar curve for monkeys, with the facilitation of the FCR response observed at 30ms ISI. Corroborating our hypothesis, the effect disappeared after cutting the ECR tendon, which meant that the muscle twitch did not pull on the tendon. Finally, we tested the main protocol in stroke and spinal cord injury human patients. Stroke patients presented a similar curve compared to healthy adults for intervals up to 30ms but the facilitation remained for intervals up to 60ms, while the inhibition was on average absent. Spinal cord injury patients showed no significant facilitation or inhibition in group average analysis. Our results provide evidence for a Ib pathway acting on the facilitation of an antagonist muscle in the forearm, which changes in disease. This experimental protocol could be used to assess the function of Ib pathways in human upper limb, since methods for such assessment are currently limited.

Title: A novel method for cortical mapping of proximal and distal upper limb muscles using transcranial magnetic stimulation

Authors: *S. L. DEJONG[1], L. A. WERNER[1], W. G. DARLING[2], R. K. SHIELDS[1]; [1]Dept. of Physical Therapy and Rehabil. Sci., [2]Dept. of Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: Transcranial magnetic stimulation (TMS) is a powerful tool that can be used to probe connectivity between cortical motor neurons and upper limb muscles. The most frequently utilized TMS methods require time-consuming procedures to determine each muscle's optimal stimulation site and motor threshold (MT), followed by stimulation of surrounding sites at a percentage of MT to determine the muscle's cortical representation. Most prior studies have focused on one or two muscles of the hand or wrist, which typically have low MTs and large cortical representations. Although many research questions can be addressed using maps of one or two muscles to represent the upper limb, more comprehensive cortical mapping may allow further examination of cortical reorganization as it relates to motor recovery in humans. The purpose of this study was to demonstrate feasibility of an expanded method of TMS cortical mapping using a novel procedure. Ten healthy right-handed adults participated. An anatomical brain MRI was obtained for neuronavigation. A grid of stimulation sites was arranged over the left precentral gyrus and surrounding area. The site in the grid that was closest to the hand knob was used to identify the lowest stimulus intensity necessary to elicit motor evoked potentials (MEPs) ≥50 μV peak-to-peak in the first dorsal interosseous in ≥ 5 of 10 trials. Each site in the grid was stimulated 5 times at each of 3-5 stimulus intensities in increments of 10% of maximum stimulator output. MEPs were simultaneously recorded from nine proximal and distal muscles of the right upper limb. Each TMS stimulus was a single monophasic pulse, 70 μs, delivered

perpendicular to the precentral gyrus using a 75 mm butterfly coil. The order of stimulation sites, intensities, and inter-stimulus interval durations (4-10 s) were randomized. For each muscle, MEP amplitudes were expressed as a percentage of maximal EMG, cortical map volumes were calculated, and recruitment curve slopes were determined for sites where MEPs were elicited using 3 or more stimulus intensities. Results demonstrate feasibility of mapping multiple upper limb muscles simultaneously within a single session. While distal muscles showed greater map volumes as expected, maps of proximal muscles were also produced, with MEPs that typically exceeded 20% of maximal EMG. In future studies, this method may be a useful tool to probe connectivity after neural injury such as stroke, to predict potential for recovery, and to quantify changes in cortical organization.

Title: Stimulation of low-threshold proprioceptive fibers increases density of glutamatergic and cholinergic boutons on the ankle extensor α-motoneurons in the adult rat

Authors: *O. GAJEWSKA-WOZNIAK, J. CZARKOWSKA-BAUCH, K. GRYCZ, M. SKUP;
Nencki Inst. of Exptl. Biol., Warszawa, Poland

Abstract: In our previous study chronic stimulation of low-treshold muscle afferents (Ia) in the tibial nerve in awake rats caused clear increase of expression of neurotrophin NT3, in the spinal cord and soleus muscle, being a good predictor of synaptic plasticity in this spinal circuit (Gajewska et al., 2013). This paradigm of stimulation can reinforce NT3-dependent, glutamatergic Ia input to the extensor α-motoneurons (MNs) but also effect indirectly, through spinal interneurons, including cholinergic V0c group modulating activity of MNs via C-terminals. We aimed to examine the effectiveness of the same paradigm of stimulation, which caused an increase in NT-3, on morphology and density of both inputs to α-motoneurons (MNs)

of the lateral gastrocnemius (LG) muscle. Tibial nerve was stimulated unilaterally for 7 days with continuous bursts of three pulses in four 20 min sessions daily. The Hoffmann reflex recorded from the soleus muscle, LG synergist, allowed controlling low-threshold stimulation. LG MNs were identified with intramuscularly injected tracer. Glutamatergic Ia terminals and cholinergic C-terminals were detected immunohistochemically, using input-specific anti-VGLUT1 and anti-VAChT antibodies, respectively. The total population of synaptic terminals was identified with Synaptophysin immunolabeling. Quantitative analysis of terminals on LG MNs, captured with confocal microscopy, revealed that the number of VGLUT1 and of VAChT immunoreactive terminals contacting the soma increased after stimulation by 35% and by 20%, respectively, comparing to the sham-stimulated side. Analysis of frequency distribution of boutons, distinguishing arbitrarily 4 classes of terminals volumes, revealed that this enrichment occured in groups of smallest boutons (VGLUT1: 1-5 μm^3 VChAT: 5-10 μm^3) in expense of the larger boutons (volume > 10 μm^3). This combined data may indicate that 7 days of stimulation of Ia afferents is sufficient to cause a formation of new glutamatergic and cholinergic terminals, both characterized by their small volume at this stage. Moreover, an increase of labeling intensity in the larger cholinergic and glutamatergic terminals (>10 μm^3; $p<0.03$ and $p<0.23$, respectively) was observed. On the contrary, labeling intensity in the smallest boutons did not change, suggesting that newly formed boutons contain a smaller number of the vesicular transporter molecules. To conclude, one week of stimulation of proprioceptive Ia input to LG MNs is effective in enrichment of their direct glutamatergic but also indirect cholinergic innervation. Our findings confirm also that this input is adequate for activation of $V0_C$-cholinergic interneurons.

Title: Unilateral wrist extension training after stroke improves function bilaterally

Authors: *Y. SUN[1,2,3,4], N. LEDWELL[5], L. BOYD[5], E. ZEHR[1,2,3,4,6];
[1]Rehabil. Neurosci. Laboratory, Univ. Victoria, Victoria, BC, Canada; [2]Ctr. for Biomed. Research, Univ. of Victoria, Victoria, BC, Canada; [3]Human Discovery Science, Intl. Collaboration on Repair Discovery (ICORD), Vancouver, BC, Canada; [4]Exercise Science, Physical & Hlth. Education, Univ. Victoria, Victoria, BC, Canada; [5]Brain Behaviour Laboratory, Univ. of British Columbia, Vancouver, BC, Canada; [6]Div. of Med. Sciences, Univ. of Victoria, Victoria, BC, Canada

Abstract: Stroke produces muscle weakness seen on both more (MA) and less affected (LA) sides. "Cross-education" describes the phenomenon that training one side of the body increases strength or motor skill in the same muscles on the untrained side. This can be applied to enhance muscle strength in the MA side and we found that 6 wks of dorsiflexion resistance training with the LA leg improved strength bilaterally in chronic stroke. Whether this can be observed in the arms was assessed with a 5-week unilateral wrist extension training intervention using the LA arm in 24 participants (> 6 m post-stroke, 65.6±6.7 y/o; 12 at UVIC, 12 at UBC). Maximal voluntary contraction (MVC) wrist extension force was measured with a 6-axis load cell using Cartesian coordinates (F_z = extension). Electromyography (EMG) of extensor (ECR) and flexor (FCR) carpi radialis (ECR), biceps (BB) and triceps brachii (TB) were recorded and the Fugl-Meyer and partial Wolf Motor Function Test were performed by the same physical therapist at each location. Reciprocal inhibition (RI) from wrist flexors to extensors, cutaneous reflexes evoked by median (MED) and superficial radial (SR) nerve stimulation were assessed in those at UVIC. Cortical silent period (CSP), short-interval intracortical inhibition (SICI), intracortical facilitation (ICF) and transcallosal inhibition (TCI) from transcranial magnetic stimulation were measured in participants at UBC. Twenty participants completed follow- up MVC extension force and EMG tests in both arms 5 wk after training.
F_z increased ~21% ($p<0.01$) in the LA arm and ~24% ($p=0.057$) in the untrained MA arm. Total force (F_{tot}) increased ~17% ($p<0.01$) and ~24% ($p<0.05$) in LA and MA respectively. Eighteen of 24 participants showed significant increases in F_z in their trained LA side and 11 showed significant increases in the untrained MA side. Improvement was also found in Fugl-Meyer motor function score ($p<0.01$). Significant correlations between muscle activation and size of RI were found only in the LA side before and after training. Correlation between muscle activation and SR cutaneous reflexes was significant bilaterally after training. LA CSP significantly decreased after training. Strength in 10 of 18 who showed strength increases in LA F_z, was retained, and 5 of 9 retained MA strength gains at follow up.
Results show LA training can facilitate wrist extension strength and function bilaterally with clinical transfer and neural plasticity. However, response variability between participants indicate that cross-education between arm muscles strength training might not as strong as in the legs in stroke participants.

Title: Changes in spinal reflex excitability associated with motor imagery training

Authors: *S. KUBOTA[1,2], M. HIRANO[1,2], S. TANAKA[1], S. TANABE[3], K. FUNASE[1]; [1]Dept. of Human Sciences, Grad. Sch. of Integrate Arts and Sci., Hiroshima Univ., Higashi-hiroshima, Japan; [2]Res. Fellow of the Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Fac. of Rehabilitation, Sch. of Hlth. Sci., Fujita Hlth. Univ., Toyoake, Japan

Abstract: Objective: Motor imagery training has a significant impact on the functional alterations in brain regions. However, the effect of motor imagery training on the alternations in the spinal cord has not been clarified. The aim of this research is to investigate whether the motor imagery training can alter the spinal cord excitability. **Methods:** Ten healthy subjects participated in two experimental sessions (motor imagery training, no-training), conducted on 2 separate days, with an interval of 7 to 9 days between two consecutive sessions. The experiment procedure included a pre-training (motor execution), pre-test, motor imagery training/no-training, and post-test. In motor imagery training session, subjects imagined ankle dorsiflexion movement acording to visual guide that was used by motor execution period. In no-training session (control), subjects were instructed not to imagin any movement and was not given visual guide. The soleus H-reflex and the amount of Ia presynaptic inhibition (D1 inhibition) were assessed at pre-test and post-test period, which were measured under resting and motor imagery condition. **Results:** In motor imagery training session, the size of H-reflex decreased and the amount of D1 inhibition increased in 8 out of ten subjects. These changes were only observed in a motor imagery condition, but not in a resting condition. In control session, there were no changes observed in the size of H-reflex and the amount of D1 inhibition. **Conclusion:** Our results demonstrated that motor imagery training can alter not only the activity of brain, but also that of spinal cord. Previous studies have shown that motor imagery training improves motor performance in patients with central nervous disorders. Our findings provide new insight into the mechanisms underlying motor recovery associated with motor imagery training.

Title: Prolonged excitability and morphological changes following strenuous repetitive activity in mouse motor axons

Authors: S. ALVAREZ[1], C. KRARUP[1,2], *M. MOLDOVAN[1,2];
[1]Univ. of Copenhagen, Copenhagen, Denmark; [2]Dept. of Clin. Neurophysiol., Rigshospitalet, Copenhagen, Denmark

Abstract: During prolonged repetitive activity, the restoration of axonal ionic homeostasis lags behind the restoration of electrical properties. Most notably, the intra-axonal Na^+ accumulation due to influx through the voltage-gated Na^+ channels is counteracted by the activation of the energy-dependent Na^+/K^+ pumps leading to membrane hyperpolarization. We previously found that in mature mice, a strenuous repetitive electrical stimulation (RS) protocol (200 Hz for 3 hours) does not cause axonal degeneration. Nevertheless, even at 3 days after RS, the motor axon excitability remained changed. Given the very long timescale it was unlikely that these changes could be attributed to Na^+/K^+ hyperactivity. The aim of this study was to specifically investigate in adult mice (C57BL/6 background) the recovery of motor excitability up to 2 weeks after RS. Serial multiple measures of motor axon excitability of the tibial nerve at ankle were obtained by "threshold-tracking" of the evoked plantar compound muscle action potentials. To facilitate serial in vivo imaging using the Confocal Laser Endomicroscopy (Cellvizio Lab) we used mice expressing YFP fluorescent reporter under the mouse thymus cell antigen 1 - Thy1 promoter. At 1 week, the excitability on the RS side was undistinguishable from the contralateral side. At 3 days, however, the excitability was still reduced after RS, as indicated by the increased rheobase and larger than normal threshold changes during hyperpolarizing electrotonus. Interpretation of multiple excitability changes was carried out by optimizing the "Bostock" space-clamped myelinated axon model where the node and the internode are connected by a leak pathway referred to as the Barrett-Barrett conductance (GBB). We found that the prolonged excitability abnormalities after RS could largely be explained by changes in passive cable properties, most notably the increase in GBB. This was consistent with thinning of the internodal axon associated with altered paranodes quantified by automatic image analysis of optic cross-sections at the

stimulation site. Our data suggest that strenuous RS in mice leads to axonal thinning, possibly due the increased periaxonal space under the myelin, which leads to a prolonged impairment of motor axon excitability.

Title: Chemical Neuro Stimulation of the upper alimentary canal by TRPV1 and TRPA1 activation decreases muscle cramp frequency and severity

Authors: *G. SHORT[1], L. B. ROSEN[1], R. SUTHERLAND[1], J. LIU[1], J. M. CERMAK[1], G. MAIER[2], T. WESSEL[1];
[1]Flex Pharma Inc, Boston, MA; [2]MaierMetrics, Boston, MA

Abstract: Chemical Neuro Stimulation is the treatment of neurological disorders by using small molecules applied topically to sensory neurons to alter the behavior of distinct neural circuits within the central nervous system. We have devised one such approach whereby the co-activation of TRPV1 and TRPA1 ion channels in the upper alimentary canal decreases muscle cramp frequency and severity. Based upon evidence that α-motoneuron hyperexcitability is the underlying cause of cramps and spasticity, we hypothesized that TRP activation could provide sufficient excitatory sensory input via the solitary tract to modulate descending spinal pathway signaling to increase interneuronal inhibition and dampen motor neuron hyperexcitability. We have generated data that suggests that either an oral solution containing a mixture of naturally-derived TRP activators (TRP-Stim) or FLX-787, a synthesized single molecule TRPV1/TRPA1 co-activator, stimulate TRP ion channels in the mouth, oropharynx and esophagus in a local, topical fashion to inhibit muscle cramping. Efficacy studies using an electrically-induced cramp (EIC) model demonstrated that both TRP-Stim and FLX-787 significantly reduced cramp intensity by as much as 3-fold relative to inactive control ($p<0.01$). Moreover, the pharmacokinetic profile of FLX-787 could not account for its EIC efficacy, as no systemic exposure of the parent form of FLX-787 in human plasma was observed. In both animals and humans, FLX-787 was found to undergo rapid phase 2 metabolism, resulting in extensive conjugation 15 minutes after ingestion, predominantly to glucuronide and sulfate metabolites. Even at doses up to 250 mg/kg in rats, the conjugates of FLX-787 accounted for >90% of circulating drug. To understand if topical exposure to mucous membranes in the mouth,

oropharynx and esophagus mediates the TRP-Stim and FLX-787 effect (given the lack of systemic exposure to FLX-787), the TRP-Stim mixture was encapsulated in gelatin capsules. Ingestion of the encapsulated mixture afforded no EIC efficacy relative to vehicle control. These results suggest that the observed effect on electrically-induced muscle cramps does not depend on the systemic bioavailability of TRP activators but rather on topical exposure of sensory neurons and consequent neuronal signaling. Given that efficacy has also been observed in nocturnal leg cramp (NLC) subjects with TRP-Stim (cramp-free days, $p<0.01$), Chemical Neuro Stimulation may be a general approach to develop novel treatments for cramps, spasms and spasticity. Based upon these findings, we expect to initiate studies with a chemically-synthesized single molecule TRP activator in NLC, MS and ALS.

Title: A computational motor neuron pool model for the development of motor decoder algorithms for prosthetic control

Authors: *J. M. ALLEN[1], S. M. ELBASIOUNY[2];
[1]Neuroscience, Cell Biology, & Physiol., [2]Neuroscience, Cell Biology, & Physiol. and Biomedical, Industrial, & Human Factors Engin., Wright State Univ., Dayton, OH

Abstract: Amputees have some intact neural circuits that are no longer connected to a muscle. Accordingly, the firing rates of their residual motor nerves can still code the characteristics of the intended movement. If decoded successfully, these signals could serve as the control for driving their prosthetic device. This study aims to develop motor decoder algorithms that predict the motor intent from motor unit firing rates for prosthetic control. To accomplish this goal, a high-fidelity computational model of a spinal motor neuron pool innervating the gastrocnemius muscle was developed. The model includes detailed representations of the 3 types of α-MNs (S, FR, and FF) which are built upon experimentally-obtained 3-dimensional anatomical data. The cells are represented in their respective proportions within the motor unit pool for this muscle. The passive cell membrane and active conductance data were set to match experimental data from cat α-MNs.
Initially, cells were stimulated using current injection, and optimized to behave comparably to in vitro electrophysiological recordings obtained from similar cells under a current clamp protocol. Later, uniform systems of sensory and motor synapses were applied across the dendritic arbor of the model cells and used to generate an output in the form of pool and individual cell firing data. Firing data from the model was able to be encoded to simulate production of muscle force and EMG. Results to date also have implications for development of a direct conversion of descending synaptic input to muscle force.

Title: Effect of hyperbaric oxygen therapy on h-reflex and grip strength

Authors: *M. M. SABBAHI[1], F. OVAK BITTAR[2], M. BADGHAISH[3], A. AL MALIKI[3];
[1]Texas Electrophysiology and Physical Therapy, Houston, TX; [2]Texas Electrophysiology and

Physical Therapy Services, Houston, TX; [3]Med. Physical Therapy Services, Jeddah, Saudi Arabia

Abstract: Objectives: Hyperbaric Oxygen Therapy (HBOT) has been used for a number of pathologic conditions affecting neuromuscular and musculoskeletal conditions. It might promote cellular metabolism of different tissue systems such as promoting wound healing. It showed to be useful in decompression sickness and possibly children with Autism. However, no didactic studies have been carried out to evaluate the effects of HBOT on the physiologic and mechanical processes in human. The purpose of this study is to evaluate the effect of HBOT on H-reflexes and grip strength before and after 15 min. cycling, in healthy subjects. **Methods:** 16 healthy subjects (10 males and 6 females) with the age range of 23-69 signed a consent form. Soleus H-reflex was tested in both lower limbs during lying and standing before and after 60 min. session of HBOT at 3 PSI and after 15 min cycling. H-reflexes were recorded from the soleus muscle after stimulation of the tibial nerve at the popliteal fossa (1 msec. 0.2 PPS at H-max.) using surface electrodes and Cadwell EMG unit. Dependent parameters included the peak to peak amplitude of the H-reflex, H-latency, and maximum grip strength. Maximum grip strength was tested for the both hands before and after HBOT. Five H-traces were averaged for each trial and descriptive statistics were completed.
Results showed a significant increase in the peak to peak amplitude of the H-reflex after the HBOT ranging from 3.4-35%, which was more pronounced during lying than standing. This was associated with a mild increase in the grip strength ranging from 1.7-21.4%. Cycling appears to increase the H-amplitude further augmenting the HBOT effect on the motor neuron excitability. No change in the H-latency was recorded. These results indicate that HBOT increases the sensitivity of the muscle spindle afferents and motor neurons excitability resulting in the recorded increase of the grip strength. Cycling post HBOT appears to augment such effect due to the increased circulatory effect of the oxygenated blood in the neuromuscular system.
Discussion and conclusions: These results indicate that HBOT induces systemic effects on the neuromuscular and musculoskeletal systems of healthy subjects. Accordingly, HBOT could be useful as a rehabilitation procedure in patients with neuromuscular and musculoskeletal disorders. It is therefore recommended to use HBOT as an adjunct for rehabilitation procedures in patients with musculoskeletal and neuromuscular disorders.

Title: Changes in postural control and presynaptic inhibition after ischemic conditioning

Authors: *R. A. MEZZARANE[1], I. C. QUADRADO[2], R. B. CÂNCIO[2], B. M. SILVA[3], L. C. VIANNA[2];
[1]Univ. of Brasilia (unb), Brasília, Brazil; [2]Univ. of Brasília, Brasília, Brazil; [3]Depto. Fisiologia UNIFESP, Sao Paulo, Brazil

Abstract: A number of interventions improve the control of upright posture by alterations in spinal cord processes. Previous report showed improvement of balance after the remote (upper) limb ischemic conditioning (RLIC), but little is known about the underlying neurophysiological mechanisms. Presynaptic inhibition (PSI) of the afferent Ia terminal is an important mechanisms involved in the control of gain of the stretch reflex pathway. The aim of this work is to evaluate the contribution of PSI to a possible improvement of balance caused by RLCI of the lower limb. Five healthy, sedentary male subjects, aged between 18 and 32 years, were selected to participate. The PSI was induced by an electrical stimulus with 1 ms duration applied to the common peroneal nerve 100 ms before the delivery of the test stimulus to the tibial nerve (to elicit the H-reflex in the soleus muscle). Postural sway was assessed with the subject standing on a high density foam placed over a force platform. The balance test consisted of 6 attempts with 1 minute each and 1 minute of rest, with either eyes open or closed. The root mean square (RMS) and the mean velocity (MV) of the center of pressure were calculated. The RLIC was performed in the left thigh (after the electrophysiological and biomechanical experiments) and along the three days thereafter. On the fifth day the experiments were repeated without the RLIC. The protocol was divided into three phases. The Sham and Conditioning phases were conducted over five days each, in subsequent weeks. During the Sham phase, the RLCI was not entirely effective and was just applied to fool the participant. The same procedure was followed for the Conditioning phase with the ischemia causing full obstruction. The Follow-up phase consisted of one day with the electrophysiological and biomechanical experiments in the week following the Conditioning phase. It is expected that the RLIC improves the balance performance as reflected by the parameters RMS and MV. We hypothesized that changing in PSI values will reflect neuronal adaptations following RLCI, which might be involved in the improvement of balance performance. The preliminary results showed a slight increase in the variable VM after RLCI, which might reflect postural adjustments to increase postural stability in a challenging condition. A tendency to reduced PSI after conditioning was also noticed, but did not reach statistical significance (paired t-test). These results suggest that mechanisms of PSI within the spinal cord might reflect neuronal adaptations resulted from RLCI. Additional experiments using the same paradigm will be conducted to either confirm or refute this speculation.

Title: Changes in central and peripheral excitability during rest and a slight contraction of the elbow flexors following an intermittent submaximal isometric contraction protocol

Authors: *B. W. COLLINS[1], L. H. GALE[1], N. C. M. BUCKLE[2], M. R. MONKS[2], K. E. POWER[3,4], D. C. BUTTON[2,4];
[1]Human Kinetics and Recreation, Mem. Univ., St John's, NL, Canada; [2]Mem. Univ., St. John's, NL, Canada; [3]Mem. Univ., St. Johns, NL, Canada; [4]Fac. of Med., Mem. Univ., St. John's, NL, Canada

Abstract: The excitability of the neuromuscular system is history-dependent. The purpose of the current study was 1) to assess the effects of repeated, submaximal voluntary contractions of the elbow flexors on measures of central (i.e. corticospinal) and peripheral (i.e. muscle contractile properties) excitability, as well as maximal voluntary contraction (MVC) force production and 2) to determine if measures of central and peripheral excitability are state-dependent (i.e. rest versus active). Eight chronically resistance trained males completed two randomized experimental sessions (rest and 5% MVC). During each session, participants received three stimulation protocols: 1) transcranial magnetic stimulation (TMS) of the motor cortex to determine corticospinal excitability (CSE) of the biceps brachii, 2) electrical stimulation of the biceps brachii motor point to determine evoked contractile properties of the elbow flexors and 3) electrical stimulation of Erb's point to determine maximal muscle compound action potential (M_{max}). TMS-induced motor-evoked potentials (MEPs), potentiated twitch (PT), rate of force development (RFD), and M_{max} were recorded for 2 minutes prior to, immediately, and 5 minutes following a submaximal contraction protocol that consisted of five intermittent voluntary contractions at 50% of MVC. MVC of the elbow flexors was also recorded prior to and 7 minutes post-contraction protocol. During rest, MEP amplitudes increased (213 ± 52% and 158 ± 29% of maximal M wave) at 1 and 5s post-contraction protocol, respectively but did not differ at any other time points thereafter. PT and RFD increased immediately post-contraction protocol and remained elevated for two minutes (PT: range 127 to 147% increase; RFD: range 127 to 141% increase). Both PT and RFD did not differ between pre- and 5 minutes post-contraction protocol. During a 5% MVC contraction there were no changes in MEPs from pre- to immediately and 5 minutes post-contraction protocol. PT and RFD increased immediately post-contraction protocol and remained elevated for two minutes (PT: range 123 to 134% increase;

RFD: range 128 to 139% increase). Both PT and RFD did not differ between pre- and 5 minutes post-contraction protocol. There was no effect of the contraction protocol on MVC force. In addition, immediately post-contraction protocol changes in resting CSE were positively correlated with PT (r = 0.886) but not during the 5% MVC. In conclusion, the changes in central and peripheral excitability following a submaximal contraction protocol are state (rest versus 5% MVC) and time (immediate but not at 5 minutes) dependent.

Title: The effect of hunger on skeletal muscle innervation by octopaminergic modulatory neurons in larval and adult fruit flies, *Drosophila melanogaster*.

Authors: *H.-J. PFLUEGER, T. MATHEJCZYK;
Freie Univ. Berlin, Berlin, Germany

Abstract: Biogenic amines are important modulators of behavior in all organisms. In insects, Octopamine, the homologue to vertebrate norepinephrine, is associated with either associative learning, energy demanding motor behaviors or adaptive behaviors to stress, for example caused by hunger. It had been previously shown by Koon et al (*Nature 14:190-99,2011*) and Koon and Budnik (*J Neurosci 32:6312-22,2012*) in live-imaging experiments on selected muscle fibers that a 2hr period of hunger in larvae induces significant changes in the morphology and function of octopaminergic axonal type II terminals and, in addition, of the neuromuscular junction (type I terminals). In our study we tried to unravel the dynamics of these changes with respect to the octopaminergic innervation in both larval body wall and adult flight muscles by assessing the total innervation pattern of selected muscle fibers. Although the actual periods of hunger varied greatly between larvae (2 to 6 hours) and adults (6 to 18 hours), the results nevertheless show a common theme: Compared to fed control groups a 2h period of hunger in larvae and of 6h in adults caused a temporary decrease in axonal length and number of branches before in larvae a significant increase above the control level is observed. Such an increase above control levels is not observed in adults. In larvae this corresponds well to behavioral essays of increased larval

locomotion. In order to find out about adult flies, long term monitoring the motor activity of isolated flies revealed that hungry flies move significantly for longer distances, significantly for longer durations and they move significantly faster but the number of movement bouts is not increased. Fed flies tend to stay at the bottom of the vial whereas hungry flies are more distributed.

Title: The arms really can give the legs a helping hand - rhythmic arm cycling training improves walking and interlimb connectivity in chronic stroke

Authors: C. KAUPP[1,2,3,5], T. KLARNER[1,2,4,5], Y. SUN[1,2,4,5], N. ZAPOTOCZNY[1,4], H. CULLEN[1,2,4,5], T. S. BARSS[1,2,4,5], G. E. PEARCEY[1,2,3,5], *E. ZEHR[1,2,3,4,5];

Abstract: Spinal networks regulating locomotion remain intact and partially accessible following stroke. These networks can be activated by a variety of rhythmic movements, including arm and leg cycling. Previous work has shown that activation of interlimb networks through arm and leg cycling improves walking in post-stroke individuals. This study aimed to reveal whether similar results could be achieved by training only the arms. Nineteen chronic stroke participants (> 6 months post infarct) were recruited to this 5-week (30 min @ 60rpm x 3 / wk) training study with a within-subject multiple baseline control. Rate of perceived exertion (RPE) as well as heart rate (HR) were monitored throughout the 5 weeks to ensure that the physiological cost did not exceed moderate. Resistance was added to the Sci-Fit Pro 2 ergometer only if the participant was able to maintain 60rpm without a large change in either RPE or HR. During post-tests, strength was assessed bilaterally via maximal voluntary isometric contractions of the legs (plantarflexion and dorsiflexion) and the hands via grip strength. Muscle activation during treadmill walking and rhythmic arm cycling was assessed in the more affected (MA) and less affected (LA) side via surface electromyography (EMG) in the following muscles; tibialis

anterior (TA), soleus (SOL), anterior deltoid (AD), biceps brachii (BB), triceps brachii (TB) and flexor carpi radialis (FCR). Changes to interlimb coupling during rhythmic movement were evaluated via cutaneous reflexes elicited by electrical stimulation of the superficial radial nerve (5x1.0ms trains @ 300Hz). Bilateral soleus stretch reflexes were elicited at rest and during 1Hz cycling. Clinical status was evaluated by a physiotherapist using a variety of tests, including the 6 Minute Walk (6MW), Berg Balance Scale (BBS), and Chedoke-McMaster Stroke Assessment (CMSA). Post training there was a significant increase in bilateral grip strength, as well as in force during MA plantarflexion. Several arm muscles were subject to small changes in reflex modulation during arm cycling. During treadmill walking, MA TA was significantly more active during swing phase, and less active during stance, as compared to baseline levels. Roughly half of participants showed significant changes to stretch reflex amplitudes, and these changes varied in a bidirectional manner. During clinical evaluations, walking speed and balance improved along with positive changes in CMSA ratings of the hand and foot. Taken together, these results further elucidate the need for incorporation of upper limb training in the functional rehabilitation of walking after neurotrauma.

Title: Effects of remote limb isquemic conditioning on the recruitment of motor units and synaptic transmission

Authors: ***I. C. QUADRADO**[1], R. B. CÂNCIO[2], B. M. SILVA[3], L. C. VIANNA[2], R. A. MEZZARANE[2];
[1]Lab. of Signal Processing and Motor Control, UNIVERSITY OF BRASILIA, BRASILIA, Brazil; [2]Univ. of Brasilia, Brasilia, Brazil; [3]UNIFESP, Sao Paulo, Brazil

Abstract: The mechanisms behind the effects of the ischemic conditioning (IC) are still a matter of debate. Studies have shown that sub-lethal ischemia generates a protective effect on tissues from a subsequent ischemic event. A recent work reported enhanced motor learning after an IC of the upper limb. However, the neurophysiological mechanisms responsible for these effects are

unknown. We hypothesized that spinal cord processes, such as patterns of motor unit recruitment and homossynaptic depression, might reflect the adaptations of the central nervous system following an IC of the lower limb. Five healthy and sedentary male subjects, between 18 and 32 years, participate in the present study. The recruitment curve (RC) of the right soleus H-reflex was built by changing the electrical stimulus intensity applied to the tibial nerve (TN). A sigmoid function was adjusted to H-reflex amplitude values in order to obtain parameters that reflect patterns of recruitment of the soleus motor units. The homosynaptic depression (HD) was estimated by delivering pairs of pulses to the right TN at 1 Hz. The amount HD was evaluated by the ratio of H-reflexes elicited by the first and second pulses delivered 1 second apart. The IC was performed in the left thigh. The procedures were divided into three parts: Sham, Conditioning and Follow-up. Both Sham and Conditioning experiments were conducted along five days each in subsequent weeks. On the first day of the Sham phase, both the RC containing 30 points and the HD level (average of 20 reflex responses) were obtained. After those protocols, the “Sham Ischemia” was performed on the same day and 3 days thereafter. In the fourth day the RC and HD was evaluated without IC. The same procedure was repeated in the following week for Conditioning, however, using a procedure for ischemia that induced a total block, i.e., five minutes of ischemia alternated with five minutes of rest. The ischemia procedure was repeated five times. The Follow-up consisted of experiments (without IC) performed in the third week to obtain the RC and the HD level. The preliminary results showed a general decrease in the parameters obtained from the recruitment curve ($p<0.05$; paired t-test), which means an overall reduction in reflex excitability for most of the recruited motor units of the soleus muscle. No apparent change was observed for HD. These results suggest that IC can induce plasticity at the spinal cord level in humans, but one mechanism of synaptic transmission (HD) seemed not to be affected.

Title: Serotonergic modulation of glutamate-evoked responses through 5-HT_{2A} receptors in the dendrites of rat jaw-closing motoneurons

Authors: M. DANTSUJI[1,2], S. NAKAMURA[1], K. NAKAYAMA[1], A. MOCHIZUKI[1], M. KIYOMOTO[1], S. K. PARK[4], Y. C. BAE[4], M. OZEKI[2], *T. INOUE[3,1];

Abstract: Masseter motoneurons (MMNs) have the well-developed dendrites where MMNs receive a variety of inputs. MMNs receive both glutamatergic and serotonergic inputs in the dendrites; however it is unclear how the two inputs interact with each other. In this study we examined effects of serotonin (5-HT) on the glutamatergic responses in the dendrites of the MMNs in brainstem slice preparations obtained from postnatal day (P) 2-5 neonatal rats using whole-cell recordings and laser photolysis of caged glutamate. We photostimulated 39 different spots arranged around each recorded MMN in a concave shaped array with 100 μm spacing between adjacent rows and columns. Laser photolysis of caged glutamate in the dendrites induced somatic depolarization in MMNs. Bath application of 5-HT enhanced the photostimulation-evoked depolarization and induced action potentials in the some stimulating spots. In the presence of tetrodotoxin (1 μM), the depolarizing responses were also evoked at short latencies by photostimulation. Bath application of 5-HT (0.1-100 μM) increased the amplitude of the photostimulation-evoked responses in the dendrites of the MMNs in dose-dependent manner, in addition to induction of membrane potential depolarization. The application of the 5-HT_{2A} receptor agonist TCB-2 enhanced the photostimulation-evoked responses and induced membrane depolarization. The 5-HT_{2B} selective agonist BW723C86 had no effect on MMNs. The 5-HT_{2C} selective agonist MK212 induced membrane depolarization but had no effect on the photostimulation-evoked responses. 5-HT-induced enhancement of the laser-evoked responses and the membrane depolarization were antagonized by the 5-$HT_{2A/2C}$ receptor antagonist Ketanserin. Application of the N-methyl-D-aspartate (NMDA) receptor antagonist APV blocked the 5-HT-induced enhancement, whereas application of the AMPA receptor antagonist NBQX did not affect the 5-HT-induced enhancement. Immunoelectron microscopy revealed that both NR1 subunit of NMDA receptors and 5-HT_{2A} receptors were located in the dendrites. 5-HT also enhanced the responses evoked by focal activation of glutamate receptors by two-photon uncaging of caged glutamate. These results suggest that activation of 5-HT_{2A} receptors enhanced the NMDA receptor-mediated glutamate responses in the dendrites of the neonate MMNs. 5-HT may enhance the glutamatergic motor command onto MMN during suckling.

Title: Development and testing of nustim system for urinary stress incontinence treatment

Authors: *X. HUANG[1], L. LIAO[2], G. E. LOEB[1];
[1]USC, Los Angeles, CA; [2]Urology, China Rehabil. Reserch Ctr., Beijing, China

Abstract: Pelvic floor muscle training (PFMT, also known at Kegel exercises) has been well documented to reduce urine leakage in urinary stress incontinence patients, but few patients do it properly or sufficiently. Electrical stimulation to contract weak pelvic floor muscles and external urethral sphincter (EUS) should be able to provide the same benefit as voluntary exercise. We have developed a novel, single channel, inductively powered and controlled microstimulator (NuStim®) that can be implanted percutaneously into a muscle and close to its motor axons via a minimally invasive implantation procedure. The NuStim microstimulators can be externally controlled to produce a wide range of charge-controlled stimulus intensities that can be programmed to assure complete recruitment of the motor units without voluntary effort. Power and commands are transmitted to the implant by wireless inductive coupling from a transmitter in a seat cushion. Both the clinician and the patient use an Android app to communicate wirelessly with the cushion via Bluetooth Low Energy (BLE) protocol. The complete system was validated in a chronic animal study demonstrating that the NuStim can be successfully implanted into an effective, low threshold location and the implant can be operated chronically to produce strong, stable and tolerable contraction of histologically normal skeletal muscle for up to three months. A clinical study will begin shortly to determine identify electrical stimulation patterns that are both effective and comfortable.

Title: Motoneurone excitability of the human quadriceps muscles during a submaximal fatiguing contraction

Authors: *H. T. FINN[1], D. M. ROUFFET[3], D. S. KENNEDY[4], S. GREEN[5], J. L. TAYLOR[2]; [1]Physiol., Neurosci. Res. Australia/ UNSW, Randwick, Australia; [2]Neurosci. Res. Australia/ UNSW, Sydney, Australia; [3]Victoria Univ., Melbourne, Australia; [4]Univ. of Sydney, Sydney, Australia; [5]Western Sydney Univ., Sydney, Australia

Abstract: Introduction: The effect of fatiguing exercise on excitability of the motoneurones (MN) innervating the human quadriceps muscles is unclear. To date, assessment during ongoing voluntary activity suggests that there is little change in MN excitability (Sidhu et al., 2012). For the upper arm, MN excitability is reduced during fatiguing contractions, but this is more pronounced when tested in the absence of voluntary drive during cortical silent periods produced by transcranial magnetic stimulation (TMS) (McNeil et al., 2011). Hence, we assessed the MNs of the quadriceps muscle during cortical silent periods to determine whether their excitability decreased during a fatiguing submaximal contraction. Methods: Ten (8 male) participants attended on one (n=5) or two (n=5) days to perform brief (~5s) isometric knee extension contractions before and after a 10-min sustained contraction. Surface electromyogram (EMG) was recorded from vastus medialis (VM), vastus lateralis (VL) and rectus femoris (RF) muscles, and all contractions were performed at a target level of VM EMG activity (25% maximum). Stimuli delivered during contractions evoked responses in each muscle. Femoral nerve stimuli evoked maximal M-waves (Mmax). Electrical stimuli over the thoracic spine activated descending tracts and produced thoracic motor evoked potentials (TMEPs). TMEPs were evoked both during ongoing voluntary drive and during silent periods following TMS over the motor cortex. TMS intensity was set to cause a 200 ms period of EMG silence. Thoracic stimuli were delivered 100 ms after TMS to produce TMEPs in the absence of descending drive (TMS-TMEP). The size of the TMS-TMEP in VM was set to be large (~50% Mmax; strong stimuli; n=6) or small (~15% Mmax; weak stimuli; n=9) on the two days. Results: During the 10-min contraction the force output reduced by 53 ± 1% (mean ± SEM; $p < 0.001$). The area of TMEPs evoked by strong or weak stimulation during ongoing voluntary drive did not change in VM ($p > 0.441$) or VL ($p > 0.101$) muscles. In the RF muscle TMEP area was unchanged ($p = 0.15$) for strong stimulation, but decreased by 29 ± 4% ($p = 0.008$) for weak stimulation. The average

TMS-TMEP area over the last 5 min compared to pre-fatigue values, was reduced by 41 ± 8% ($p = 0.031$) and 63 ± 7% ($p = 0.001$) in VM, 40 ± 9% ($p = 0.046$) and 62 ± 6% ($p = 0.001$) in VL, and 37 ± 4% ($p = 0.012$) and 47 ± 6% ($p = 0.019$) in RF after strong and weak stimulation, respectively. Conclusion: TMEPs evoked in quadriceps during TMS-induced silent periods become smaller during a sustained submaximal contraction. This strongly suggests that the excitability of the motoneurones innervating the human knee extensor muscles is reduced during fatiguing exercise.

Title: Potential role of spinal interneurons in genesis of muscle cramps in an animal model

Authors: *M. D. JOHNSON[1], C. K. THOMPSON[2], C. J. HECKMAN[1];
[1]Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Physical Therapy, Temple Univ., Philadelphia, PA

Abstract: Muscle cramps consist of repetitive involuntary firing of motor units resulting in prolonged muscle activation and can be considerably painful. Evidence from human studies suggests muscle cramps have a significant central nervous system component, but there remains substantial debate about mechanisms underlying cramps. Though it is widely assumed that animals such as horses, cats and dogs experience cramps, there is currently no effective animal research model of muscle cramping. We have developed the first animal model of cramps, using direct electrical stimulation of muscles in the decerebrate cat preparation. Using brief stimulation protocols similar to those that evoke cramps in humans, we generated strong cramp-like behaviors, with post-stimulation forces greater than 50% of the maximum that last many tens of seconds. Multi motor unit (MU) recordings, using an array electrode applied directly to the muscle, show progressive MU recruitment corresponding to cramp force development with small increases in individual unit firing. Three lines of evidence support a fundamental role for

prolonged firing of spinal interneurons in the genesis of cramps. First, motor unit coherence observed during evoked cramps is consistent with the notion that common synaptic drive to spinal motoneurons underlies muscle cramps. Secondly, reciprocal inhibition from three sources (electrical stimulation of antagonist muscle nerve, tonic stretch of antagonist muscle and dynamic stretch of antagonist muscle) is only effective in transiently inhibiting muscle cramp force, which rapidly recovers as soon as the inhibition ceases. Such transient inhibition of the cramp suggests sustained synaptic drive from segmental sources contributes to cramp activity. Finally, intracellular recordings from spinal interneurons and motoneurons suggest that the former are facilitated and the latter inhibited during direct muscle stimulus protocols used to induce cramps. Taken together, these data suggest spinal pre- motor interneurons play a significant role in the generation and maintenance of muscle cramps.

Title: A closed-loop neuromuscular simulation suffices to explain generation and modulation of force variability in healthy adults

Authors: ***A. NAGAMORI**[1], C. M. LAINE[1], F. J. VALERO-CUEVAS[1,2];
[1]Div. of Biokinesiology and Physical Therapy, [2]Dept. of Biomed. Engin., USC, Los Angeles, CA

Abstract: Coordinated patterns of motor unit discharges reflect characteristics of the neural signals which control muscle force. Specifically, synaptic input common to concurrently active motor units is the major determinant of human force control and is associated with oscillations in force (< ~15 Hz). This neural drive can be characterized by (i) concurrent low-frequency (<5Hz) firing modulation among active motor units, often called ‘common drive’ and (ii) physiological tremor, quantified by synchronization of motor unit discharges in the 5 - 15Hz band. The neurophysiological origin of ‘common drive’ is unknown, and the factors which influence physiological tremor are actively debated. Here, we investigated the generation, modulation, and interactions between both frequency bands of neural drive using a physiologically-grounded

closed-loop simulation. Specifically, the simulation included a Hill-type muscle-tendon model, muscle spindle, Golgi tendon organ (GTO), and a feedback controller which enabled target-guided force tracking. The simulated neural drive within this model was first recorded and then fed into a simulated spiking motor neuron pool. We found that even without neural feedback, a portion of 'common drive' can emerge naturally from the intrinsic properties of motor units in reaction to a constant input, and can be amplified in the presence of noise and the activation of persistent inward currents. We further demonstrate how the interaction between mechanical properties of the muscle-tendon complex and afferent feedback serves to shape and amplify 'common drive' as well as to generate physiological tremor. Our results suggest that both the amplitude and peak-frequency of physiological tremor depend upon the gains of afferent feedback pathways (spindle and GTO feedback), and our simulation demonstrates a known, but previously unexplained, interaction between proprioceptive feedback and 'common drive'. To best of our knowledge, this study is the first to comprehensively simulate the generation and modulation of involuntary force fluctuations during the attempted generation of a constant force. The results from this study may speak to mechanisms responsible for increases in force variability during fatigue and with age as well as mechanisms of pathological conditions such as essential tremor.

Abstract: Sensory feedback from skeletal muscles is essential for fine, coordinated motor control. The gatekeepers of this feedback are the proprioceptive sensory neurons (PSNs) whose cell bodies are in the dorsal root ganglia (DRG), and which are classified into three subtypes (Ia, Ib, and II) depending on their anatomy and physiology. Currently only electrophysiology allows precise discrimination between the different subtypes of PSNs, critically hindering investigations

into these important cells and the networks of which they are a part. We have been trying to elucidate genetic markers for the three different subtypes of PSNs using a powerful combination of mouse genetics, rabies virus mediated retrograde tracing, ex-vivo anatomical tracing, single cell transcriptomics, and bioinformatics. Analysis of single PSN transcriptomes has yielded several interesting populations that can be defined by their unique gene expression. Here we present our work to date in classifying these populations using in situ hybridisation with canonical and novel markers. We have tried to put these populations into the context of the sensorimotor circuit by co-labelling cells with anatomical tracing from spinal cord and different muscle groups.

Title: Investigating the role terminal Schwann Cells play in muscle type specific recovery following partial denervation in G93A SOD1 mice

Authors: J. M. HARRISON, *V. F. RAFUSE;
Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Amyotrophic Lateral Sclerosis (ALS) is the most common motor neuron (MN) disease, with a prevalence of 3.9 cases in 100,000. ALS is characterized, in part, by the progressive death of MNs innervating skeletal muscles fibers. As MNs die, muscles become increasingly weaker due to progressive muscle fiber denervation. This ultimately leads to death due to respiratory failure. If muscles are partially denervated in healthy individuals due to injury, uninjured MNs sprout axons to reinnervate neighboring denervated muscle fibers. This process, known as collateral reinnervation, can restore muscle force to pre-injury values and is mediated,

in part, by terminal Schwann cells (TSCs). Collateral reinnervation is compromised in ALS, which contributes to the rate of progressive weakness. Interestingly, paralysis of fast contracting muscles occurs significantly earlier in ALS compared to slow muscles. To examine whether this is due to impaired collateral reinnervation, we partially denervated soleus (slow) and plantaris (fast) muscles in $SOD1^{G93A}$ (ALS) mice and wild type (WT) littermates by ligating and cutting the 5^{th} lumbar spinal nerve (L5) at P30 to examine the effects of partial denervation (PD) pre disease-onset. Mice were allowed to recover for thirty days to determine innervation recovery, or for three days to examine the TSC response to denervation. Our results to date show that the proportion of innervated muscle fibers in partially denervated plantaris muscles was less than similarly denervated soleus muscles in ALS mice, but not WT mice following thirty days of recovery. Furthermore, we found that a significant proportion of denervated muscle fibers in the ALS PD plantaris muscle lacked TSCs. Additionally, early results suggest that numbers of TSCs at denervated endplates decrease over time during this "pre-symptomatic" stage of disease. Interestingly, at partially innervated synapses in ALS mice, TSCs were present but often only in the region of the end plate with the axon present. Also of note, denervation in the uninjured leg was seen by P60 in the ALS mice, supporting previous findings that pathologies occur in this model before obvious motor deficits. We are currently exploring potential genomic and proteomic differences between TSCs associated with fast and slow muscles as well as between ALS and WT mice. Together, these results suggest that the sprouting capacity of fast MNs in ALS is compromised even before disease onset and that this pathology may be related to abnormalities in TSCs.

Title: Navigated TMS to assess central motor fatigue in a fingertapping task

Authors: M. ROENNEFARTH, M. WITT, R. FLEISCHMANN, L. HABERBOSCH, A. JOOß, *S. SCHMIDT, S. A. BRANDT;
Vision & Motor Res. Group, Berlin, Germany

Abstract: Motor fatigue is defined as a decline in force output. This phenomenon can occur at any stage within the motor pathway between cortex and muscle. It can be due to peripheral and central mechanisms, i.e. on a cortical, spinal, peripheral neuronal, neuromuscular or muscular

level (Edwards 1980). In analogy, a reduction of motor evoked potentials (MEP) after an initial MEP-size increase is a well-established response to transcranial magnetic stimulation (TMS) after a sufficiently long and fatiguing motor task, e.g. maximum contraction (Brasil-Neto 1993). As no change of responses to peripheral stimulation is seen this effect is interpreted as a correlate for central motor fatigue.
The Fingertapping-task (FT) represents a widely used tool to evaluate more complex aspects of motor function, higher order motor control and importantly deterioration of motor function in clinical neuroscience (Shimoyama 1990). A decline in performance corresponds to a reduction in tapping rate. Yet, parameters like session length and time of MEP assessement for the evaluation of central aspects of FT induced motor fatigue remain unclear and results have been inconclusive so far (Kluger 2012, Arias et al. 2012).
The aim of this study was to evaluate central motor fatigue as induced by FT with navigated TMS and relate electrophysiological parameters to task performance change. We aimed to identify the task length necessary to induce changes in cortico-spinal excitability after FT. Therefore 9 subjects in 5 consecutive tapping sessions with different length (15 sec, 30 sec, 60 sec and maximum possible length) in random succession order were studied. MEPs in response to navigated TMS over dominant M1 (FDI-hotspot) were recorded before, directly after (2 min continuously) and 3 minutes after each tapping session. Subjective fatigue, Intertapinterval and tapping force were recorded as well.
The task was perceived as more fatiguing when lasting longer. Tapping rate but not tapping force was significantly lower in the longer tapping sessions and decreased over time in each session. Additionally a carry over effect over session succession with an increase in tapping force was seen probably reflecting intrasession fatigue and central compensatory mechanisms ($F=9.73$, $p<0.01$). Change of tapping force was present mainly in the first up to 30sec of the respective session. A significant reduction in MEP-size as compared to baseline was present only after 60 sec and max Tapping ($p<0.05$). Thus the usual 30 seconds lasting FT seems to be too short to induce central motor fatigue that can be detected with TMS. Alternatively Tapping force could be an appropriate measure to detect subtle changes over time in FT.

Title: Systemic inhibition of oxytocin receptors blocks stress induced social anxiety in female California mice

Authors: *N. DUQUE-WILCKENS[1,1], M. Q. STEINMAN, 95618[2,3], P. B. TAN[3], R. HAO[3], B. C. TRAINOR[3];
[1]Animal Behavior Grad. Group, [2]Molecular, Cellular, and Integrative Physiol. Grad. group, [3]Psychology, Univ. of California, Davis, Davis, CA

Abstract: Oxytocin (OT) is often considered as pro-social and anxiolytic, but recent evidence suggests that the effects of OT are context-specific. It has been proposed that OT increases the salience of social cues, which can explain why OT can either enhance or inhibit social behaviors. We recently discovered that social defeat stress induces hyperactivity in OT neurons in the bed nucleus of the stria terminalis (BNST) and paraventricular nucleus, and that this effect is primarily observed in females but not males. These studies used the monogamous California mouse, which is one of the few species in which social defeat stress can be studied in both males and females. We found that intranasal infusions of OT (INOT) reduced social interaction behavior in females that are naïve to defeat, which mirrors the effects of social defeat stress on this behavior in females. Here we used Egr-1 expression to assess the potential neuroanatomical substrates underlying the sex specific response to INOT. We found than in females but not males naïve to defeat, INOT increases Egr-1 binding in nucleus accumbens core (NAcc) and anterior BNST, two areas previously associated with stress-induced social withdrawal. Next we used a pharmacological approach to determine whether increased activation of OT receptor (OTR) in stressed females contributes to stress-induced decreases in social interaction behavior. Control and stressed females were randomly assigned to receive an IP injection of saline or OTR antagonist (L-368,899, Sigma) 30 min before behavior testing. Control females showed high levels of social interaction (SI), and in an odor preference test (OP) preferred an odor of an unfamiliar individual vs. the familiar odor of a cagemate. Stress not only reduced SI, but also reversed the OP such that stressed females preferred the odor of a familiar cagemate over an unfamiliar odor. Interestingly, OTR antagonist treatment rapidly blocked the effects of stress on both SI and OP. This suggests that stress-induced increases in OTR activation, possibly in NAcc and anterior BNST, may drive females away from unfamiliar and towards familiar (and possibly safer) social contexts. These results suggest that the use of OTR antagonists could have unappreciated benefits as an anxiolytic agent in social contexts.

Title: *In vitro* and *In vivo* pharmacological profiles of non peptidic selective oxytocin receptor ligands

Authors: *J. BECKER[1], J. GANDIA[1], L. PELLISSIER[1], I. KARPENKO[2], D. BONNET[2], M. HIBERT[2], J. LE MERRER[1];
[1]INRA U085 - CNRS UMR7247, Nouzilly, France; [2]Lab. d'Innovation Thérapeutique, CNRS UMR-7200, Illkirch, France

Abstract: The neuropeptide oxytocin plays a crucial role in controlling many aspects of social behavior, such as social cognition and empathy, sexual, parental and affiliative behaviors or aggressiveness. In this context, deficient oxytocin activity has been linked to several neuropsychiatric disorders, including schizophrenia, drug addiction and autism spectrum disorders (ASD). Oxytocin binds its G protein coupled receptor (OTR), as well as arginine vasopressin receptors (V1A, V1B and V2). To disentangle the respective contributions of OTR and vasopressin receptors in mediating the oxytocin effects on social behaviour, there is a crucial need for developing brain penetrant, stable and selective agonists and antagonists of OTR. We present here the *in vitro* pharmacological profiles of newly synthesized compounds targeting selectively OTR and their *in vivo* activity in a mouse model of ASD.

Title: Cerebrospinal fluid oxytocin according to the social context and a body pressure jacket

Authors: *J.-L. RAULT;
Fac. of Vet. and Agr. Sci., Univ. of Melbourne, Parkville, Australia

Abstract: Oxytocin (OT) underlies numerous socio-behavioral processes as a neuropeptide. Nevertheless, the sensitivity of the endogenous oxytocinergic system to changes in the social environment remains poorly understood. This is mainly due to the technical difficulty to sample central OT and the methodological difficulty to validate reliable proxy measures of central OT. This study investigated the effects of varying social contexts and a body pressure jacket on OT concentration in the cerebrospinal fluid (CSF). The pig (*Sus scrofa*) was used as a model, with repeated CSF sampling through a spinal catheter using a within-subject design. The pigs were subjected to two tests two days apart. The first test was a three phases Union-Separation-Reunion paradigm to assess the effects of social presence and social separation and isolation on CSF OT concentration, with each phase lasting 30 min and two companion pigs present for the Union and Reunion phases. The second test consisted of fitting a jacket on the pigs (ThunderShirt®) that provided gentle body pressure and is believed to mimic the relaxing response seen in pigs, humans and other animal species following gentle body squeeze. The hypothesis was that the jacket may stimulate central OT release, as physical contact can trigger OT release and OT can have anxiolytic effects. The present findings showed that the jacket resulted in inconsistent individual differences in CSF OT, with one individual showing a 3 fold increase in CSF OT after 10 min of wearing the jacket but also an hour after the jacket was removed, while another individual remained at baseline level. The jacket effect requires research with a larger sample size. The Union-Separation-Reunion social testing paradigm did not result in consistent changes in CSF OT, but CSF OT changes were positively correlated with explorative behaviors (root, manipulate) in a novel environment in presence of conspecifics. Accumulating evidence supports that OT actions are context-specific, possibly explaining the discrepancy in the literature on OT and its (sometimes contradictorily) relationship with positive or negative social behaviors. In the present experiment, CSF OT inconsistent concentration changes could be partly explained by simultaneously considering behavior in response to the context, as CSF OT concentration related to exploratory drive in the social paradigm. The influence of the context ought to be considered in OT research given the multitude of factors that may affect the oxytocinergic system or potentiate its effects. This should help identify effective and repeatable clinical interventions or situations conducive to endogenous central OT release.

Title: An eye tracking system revealed the face scanning pattern and the effect of oxytocin for enhancing eye contact in common marmosets

Authors: M. KOTANI[1], K. SHIMONO[2], T. NAKAKO[1], Y. IWAMURA[1], H. IMAI[1], A. KIYOSHI[1], K. MATSUMOTO[1], A. MATSUMOTO[1], M. IKEJIRI[1], T. NAKAYAMA[1], Y. OGI[1], N. KONOIKE[4], K. NAKAMURA[4], *T. ISHIYAMA[3], K. IKEDA[1];

Abstract: Introduction Eye contact is a useful biomarker of social communication and known to be deficient in patients with some psychiatric conditions. An eye tracking system has been used to investigate the face scanning pattern in patients with autism spectrum disorders (ASDs) and found that oxytocin, a neuropeptide that regulates social behavior and cognition, increased the gaze to the eye region of human face (presumed as eye contact). Interestingly, eye tracking has been used to directly compare the face scanning in some non-human primates with that in human. Thus, eye tracking is expected to be a translational technique between human and non-human primates to evaluate the effect of psychiatric drug candidates. Here we have established the method of eye tracking in common marmosets, unique New World primates that resembles human's behavioral characteristics such as eye contact as a means of communication, in order to firstly characterize their face scanning pattern and evaluate the oxytocin's effect for eye contact. Materials and methods Head posts were surgically implanted in five male adult marmosets and used to stabilize their heads through pretest and test. Oxytocin of the common marmoset was synthesized and intranasal administration of vehicle or 100IU oxytocin was made in a cross-over manner, immediately and thirty minutes before pretest and test, respectively. For pretest and test, common marmosets were free to view close-up pictures of conspecific face for 5 s on the computer screen, and their eye positions were continuously recorded with the infrared eye tracking camera (ETL-400, ISCAN Inc.). Viewing time for the eyes, the mouth, and the other face parts (the face) in a picture were measured, and the ratio of viewing time for eye or mouth to face was calculated. T-test was done for any statistical comparisons. All experimental procedures involving animals use were reviewed and approved by the Institutional Animal Care and Use Committee of Sumitomo Dainippon Pharma, Co., Ltd. Results The viewing time in non-treated marmosets was apparently longer ($P = 0.003$) for the eyes (2.24 s, 59.58% as eye/face ratio) than for the mouth (0.32 s, 9.29% as mouth/face ratio). In oxytocin treatment study, only the change of eye/face ratio from pretest to test was significantly greater ($P = 0.011$) in oxytocin group than

in vehicle group. Conclusion We could successfully measure the unique eye contact behavior in common marmosets with the newly-established method of eye tracking and demonstrate that oxytocin enhanced the eye contact. This system will be useful for further testing of therapeutic compounds for psychiatric conditions, especially including ASDs.

Title: Expression of neuropeptide arginine vasopressin and its receptors 1a and 1b in the canine amygdala

Authors: ***G. KAUR**[1], M. SAILOR[1], H. MIRRASHED[1], F. SHAHRIAR[2], W. KHAMAS[1]; [1]Western Univ. of Hlth. Sci., Pomona, CA; [2]Animal Diagnos. Lab., Tustin, CA

Abstract: Neuropeptide arginine vasopressin (AVP) is known to modulate social behavior in several species. The AVP receptors 1a (V1a) and 1b (V1b) are broadly distributed in the limbic system of rats, mice and hamsters, with several studies documenting their involvement in behavior regulation. AVP has been shown to modulate aggression by acting through V1a and/or V1b receptors in hamsters, rats and mice. However, the role of AVP and its receptors in canine aggression is unknown, due to lack of studies and species differences. Here, as the first step, we investigated the presence of AVP, V1a, and V1b in the canine amygdala by using immunohistochemistry and Western blot analysis on post-mortem canine brain tissue. Immunohistochemistry applied to freely floating canine brain tissue sections successfully identified the presence of neurons immunoreactive for AVP, V1a, and V1b in the amygdala of both sexes. Following validation of protein extraction from formalin fixed canine tissue, the expression of AVP and receptors was confirmed successfully by Western blotting. The identification of AVP, V1a, and V1b immunoreactive neurons in the canine amygdala suggests a potential role in regulating social behaviors including aggression in domestic dogs. This study is the first demonstration of the presence of AVP and its receptors in the canine amygdala. The data

from this and subsequent studies may lay groundwork for research to design novel therapeutic interventions to regulate canine behavioral problems.

Title: Play and social approach in juvenile F344 and Lewis rats: Effects of oxytocin in the central amygdala

Authors: S. R. ECK, L. A. MCDOWELL, *S. M. SIVIY;
Dept Psychol, Gettysburg Col., Gettysburg, PA

Abstract: Previous work from our laboratory has shown that the Fischer 344 (F344) rat is consistently less playful than other inbred and outbred strains and we have been recently investigating the extent to which oxytocin (OT) may be contributing to the differential levels of playfulness in this strain. Accordingly, we have begun to assess the effects of intracranial infusions of OT into limbic structures thought to be involved in play and that have abundant OT receptors. In an initial study (SFN 2015) we reported that oxytocin (0.5 µg/0.5 µl) infused into the central amygdala (CeA) had no effect on play in either F344 or Lewis rats but resulted in a robust increase in self-grooming that was especially prominent in the Lewis strain. Since OT-induced hyper-grooming may have obscured any potential effect of OT on play we looked at the effects of lower doses of OT when infused into the CeA of male and female juvenile F344 and Lewis rats. Rats were isolated for 4 hours prior to testing with an untreated Sprague-Dawley partner for 10 minutes. Two doses of OT (10, 50 ng) plus a vehicle control were assessed over 3 test days and infused (0.5 µl over 1 minute) 5 minutes before testing. Each inbred rat received each dose in a counter-balanced order. Play was quantified primarily by the frequency of pounces and pins directed towards the SD partner. Amount of time spent in active social investigation (sniffing, grooming) as well as time spent in self-grooming were also measured. As expected, F344 rats exhibited fewer pounces and pins than Lewis rats. F344 rats were also less likely to engage in self-grooming than Lewis rats. OT infusions had no effect on either measure of play, nor did it affect either social investigation or self-grooming. In order to confirm the

reliability of the hyper-grooming effect all of the rats were subsequently infused with 500 ng (0.5 µg)/0.5 µl as in our previous study. As expected, this dose of OT yielded a substantial amount of self-grooming that was especially prominent in Lewis rats. These data, combined with our earlier findings, suggest that OT in the CeA may not have a significant modulatory influence on overall levels of playfulness in the juvenile rat, nor can differential sensitivity to OT within this area account for the strain differences observed in play behavior. However, the data do point towards a robust strain difference in the extent to which OT can induce self-grooming when infused into the CeA. In order to further examine any prosocial effects that may be associated with OT in juvenile rats we have also begun to assess strain differences in a more selective test of social approach and will be assessing the effects of OT in this model as well.

Title: Nasal oxytocin in a genetic knockout: Pharmacokinetics and behavior

Authors: *A. S. SMITH[1], A. C. KORGAN[2], J. FASTMAN[3], M. C. GRANOVETTER[3], J. SONG[3], W. S. YOUNG[3];
[1]Dept. of Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS; [2]Dept. of Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada; [3]Section on Neural Gene Expression, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The hormone oxytocin (Oxt) has been shown to promote social behavior in numerous mammalian species. This has led to its use as a therapeutic to target human conditions characterized by deficits in social functioning, especially autism spectrum disorder and schizophrenia. One significant conundrum has been how to deliver Oxt to the brain without resorting to invasive administration procedures, as only 1% of an injected, peripheral dose of Oxt crosses the blood-brain barrier. Intranasal administration of Oxt has become the primary non-invasive delivery route, from basic research to experimental clinical trials. Despite the growing number of human studies using the nasal route of administration, there is no direct evidence for central uptake of Oxt from this administrative route and limited knowledge regarding the effect of chronic application on behavior and the endogenous Oxt system. Such information is vital to

inform the efficacy, tolerability, and safety of intranasal-administered Oxt in humans. Here, we provide a detailed pharmacokinetic examination of nasal-administered Oxt concurrently in the circulatory and central nervous systems of mice. Most significantly, we utilized an Oxt knockout mouse to monitor the distribution of nasally delivered Oxt in the absence of endogenous production of Oxt to validate the origin of the Oxt being monitored. Our study demonstrates for the first time that nasal administration of Oxt permeates into specific areas of the brain. Furthermore, chronic nasal Oxt administered every other day can increase social behavior, particularly olfactory-based social investigation, and boost Oxt receptor production in brain regions associated with the olfactory system. These effects depend on the dose administered. By contrast, chronic daily nasal Oxt suppresses social behavior and Oxt receptor expression in the brain. Thus, chronic nasal Oxt has impacts on behavior and the endogenous Oxt system in an intriguing dose- and schedule-specific manner. These data have interesting implications for the interpretation of various behavioral and physiological effects described in animal and human studies after nasal administration of Oxt and provide the pharmacokinetics necessary to rationally develop this drug delivery route for therapeutic purposes.

(DKFZ), Heidelberg, Germany; [4]Dept. of Neurobio., Howard Hughes Med. Institute, Harvard Med. Sch., Boston, MA; [5]Dept. of Mol. and Cell. Biol., Ctr. for

Brain Science, Harvard Univ., Boston, MA; [6]Central Inst. of Mental Hlth. (ZI), Mannheim, Germany

Abstract: Oxytocin (OT) is the neuropeptide synthesized by neurons of the paraventricular and supraoptic nuclei of the hypothalamus. It is well established that OT within the brain acts as a neuromodulator and plays an important role in reproduction, social recognition, pair bonding, maternal behavior, anxiety, and generally is involved in a wide variety of social behaviors in diverse species. The medial prefrontal cortex (mPFC) is one of the key brain regions, which coordinates social behavior and also a potential target for OT. In the present work we focused on anatomical and functional connectivity of OT neurons within mPFC, specifically infralimbic cortex (IL), as well as on the effects of OT release within the IL on social behavior. Using latex beads and viral vectors we showed that there is a direct projection of OT neurons to the IL. In addition, by using transgenic OTR-reporter animals and immunohistochemistry, we revealed that the vast majority of cells expressing OT receptors in the IL were GABAergic neurons. Furthermore, by applying viral-mediated expression of channelrhodopsin 2 (ChR2) in OT neurons and their axons (Knobloch et al., 2012; Eliava et al., 2016), we recorded cellular responses of individual neurons in acute slices of the IL. The whole-cell recordings revealed that blue light illumination of OT axons carrying ChR2, resulted in an increase of IPSC frequencies in subpopulations of GABAergic and pyramidal neurons of the deep layers. Recently, in order to investigate the behavioral effects of endogenous OT within IL, we subjected female rats to social interaction test. Prior to the test, the rats were injected with a virus expressing ChR2 under the control of OT promoter and implanted with optic fibers above the IL. The control animals expressed Venus instead of ChR2. Preliminary results suggest that rats expressing ChR2 spent more time interacting with unknown conspecifics compared to control rats after blue light illumination of the IL in both groups. In conclusion, OT facilitates social behavior in female rats via activation of GABAergic interneurons, suggesting that the inhibition/excitation balance within local IL network is an important factor, which can modulate “the degree” of pro-social behavior. Furthermore, numerous studies demonstrated that intranasal OT application in humans can change mPFC activity, thus the dissected hypothalamic-mPFC functional circuit might help in the understanding of neuronal mechanisms underlying socio-emotional deficits in human patients afflicted with psychiatric disorders.

Abstract: The brain rapidly evaluates incoming visual information. Emotionally charged images stimulate greater neural response compared to emotionally neutral input, with negatively valenced images creating the most intense response. Studies report that emotional behaviors differ as a function of a person's oxytocin receptor genotype for the rs53576 single nucleotide polymorphism. Measuring visually evoked EEG responses recorded at the PZ electrode placement, negative images stimulated a higher peak response in the early phase (250 -450 msec post stimulus) of the Late Positive Potential (LPP) in people who have the GG genotype compared to those with either the combined GA / AA genotype. ($t(35) = 3.63$, $p < .05$). The mid phase (450 - 650 msec post stimulus) of the LPP was not statistically different between genotypes, nor was the late phase of the LPP (650 - 900 msec post stimulus). For the mid phase of the LPP, there was a significant correlation between the participants scores on a self-report altruism scale and their peak EEG response ($r(35) = .432$, $p < .05$). Cardiac response to visual image presentation will also be measured as a function of genotype and self-report altruism score.

Title: Social tuning of vasopressin 1b receptor-expressing pyramidal neurons in CA2 hippocampal subfield of mice

Authors: *A. CYMERBLIT-SABBA, M. C. GRANOVETTER, S. WILLIAMS AVRAM, A. S. SMITH, J. FASTMAN, H.-J. LEE, J. SONG, W. S. YOUNG;
NIMH, Bethesda, MD

Abstract: The idea that the hippocampus provides a neural basis for cognitive mapping has served as the starting point for many studies that demonstrated its involvement in encoding the map of an individual's spatial location. Nevertheless, these highly important findings present a narrow approach to the original proposal, limiting the hippocampus to spatial organization. Although still elusive, the hippocampus involvement in social cognition is of great interest for social neuroscience. The CA2 subfield has become a focus of recent research due to its unique characteristics and distinct patterns of connectivity with other brain regions. Together with selective expression of the vasopressin 1b receptor (Avpr1b) for the 'social' neurohormone vasopressin, it plays a crucial role in social memory and behavior. By activating GCaMP6s expression in Avpr1b-*Cre* recombinase transgenic mice, we imaged the calcium transients in selective pyramidal neurons within the CA2 subfield while utilizing well-established behavioral paradigms, such as social recognition and social habituation/dishabituation. Our results indicate these cells are responsive to social stimulation, with sparser representation upon repetition. In the neural population imaged, a subset of cells initially demonstrates increased firing rate when the mouse is presented with a social stimulus followed by a significant decrease across repeated exposures. Since a global reduction in firing rate in the entire population is not observed, the effect appears to be stimulus-specific. Further decoding this neural activity in the CA2 will deepen the understanding of the social neural network.

Title: Temporal aspects of social recognition memory in oxytocin receptor knockout mice

Authors: *T. V. MILLER, B. DONELL, H. K. CALDWELL;
Kent State Univ., Kent, OH

Abstract: Oxytocin (Oxt) is a neuropeptide important for displays of social behaviors in many mammalian species and has been implicated in the neural modulation of social memory. In rodents, social recognition memory is olfactory-dependent and important for context-appropriate displays of social behaviors. Tests for social memory in mice are predicated on their preference to spend time investigating odor cues from novel conspecifics rather than familiar conspecifics. It is well established that mice with either a genetic disruption of Oxt or the Oxt receptor (Oxtr) display a form of social amnesia; though, in Oxtr knockout (Oxtr -/-) mice that social amnesia does not manifest with a ten minute retention interval in a habituation-dishabituation test, but does with a thirty minute retention interval in a two-trial social discrimination test. However, these retention intervals have yet to be manipulated within the same test. In order to determine the temporal parameters of social memory in Oxtr -/- mice, we performed a two-trial social discrimination test and varied the retention interval (10 min, 20 min, and 30 min). We found that while wild type controls have normal social recognition memory, being able to distinguish novel from familiar stimulus animals at all of these retention intervals, Oxtr -/- mice do not appear to have social recognition memory with any of the retention intervals. These data suggest that social memory in Oxtr -/- mice is flexible and depends on the difficulty of the behavioral test.

Title: Oxytocin signaling in the nucleus accumbens modulates correlated activity across forebrain nuclei during mating in male prairie voles

Authors: *Z. V. JOHNSON[1,2], H. WALUM[2], L. KING[2], Y. XIAO[2], P. RIEFKOHL[2], L. YOUNG[2];
[1]Emory University, YNPRC, Atlanta, GA; [2]Silvio O. Conte Ctr. for Oxytocin and Social Cognition, Dept. of Psychiatry, Yerkes Natl. Primate Center, Emory Univ., Atlanta, GA

Abstract: Oxytocin receptors (OXTRs) modulate vertebrate social behavior and exhibit diverse patterns of central expression both across and within species. Recent models hypothesize that neuropeptide receptors (e.g. OXTRs) modulate distributed patterns of functional coupling across conserved neural networks during social contexts, but few experiments have tested this hypothesis. OXTR in the nucleus accumbens (NAcc) plays a role in social reward in mice and pair bond formation in monogamous prairie voles. OXTR density in the NAcc has been associated with species differences and individual variation in social behaviors associated with monogamous mating systems. We hypothesized that variation in OXTR signaling in the NAcc of prairie voles would result in variation in functional coupling across an associative social olfactory learning network in the brain. Using Fos immunoreactivity as a proxy of neural activation, we applied pharmacological and genetic approaches to investigate whether variation in accumbal OTR signaling modulates functional coupling across this network in male prairie voles during sociosexual interaction. We find that site-specific blockade of OTR in the NAcc decreases coupling (i.e. correlated Fos expression) between the NAcc shell and other social olfactory, limbic, and mesolimbic reward nuclei ($p=0.02$) during sociosexual interaction in male prairie voles. Next, we use a naturally occurring polymorphism in the prairie vole OXTR gene (*Oxtr;* NT213739) that strongly predicts individual variation in NAcc OXTR binding to show that genetic *Oxtr* variation associated with NAcc OXTR density is also associated with different patterns of coupling across the network ($p<0.05$) during sociosexual interaction. Collectively, these data support previously hypothesized links between central neuropeptide systems and neural network function during social contexts, and provides a mechanism by which OTR signaling may modulate salience and reinforcing value of social stimulidurin pair bond formation.

Title: Conditioned partner preference in male and female rats for a somatosensory cue

Authors: *G. R. QUINTANA ZUNINO[1], S. DESBIENS[2], S. MARCEAU[2], N. KALANTARI[2], J. BOWDEN[2], J. G. PFAUS[2];
[1]Psychology, [2]Concordia Univ., Montreal, QC, Canada

Abstract: We have shown previously that male and female rats form conditioned preferences for sex partners bearing an odor paired previously with either the postejaculatory reward state of the male or the reward state induced by paced copulation in the female. The odor thus acts as a discrete, partner-related cue for sexual reward. The present experiment examined whether a somatosensory cue (a rodent tethering jacket) could act similarly as a discrete partner-related cue. In the first study, 60 sexually-naïve Long-Evans males and females underwent 14 optimal conditioning trials with their opposite-sex partners in unilevel pacing chambers. Paired males were trained using a 1-hole Plexiglas divider with sexually receptive females wearing the rodent tethering jacket. Explicitly-paired females were given 14 trials in sequential order in the same chamber. Half of the trials were conducted using a 4-hole Plexiglas divider always associated with males wearing the jacket, and the other half without the divider associated with males not wearing the jacket. On the final test, experimental males were placed into a large open field with two sexually receptive females, one wearing the jacket and one without the jacket. Experimental females were placed into the same open field with two Plexiglas dividers with six holes each. A male with the jacket was placed on one side, and a male without the jacket was placed on the other side, and the female could pass freely from the central area to one side or the other. Results showed that males ejaculated first more times with the females wearing the jacket relative to females not wearing the jacket, similar to the results obtained previously for females bearing odor cues. However, females had no significant preference for males with or without the jacket. In the second study, 30 males underwent seven trials with sexually receptive jacketed females and seven trials with non-sexually receptive unjacketed females. 30 females were also tested in which the unjacketed male was a long-term castrated male and thus sexually nonreceptive. The final open field test was run identically to the first experiment. Both experimental males and females displayed a significant preference for the partner with the jacket relative to the partner without the jacket. Following this test, two more conditioning trials were conducted with partners wearing the jacket. These results demonstrate that a somatosensory cue can become a

discrete, partner-related conditional stimulus for sexual reward. However, it is easier to establish this relationship in males than females, who seem to require the jacket to differentiate sexually receptive versus nonreceptive partners explicitly.

Title: Preoptic glutamate and estradiol release during male sexual behavior

Authors: C. DE BOURNONVILLE[1], M.-P. DE BOURNONVILLE[2], N. AOURZ[3], A. VAN EECKHAUT[3], I. SMOLDERS[3], G. F. BALL[4], J. BALTHAZART[2], *C. A. CORNIL[2]; [1]Univ. of Massachusetts, Amherst, MA; [2]GIGA Neurosciences, Univ. of Liege, Liege, Belgium; [3]Ctr. for Neurosciences (C4N), Vrije Univ. Brussel, Brussels, Belgium; [4]Dept. of Psychology, Univ. of Maryland, College Park, MD

Abstract: Beside its long-term control by steroids, male sexual behavior is also modulated by neuroestrogens in a dynamic way (within minutes) in a number of species ranging from fishes to mammals. Studies in male Japanese quail have also identified following exposure to a receptive female a rapid decrease in the activity of brain aromatase (AA) the enzyme responsible for the conversion of androgens into estrogens. These effects occur mainly within the medial preoptic nucleus (POM), a sexually dimorphic structure of the preoptic area that plays a key role in the activation of male sexual behavior and contains the highest AA in the brain. *In vitro* studies demonstrated that AA can be rapidly inhibited by calcium-dependent phosphorylations of the enzyme triggered by the activation of AMPA and kainate receptors. We confirmed here this rapid effect of glutamate on AA by injecting kainate in the POM of anesthetized males and measuring AA in the tissue after brain collection. AA in POM was inhibited in the kainate-injected hemisphere compared to the control hemisphere injected with vehicle. In a second experiment, we showed by *in vivo* microdialysis that glutamate is released in POM during copulation. These results thus suggest that glutamate controls dynamic changes of AA that occur

in the brain during sexual interactions. To confirm that the decrease in AA leads to an actual reduction of local estradiol concentration, we quantified via microdialysis and radioimmunoassay changes in estradiol concentration in the male POM during sexual interactions with a female. Surprisingly, a dramatic elevation of estradiol was observed during copulation. Estradiol has been shown to enhance acutely male sexual motivation, therefore the function of its increase in the POM could be to maintain motivation during the entire sexual encounter. The decrease of AA observed *ex vivo* after copulation would then reflect a compensatory mechanism to restore baseline pre-copulatory conditions. Importantly, these results highlight that although long-term changes in AA are often used as a proxy for local estradiol concentrations, these two measures can show major short-term discrepancies possibly reflecting variations in estrogen turnover.

Title: Sexual experience influences gene expression pattern of corticotropin-releasing hormone (CRH) and vgf nerve growth factor inducible (VGF) in the medial preoptic nucleus (MPN) in male rats

Authors: *S. MAEJIMA, S. YAMAGUCHI, K. UCHIYAMA, M. MORISHITA, S. TSUKAHARA;
Grad. Sch. of Sci. and Engin., Saitama Univ., Saitama, Japan

Abstract: The MPN is a regulatory center of male sexual behavior and consists of male-biased sexually dimorphic structures that are found in the central part of the MPN (MPNc). It is suggested that the function of the MPNc involved in male sexual behavior is dependent on sexual experience, although the mechanisms are largely unknown. We previously found that the MPNc highly expressed c-Fos protein in male rats that displayed sexual behavior followed by ejaculation, and this increase was higher in males having first ejaculation than in males having second ejaculation. These results suggest that neural activity of the MPNc is modulated by sexual experience. In this study, we performed DNA microarray analysis of male rats displaying sexual behavior followed by ejaculation to determine the effects of sexual experience on gene

expression in the MPNc. In first ejaculation-experienced males, mRNA expression of CRH and VGF were significantly increased and these increases tended to decrease after second ejaculation. Next, we performed morphological analyses to examine whether CRH and VGF neurons in the MPNc are involved in the sexual experience-dependent regulation of sexual behavior. Brain sections obtained from male rats, which experienced ejaculation, were subjected to immunohistochemistry of CRH and *in situ* hybridization of VGF mRNA with combination with c-Fos-immunohistochemistry. Immunohistological analysis of CRH revealed that the MPNc contained CRH-immunoreactive cell bodies and fibers, and CRH-immunoreactive signals were decreased by ejaculation with or without sexual experience. These results suggest that CRH in the MPNc is released by ejaculation stimuli independently of sexual experience. On the other hand, histological analyses of VFG mRNA and c-Fos protein showed that the increased expression of VGF mRNA and c-Fos protein in the MPNc with ejaculation was higher in males when they had first ejaculation compared with second ejaculation. However, most of VGF neurons did not express c-Fos protein. These results suggest that the VGF-expressing neurons in the MPNc are involved in male sexual behavior in a sexual experience-dependent manner, although there may be other neuronal populations, the neural activity of which is changed by sexual experience.

Title: Testosterone increases soma size of neurons in the posterodorsal medial amygdala in a cell-autonomous manner

Authors: ***N. J. HOBBS**, C. L. JORDAN, S. M. BREEDLOVE;
Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: The posterodorsal medial amygdala (MePD) is a sexually dimorphic brain region in adult rodents. Previous work in our lab found that circulating androgens such as testosterone (T) maintain sex differences in the volume of the MePD as well as neuronal soma size, with males having a larger MePD with larger neurons. These androgen responses are mediated by the

androgen receptor (AR) since Tfm rats and mice with dysfunctional AR are demasculinized in these measures. However, it is unclear if this increase in cell size in wildtype animals is an effect of T acting directly on the cell via the AR or if it is an indirect effect of T acting on neurons in other brain region(s) connected to the MePD, such as the preoptic area (POA). Therefore we conducted a mosaic analysis of AR+ and AR- cells in the MePD of wildtype mice to determine if there is a cell-autonomous effect of T on cell size mediated by AR. Male mice were castrated at 60 days of age and given either a Silastic capsule containing free T or a blank capsule. Thirty days later, brains were collected and sectioned. Tissue underwent AR immunohistochemistry and was counterstained with thionin to stain for Nissl substance. We found that MePD neurons were larger in castrates given testosterone than those given blanks. In blank-treated animals there was no difference in the soma sizes of AR+ versus AR- neurons. However, analysis of T-treated animals revealed that only AR+ cells increased in size in response to T. AR- cells in T-treated mice were similar in size to both AR+ and AR- cells in blank-treated control mice. These results indicate that androgens acts directly on MePD neurons to increase their size in a cell-autonomous manner since only AR+ cells responded to the hormone. A similar effect was seen in the motoneurons of the spinal nucleus of the bulbocavernosus of rats (Watson et al., 2001). These results indicate androgen acts within the MePD to alter its anatomy and so may also affect the region's function in analyzing pheromonal and olfactory stimuli.

PERINATOLOGIA, MEXICO, Mexico; [3]Inst. de Neurobiologia, MEXICO, Mexico; [4]Emory Univ., ATLANTA, GA

Abstract: The prairie vole (*Michrotus ochrogaster),* is a monogamous mammal. It has been shown that cohabitation with mating for 6h induces a pair bond that in most cases is permanent. However, a detailed characterization of the components of sexual behavior in relation to experience in prairie voles has not been reported. The current study further quantifies components of sexual behavior in prairie voles and evaluates whether sexual experience modifies the expression of sexual behavior. To this end, we compared female and male sexual behavior during three sessions of one or six hours, respectively, with an interval of 24 hours between each session. For females, lordosis response was measured and reported as the lordosis coefficient (LQ). Male sexual behavior was registered including the number and latency to mount (NM, ML), intromit (NI,IL) and ejaculate (NE,EL), in addition the interintromission (III) and postejaculatory interval (PEI) were calculated. Thirty two voles (sixteen males and sixteen females), with no sexual experience were used in this study. All females were ovariectomized and supplemented with estradiol during nine days to induce and maintain sexual receptivity during the three behavioral tests; males remained gonadally intact. There were no significant differences between the sexual behavior parameters in either males or females during the three sessions in which they mated for 1 h with the same partner. On the other hand, in the 6 h tests the intromission latency was significantly reduced in the second and third test in comparison to the first test. These results indicate that contrary to what is observed in rats and mice, voles do not show an improvement in the mating pattern associated with experience. This research was supported by grants CONACYT 252756, 167101; Fronteras 374; UNAM-DGAPA-PAPIIT IN203615, IN210215; Instituto Nacional de Perinatología 212250-3230-21216-05-15. Title: Effect of maternal care on the display of copulatory behavior in the subline that differ in spontaneous yawning

Authors: *A. DORANTES, C. CORTES, A. UGARTE, J. R. EGUIBAR;
Inst. de Fisiología, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Sexually experienced male rats usually ejaculates after 10 to 15 intromissions in about 7 to 15 min. Males with a long delay to ejaculate or fail to reach it in tests lasting 30 min are sluggish (S), but if they did not copulate (without mounts) are non-copulating (NC) males. High-yawning (HY) rats had a higher percentage of S and NC than Sprague-Dawley (SD) rats. Additionally, HY and LY (low-yawning) dams have a different maternal care because HY spend less time in the nest, and also showed higher reretrievings and atypically retrievings respect to LY and SD dams. The aim of this study was determine if the poor sexual performance in HY rats is due to atypical maternal care. We used cross-fostering between HY and LY sublines and SD rats, in order to establish how maternal care affects male sexual behavior, we also measured the yawning frequency. Our results indicate that male rats HY raised by mothers LY decrease their yawning frequency until 7 ± 2.8 yawns per hour (y/h; $P < 0.05$), HY rats reared by their biological mothers yawned 25 ± 2.8 per hour, similar values were obtained when HY males were reared by SD dams reaching 17 ± 3.8 y/h ($P < 0.05$). In the first copulatory series, both groups of HY rats reared by LY and SD dams reach ejaculation in less than 30 min. However, LY rats reared by HY dams decreased their sexual performance because they never attempt to mount respect to LY reared their own mothers which were able to display mounts and intromissions. Using a binomial proportion inference the probability that HY dams reared offspring with higher incidence of NC and S are being significantly higher than LY and SD dams ($P<0.05$) In conclusión, HY dams phenotype impair sexual perfomance in their siblings independently of their origin.

Title: Proceptivity differs in high-yawning respect to low-yawning and Sprague-Dawley rats

Authors: *A. MORA-BOLAÑOS, C. CORTES, J. R. EGUIBAR;
Inst. de Fisiología, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Receptive behavior in females is characterized by lordosis and proceptive behaviors consist in hopping, darting, and ear wiggling displays. Receptivity in female rats is stimulated during the estrous cycle due to sequential secretion of ovarian steroids. The female sexual behavior in ovariectomized rats can be induced by the sequential administration of estradiol and progesterone. Previous studies showed that high-yawning (HY) male rats had a deficient sexual performance when tested with outbred Sprague-Dawley (SD) female rats. The aim of the present study, was to analyze female sexual behavior display in rats selectively bred for HY and low-yawning (LY) spontaneous frequency, and outbred SD subjects tested in pairs with HY, LY and SD sexual experienced males. So, sexual receptivity was induced by sequential administration of estradiol benzoate (5 μg) and 44 h later by progesterone 2 mg diluted in olive oil and administered subcutaneously in 0.2 mL in the dorsal neck region. All subjects were tested 4h later with a sexual vigorous male of the same or different group of rats in circular Plexiglas arena (50 cm diameter). Our results showed that SD, HY and LY female rats showed lordosis quotients being 80 to 100% responsive to steroid treatment independently of the copulating male. However, HY female subjects showed less hopping behavior respect to LY and SD rats ($P<0.05$), but all groups of rats display similar amounts of darting's. In conclusion, only hopping differs among female groups tested suggesting that the neural circuits involve in hopping are less sensible to ovarian steroids in HY rats, but it is not the case with ventromedial hypothalamus that mediate lordosis which showed similar sensitivity to ovarian steroids in all subjects.

Title: Gonadal steroids during puberty are necessary for steroid-independent male sexual behavior in castrated B6D2F1 hybrid male mice

Authors: *J. S. TEMPLIN, A. R. BARTLETT, A. BALA, A. L. ROKICKI, J. C. WYROSDIC, Z. Z. KHAN, J. PARK;
Psychology Dept., Univ. of Massachusetts: Boston, Boston, MA

Abstract: Gonadal steroids play an integral role in male sexual behavior (MSB), and in most rodent models, this relationship is tightly coupled. However, many other species, including humans, continue to demonstrate MSB in the absence of gonadal steroids, and the mechanisms that regulate steroid-independent MSB are not well understood. ~30% of castrated male B6D2F1 hybrid mice display MSB up to 26 weeks after castration, allowing for the investigation of individual variation in steroidal regulation of MSB. During both the perinatal and pubertal critical periods, the organizational effects of gonadal steroids on sexual differentiation of the neural circuits controlling MSB are well-documented. Several factors can alter the normal range of gonadal steroids which may lead to the disruption of the normal processes of masculinization and defeminization. It is unknown whether the organizational effects of gonadal hormones during puberty are necessary for steroid-independent MSB. Our results indicate that gonadal steroids during puberty are necessary for steroid-independent MSB in adulthood. Furthermore, gonadal steroids during puberty were not necessary for either testosterone (T) or estradiol to activate MSB in adulthood. Additionally, T has been correlated with reduced anxiety-like behavior in adult rodents, and prepubertal castration alters adult anxiety-like behavior. B6D2F1 hybrid male mice that were castrated prior to puberty displayed heightened anxiety-like behavior relative to controls, suggesting that testicular steroids during puberty are required for the normal organization and maturation of the developing stress axis. Anxiety-like behavior of B6D2F1 hybrid male mice, that were castrated in adulthood and expressed steroid-independent MSB, did not differ relative to those that ceased to express MSB. Furthermore, testosterone- and estradiol-treated males that were castrated prior to puberty exhibited less anxiety-like behavior relative to sham controls in adulthood, indicating that exposure to gonadal steroids during puberty was not necessary for the activation of the anxiolytic action of gonadal steroids. In summary, gonadal steroids during puberty are necessary for the normal maturation of neural circuitry that mediates steroid-independent MSB in adult castrated B6D2F1 male mice, but not necessary for the activation of MSB with T or estradiol. Whether the MSB that is activated with T or estradiol in hybrid males castrated prior to puberty differs from the steroid-activated MSB of males that were castrated in adulthood that do not demonstrate steroid-independent MSB warrants further investigation.

Title: Survival of new neurons in the olfactory bulb induced by paced mating in the female rat

Authors: *R. A. ALVARADO, M. SANTOYO-ZEDILLO, R. G. PAREDES;
INB, UNAM, Queretaro, Mexico

Abstract: Previous research from our laboratory showed that when female rats pace the sexual interaction, the number of new cells increases in the accessory olfactory bulb (AOB) and the main olfactory bulb (MOB) 16 days after mating, in comparison to females that did not pace the sexual interaction. We also reported that repeated sessions of paced mating increases the number of new cells, compared to females that mated just once. The aim of present experiment was to evaluate if 10 paced mating sessions maintains this initial increase in the number of cells 45 days after mating and whether there are changes in the phenotype of these new cells. Female Wistar rats (220-250 grs), were ovariectomized and injected the first day of testing with DNA synthesis marker 5'-bromo-2`-deoxyuridine (BrdU, 300 mg / kg). After the last mating session subjects were anesthetized and sacrificed, their brain collected and placed in TBS with sucrose (at 30%) for protection against the cold. The brain was cut in sagittal sections (30 microns). For histological analysis we select those slices in which the AOB and MOB were present. For detection of the new cells with BrdU we used the chromogen solution nickel chloride-3,3'-diaminobenzidine (DAB). No differences were found in the number of cells between groups in the different layers of the OB, contrasting with what we have observed at day 16. Futures studies need to analyze the number of new neurons. Grants: CONACyT 253631, Fronteras 374; PAPIIT 210215. PhD. Fellowship CONACyT 245202

Title: Changes in c-fos expression patterns due to sexual experience in the female mice brain

Authors: *P. MARCO MANCLUS, W. PORTILLO, R. G. PAREDES;
Neurobiologia conductual y cognitiva, Inst. de Neurobiología De La UNAM, Queretaro, Mexico

Abstract: In mice, unlike rats, naïve females showed low levels of sexual receptivity toward males in their first sexual experience. Female mice have a stereotypical posture called Lordosis, in which they flex their back exposing the genitalia and facilitating penetration. Using this reflex, sexual receptivity can be measured with the Lordosis Quotient (LQ, number of lordosis displayed/number of mounts). The activity of the brain cells displayed during a determined behavior can be evaluated by the detection of the proteins resulting of the product of the transduction of the "early expression genes" (genes expressed immediately after the activation of the cell).
The aim of this study is to evaluate if sexual experience induces plastic changes that involved the increase in cell activity in those areas related with the female sexual behavior such as: the Olfactory bulb, the Medial Preoptic Area, the Ventromedial Hypothalamus and the Bed nucleus of the Stria Terminalis.
In this study 54 CF1 female mice (Mus Musculus) were ovariectomized and randomly assigned to 1 of 3 groups: Experienced females (n=20), which received 6 mating sessions; Unexperienced females (n=18), which receive only one session; and Naïve females (n=18), which had no previous sexual experience. The mating sessions consist in placing the female in the male's cages for an hour, and during the test sexual behavior was registered. Females were hormonally primed with 1 µg of Estradiol and 100 µg of progesterone (48h and 4h respectively, before the test). All females receive 6 injections of each hormone to make groups comparable. Each group was divided in 3 other subgroups: Mating group, which receive a 7^{th} mating session; Olfaction group, which was exposed to bedding impregnated with male sexually relevant odors; and Control group, which were exposed to clean bedding. 90 min after the last test, animals were euthanized and perfused, and their brains were collected and sliced (20 µg thick). Brain sections were immunostained for C-fos, using Nissl technique as a counterstaining,

in order to evaluate the expression of this protein. Our behavioral results showed that, as expected, females increase their LQ with repeated testing, and our preliminary immunohistochemistry results suggest that females that mate 7 times have a higher number of C-fos immunoreactive cells in the ventromedial hypothalamus that those that mated twice, suggesting that sexual experience increases the number of cells that respond to mating stimulation.

Title: The effects of intranasal oxytocin on anxiety, social, and sexual behaviors in male rats prenatally exposed to valproic acid

Authors: *S. M. HARDING[1], E. C. MASTERS[2];
[1]Psychology Dept, [2]Psychology, Fairfield Univ., Fairfield, CT

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects 1 in 68 children, and is characterized by impairments in social behaviors and communication. In utero exposure to the antiepileptic drug valproic acid (VPA) during prenatal development is associated with ASD-like symptoms in children, making this a plausible rodent model. One potential treatment for ASD symptoms is the neuropeptide oxytocin (OXT), which contributes to social recognition, communication, and social bonding. Therefore, the present set of experiments was designed to examine whether intranasal administration of oxytocin would improve behaviors in male rats that were prenatally exposed to VPA. Pregnant Long-Evans female rats (n=3) were injected subcutaneously with either 600 mg/kg of VPA or saline on gestational day 12.5. After weaning, male pups were housed in same-sex conditions and received 0.8 IU/kg of intranasal OXT or saline daily from P21 to P41, forming three groups: VPA (VPA plus saline treatment, n=9), VPA-OXT (n=8), and Controls (saline plus saline treatment, n=4). Behavioral tests for anxiety, sociability, and sociosexual behaviors were conducted to investigate acute and long-

term effects of intranasal OXT treatment. On the elevated plus maze test, VPA rats showed an increased latency to enter the open arm compared to controls ($p<.05$), suggesting heightened anxiety. Likewise, during the sociability test, VPA rats spent more time in a neutral chamber than the Control rats ($p<.05$), suggesting they were less social. On both tests, the VPA-OXT group did not differ from Controls, providing evidence that OXT treatment may restore behaviors. To examine whether OXT treatment early in life had long-term effects on behavior, we tested all groups for social interactions with female rats in adulthood (P82-P98), well after OXT treatment had ceased. Sociosexual behaviors were assessed with tests for copulation, partner preference and ultrasonic vocalizations / scent marking. Surprisingly, early OXT treatment in VPA rats was associated with reduced sociosexual behaviors in adulthood. On copulation tests, the VPA-OXT group showed fewer mounts than both VPA and Control groups ($p<.01$). The VPA-OXT group also showed fewer scent marks than the VPA group, although the difference was did not reach statistical significance. Taken together, these findings have direct implications for the treatment of neurodevelopmental disorders like ASD with OXT. However, the long-term effects of early OXT exposure may require additional study.

Title: Motivational state, sexual experience and vaginal stimulations during mating influence Oxytocin

Authors: *M. L. LANGETT, N. M. CAMERON;
SUNY Binghamton, Binghamton, NY

Abstract: Various mating paradigms have shown to affect oxytocin (OT) neuron populations in the paraventricular nucleus (PVN) and the supraoptic nucleus (SON). However, the effect of various mating conditions on female plasma OT levels has not been fully investigated. Furthermore, the sexual experience state of the females is not consistent between experiments, making results difficult to interpret. We hypothesize that OT production and release are linked to the quality of sexual experience, the physical stimulations received and the motivational state of the female. We designed two studies to test this hypothesis. In Experiment 1, the effect of mating experience in ovariectomized (ovx) steroid-primed females on OT levels was investigated under paced mating conditions. We found a significant positive correlation in the virgin females

between plasma OT levels and para-copulatory behaviors (hopping, darting and ear wiggling) that was not observed in sexually- experienced females. We also found no significant effects of sexual experience on OT levels. In Experiment 2, sexually-experienced ovx females were used to investigate the effects of vaginal cervical stimulation (VCS) and paced mating on brain and plasma OT levels. These females were placed in four mating conditions (either paced or not paced, and with or without vaginal mask). Across the four groups, there was a significant negative correlation between PVN OT levels and para-copulatory behaviors. In animals that received VCS, a significant positive correlation between plasma OT levels and para-copulatory behaviors was found. There was a significant positive correlation between PVN and SON OT levels in females that mated but did not receive VCS. Additionally, experienced females that received VCS and were paced mated showed a significant negative correlation between PVN and plasma OT levels. In both of these experiments, brain and plasma OT was collected and analyzed using an ELISA. Overall, these results indicate the importance of mating conditions and sexual experience on OT production and release. Para-copulatory behaviors, which are voluntary behaviors that could reflect the motivational state of females, seem to be particularly important in the modulation of OT levels, decreasing it in the PVN and increasing it in the plasma. This suggests a relationship between PVN and plasma OT levels. Interestingly PVN and SON levels correlated only when females did not receive VCS, further suggesting a link between sexual experience and brain OT release. In conclusion, motivational state, sexual experience and vaginal stimulations during mating may influence production and release of OT after mating in the rat.

Title: Getting real: Oxytocin facilitates goal-tracking to a real sex partner relative to a distal second-order sexual cue in male rats

Authors: *L. M. SPARKS, V. PALLIKARAS, J. G. PFAUS;
Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Repeated pairings of a conditioned stimulus (CS) with an unconditioned stimulus (US) result in individual differences in Pavlovian-conditioned approach (PCA) toward the CS (sign-tracking; ST) or US (goal-tracking; GT) using sexual reward. Furthermore, a subset of animals termed intermediates (IN) exhibit PCA toward both the CS and US equally. Oxytocin (OT), a neuropeptide involved in sexual arousal and social bonding, enhances the acquisition of conditioned ejaculatory preference (CEP) for olfactory stimuli. Whether OT can potentiate cue- or goal-directed behaviour through the development of CEP in rats identified as ST, GT or IN has yet to be elucidated. ***Objective***: The present study examined whether OT alters the expression of a CEP toward a visuo-tactile cue in ST, GT and IN male rats. ***Method***: Sexually-naïve, male Long-Evans rats received 13 Pavlovian conditioning sessions in an individualized compartment of an open field chamber, where an orange cone CS (2-min/presentation) predicted the opportunity to copulate to ejaculation in a separate compartment with a receptive female (US). On sessions 7-13, rats received injections of saline or OT (5µg/ml/kg; s.c.) 4-h, 2-h, and 15-min prior to the start of the trial. Pavlovian-conditioned approach toward the CS (ST) and US (GT) was measured by the proportion of time spent in an area centered around the CS or the door to the female compartment, respectively, in the absence and presence of the cue. ***Preliminary Results***: Between sessions 1 and 7, rats did not display ST or GT behaviour; no differences were observed in PCA toward the CS- or US-designated areas. By session 13, individual differences in PCA were observed, where a subset of rats spent a significantly greater proportion of time in either the CS- (ST) or US-designated (GT) areas. Interestingly, OT did not facilitate the development of ST or GT behaviour in animals displaying such phenotypes. However, in IN animals, OT shifted PCA toward the US in both the presence and absence of the cue. ***Conclusions***: These results provide further evidence that conditioned cues acquire incentive motivational properties through Pavlovian conditioning with sexual reward as the US. Moreover, our preliminary results suggest OT may be important in the formation of Pavlovian associations between the CS and US, and may guide IN rats toward a GT behavioral phenotype.

Title: Ovarian hormones alter the expression of 50 kHz ultrasonic vocalizations induced by distributed clitoral stimulation in female rats

Authors: *C. A. GERSON[1], T. SCARDACHIO[1,2], G. R. QUINTANA[1], P. B. S. CLARKE[2], J. G. PFAUS[1];
[1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Pharmacol., McGill Univ., Montreal, QC, Canada

Abstract: Adult rats emit frequency modulated 50kHz ultrasonic vocalizations (USVs) in response to rewarding stimuli. Male rats, for example, emit these calls as they are about to ejaculate. Investigations of the incentive-reward value of female vocalizations during sexual interaction with either devocalized or vocally-intact males suggest that female USVs are activated by ovarian hormones and the presence of a male overall, and are not correlated with copulatory stimulation. We have shown previously that artificial distributed clitoral stimulation (CLS) that mimics the tactile CLS experienced by the female during male mounts with pelvic thrusting induces a sexual reward state capable of supporting both conditioned place and partner preferences. The present study examined whether distributed CLS might induce specific frequency-modulated calls in female rats, and whether the calls would be altered by different hormone priming. Virgin female rats were ovariectomized and injected with either estradiol benzoate (EB) and progesterone (P), EB alone, P-alone, or the oil vehicle, prior to the administration of distributed CLS. CLS was made by lightly brushing the clitoris in a downward stroke using a No. 4 paintbrush. CLS was applied every 5 sec for 1 min after a 4 min baseline USV measurement and this was repeated for 6 cycles over a period of 34 min, for a total of 72 CLSs. USVs were recorded and analyzed before, during, and after each bout of CLS. Females primed with EB+P displayed a large number of 50 kHz-range trills and flats that were long in duration and primarily of the trill subtype. Females primed with EB-alone emitted a moderate number of 50-kHz calls during CLS, whereas females primed with P-alone emitted few calls during CLS. Unprimed females rarely called, and those that were emitted were of very short duration and usually of the flat subtype. Thus, in contast with previous reports, we show that female rats emit a consistent pattern of 50 kHz calls in response to rewarding stimulation of the clitoris, and that the sensitivity to CLS in the induction of these calls is augmented by steroid hormones. Title: Inhibition of anterior dorsomedial accumbens shell neurons prevents stress-induced decrease in sucrose intake.

Authors: *A. MITRA[1], J. SEIGNEUR[2], G. GUEVREMONT[1], I. TIMOFEEV[2], E. TIMOFEEVA[1];
[1]IUCPQ, Univ. Laval, Quebec, QC, Canada; [2]IUSMQ, Univ. Laval, Quebec, QC, Canada

Abstract: Introduction: Accumbens shell is a reward and stress responsive area of the brain. It's pharmacological and optogenetic inhibition leads to increased food intake whereas its specific temporal activation terminates the ongoing feeding bout. Acute stress leads to anorexic response towards normal and palatable food. We hypothesized that stress activates the accumbens shell neurons, hence leading to decreased sucrose consumption; and thus, its inhibition following acute stress could rescue the stress-induced anorexia. **Method**: Male Sprague Dawley rats were implanted with metal microelectrodes in the anterior dorsomedial accumbens shell (admAcbSh) and extracellular recordings performed during 1 h of 10% sucrose solution access, with or without foot-shock stress. Electrophysiological parameters were used to characterize neurons into putative medium spiny GABAergic neurons (pMSN), putative fast-spiking GABAergic interneurons (pFSI) and putative tonically-active cholinergic interneurons (pTAI). Firing rate changes of these putative neurons were studied around the sucrose licking clusters. Separate cohorts of rats were microinjected with channelrhodopsin (ChR2), halorhodopsin (eNpHr) or control non-opsin (eYFP) viral constructs in admAcbSh followed by implantation of fiber-optic cannula in the same region. Effect on sucrose intake and general anxiety status was tested using various optical parameters during non-stressed and stressed conditions. To validate the in-vivo optical stimulation parameters, in-vitro whole cell recordings were performed. **Results**: Acute stress decreased sucrose intake by modulating lick microstructure. The admAcbSh had higher percentage of pMSN population which showed increased firing rate during sucrose intake following stress. Specifically, it was the cluster-start excited neurons that increased in percentage and firing rate following stress. Optogenetic activation of the admAcbSh led to a significant decrease in sucrose consumption by decreasing motivational value of sucrose. Conversely, optogenetic inhibition of the admAcbSh attenuated stress-induced anxiety and increased sucrose intake in both experimental conditions. Patched

pMSN neurons expressing ChR2 or eNpHr show robust excitatory or inhibitory responses, respectively, when optically stimulated. **Conclusion**: Increase in firing rate of the admAcbSh neurons induced anorexia towards palatable food, and inhibition of admAcbSh reinstates the normal eating behavior in stressed rats. Specific modulation of this structure could therefore be used to prevent stress-induced ill-metabolic consequences of eating disorders.

Title: Dorsomedial striatum lesions affect adjustment to reward uncertainty, but not to reward devaluation or omission

Authors: *M. R. PAPINI[1], A. C. GLUECK[1], S. E. CONRAD[1], I. MORON[2], C. TORRES[3]; [1]Dept of Psychology, Texas Christian Univ., Fort Worth, TX; [2]Univ. of Granada, Granada, Spain; [3]Univ. of Jaen, Jaen, Spain

Abstract: The proposal suggesting that the dorsomedial striatum (DMS) is implicated in the acquisition of reward representations leads to the hypothesis that it should play a role in situations involving reward loss. The current experiment explored the effects of DMS excitotoxic lesions on consummatory successive negative contrast (cSNC; reward devaluation), autoshaping training with partial vs. continuous reinforcement (PR, CR; reward uncertainty), and appetitive extinction (reward omission). For reward devaluation testing, animals having access to 32% sucrose for 5 min during 10 daily sessions were unexpectedly downshifted in 5 subsequent sessions to 4% sucrose. Their consummatory behavior was compared to that of animals that received access to 4% sucrose during each of 15 sessions. Animals with DMS lesions exhibited a normal cSNC effect, showing significant consummatory suppression during downshift sessions relative to unshifted controls. For reward uncertainty testing, animals received lever-pellet Pavlovian pairings with either 50% PR or 100% CR. Sham animals displayed higher lever-pressing performance under PR than under CR training (the PR acquisition effect), whereas this

effect was eliminated by the DMS lesion. Interestingly, goal entries during acquisition were also affected by the DMS lesion, but in the opposite direction relative to lever pressing. Despite its effects on acquisition, DMS animals showed unaffected extinction of lever pressing and goal entries. Finally, open field testing indicated normal motor behavior. Thus, DMS lesions selectively affected the behavioral adjustment to a situation involving reward uncertainty, producing a behavioral reorganization according to which goal tracking (goal entries) become predominant at the expense of sign tracking (lever pressing). These results suggest that the function of the DMS in situations involving reward loss is not general, but restricted to reward uncertainty. We suggest that a nonassociative, drive-related process induced by reward uncertainty requires normal output from DMS neurons.

Title: Changes in apoptotic factors in the nucleus accumbens on morphine-induced conditioned place preference in the rat: involvement of acute and subchronic physical stress

Authors: *Y. RAZAVI[1], A. HAGHPARAST[2];
[1]Cell. and Mol. Res. Ctr., Tehran, Iran, Islamic Republic of; [2]Shahid Beheshti Univ. of Med. Sci., Neurosci. Res. Ctr., Tehran, Iran, Islamic Republic of

Abstract: Introduction: It has been shown that nucleus accumbens (NAc) has an essential role in rewarding action of opiates and is also influenced by stress. Additionally, morphine and stress both can induce apoptosis in different kinds of cells such as neural cells. In this study, we have investigated the effects of morphine-induced conditioned place preference (CPP) in presence and absence of physical stress on changes in conditioning score and the level of apoptotic factors (Bax/Bcl-2 ratio, caspase-3 activation and PARP degradation) in the NAc **Material and Methods:** Male Wistar rats were divided to two saline- and morphine-treated supergroups. Each supergroup consisted of control, acute stress (AS, received forced swim stress just one day) and subchronic stress (SS, received forced swim stress for three consecutive days) groups. In all of groups, the CPP paradigm was done and following behavioral experiments, the alternation of apoptotic factors in the NAc were measured by western blot analysis. **Results:** The results indicated that in saline or morphine-treated animals, AS and SS could enhance Bax/Bcl-2 ratio,

caspase-3 activation and PARP degradation in the NAc. **Conclusion:** In the present study, These finding demonstrated that both AS and SS trigger apoptotic events in saline or morphine-treated animals as well as these effects in morphine-treated animals were more considerable than those of saline-treated animals.

Title: Examination of cortizol receptor and endogenous opioid expression in a primate model of self injurious behavior

Authors: *M. JACKSON[1], B. FORET[2], J. FONTENOT[3], E. ROMERO[3], D. HASSELSCHWERT[3], J. SMITH[3], K. SMITH[2];
[1]Biol., Univ. of Louisiana At Lafayette, Lafayette, LA; [2]Univ. of Louisiana at Lafayette, Lafayette, LA; [3]New Iberia Res. Ctr., New Iberia, LA

Abstract: Suicide is the tenth leading cause of death in the United States, the second leading cause of death for those between the ages of 15 to 24, and accounted for approximately 41,000 deaths in the year 2014. According to the Centers for Disease Control, the suicide rate has increased a dramatic 24% in 15 years. With such a prevalent impact on our society, it is important to understand the underlying mechanisms that may lead a person to self harm. Non-suicidal self-injury (NSSI) is the deliberate infliction of physical harm to one's own body without suicidal intent. While NSSI is by definition, not an attempt at suicide, it is strongly associated with future suicide ideation and has been described as a "gateway" behavior. Self-injurious behavior occurs in approximately 1-4% of the adult human population, with higher rates of incidence in the adolescent and institutionalized populations. SIB also occurs in a low percentage of captive monkeys; it is an endogenously occurring model of SIB in humans in the context of captive animals. Rhesus Macaque monkeys are evolutionarily and physiologically similar to humans, share 93% of their DNA with humans and consequently have long been used as testing subjects for vaccine and clinical trials. In order to study SIB we used 8 sex-matched pairs of rhesus macaques, eight who exhibited self-injurious behavior (SIB) and eight controls, to examine alterations in gene expression. The brain regions chosen are those closely linked to reward reinforcement and stress adaptation including the hypothalamus, orbital frontal cortex, nucleus accumbens, hippocampus, caudate, putamen and the amygdala. Previous studies have

identified reactive changes in astrocytes of animals exhibiting SIB. We have therefore collected five additional rhesus macaques, two who exhibited SIB, to examine morphological changes in astrocytes. Thus far, our findings suggest no significant changes in the gene expression of the mu-opioid receptor, mineralocorticoid receptor, glucocorticoid receptor, β-endorphin precursor molecule proopiomelanocortin (POMC), or the dynorphin A and B precursor prodynorphin in the hypothalamus, hippocampus and orbital frontal cortex. Current studies are investigating the expression levels of these genes in the nucleus accumbens, caudate, putamen, and amygdala. Previous studies have hypothesized that altered endogenous opioid expression occurs in the brains of individuals and animals that self-injure. Our studies indicate the need for further studies to identify if, and how this is occurring in self-injuring macaques.

Title: Chronic stress alters the electrophysiological properties of hippocampal-accumbens synapses

Authors: *T. A. LEGATES, S. M. THOMPSON;
Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Depression is a leading cause of disability with a lifetime prevalence of 12% and 20% in men and women, respectively. A common risk factor that increases the likelihood of depressive episodes is stress. Depressed patients report more stressful life events than non-depressed subjects. The nature of the stress-induced neuronal changes that promote depression in susceptible individuals remains unknown. There is increasing evidence that chronic stress weakens neuronal communication in multiple brain regions, perhaps accounting for the wide range of behaviors affected by stress. Previous work has focused on the changes that occur *within* specific brain regions, such as the hippocampus and nucleus accumbens (NAc). However, communication *between* these two areas is important as well, yet poorly understood. The ventral

hippocampus provides excitatory input to the NAc shell, which is thought to be important for modulating NAc activity and providing contextual information to reward processing. This synapse has received increased attention due to its potential role in mood regulation, specifically in response to reward and motivation to seek rewards, which are altered in mood disorders including depression. We used whole-cell electrophysiological recordings in the NAc shell to characterize the properties of the connections from the hippocampus to the NAc in the brains of mice, including the contributions of glutamate receptor subtypes. We found that Hip-NAc synapses become strengthened in response to high frequency activity due to classical activity-dependent long-term plasticity mechanisms but independent of dopamine receptor signaling. Furthermore, we found that α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor subunit composition remains unchanged after LTP induction. These results were similar in D1- and D2-MSNs. We then used a chronic stress paradigm to induce depression-like behavior. We found that the properties of this synapse change in response to chronic stress. However, the observed changes differ in D1- and D2-MSNs. This work defines a specified neuronal circuit that is responsible for mood regulation and further our understanding of excitatory synaptic strength as a critical mediator of this process. Understanding the neuronal changes that underlie depression and antidepressant response will provide key insight into developing new, more effective treatments for this disorder.

Title: Circadian glucocorticoid oscillations determine activity in the basolateral amygdala

Authors: F. S. DEN BOON[1], M. J. N. BAELDE[1], *M. JOELS[2], H. KARST[1];
[1]Translational Neurosci., [2]UMC Utrecht, Utrecht, Netherlands

Abstract: The hypothalamic-pituitary-adrenal (HPA) axis is a key part of the stress system. The HPA axis regulates plasma glucocorticoid levels and thereby controls the rapid response to stress. Under basal conditions, the synthesis and release of glucocorticoids occur in a circadian rhythm overarching ultradian pulses. Peak levels of glucocorticoids are seen at the start of the active phase, which is nighttime in most rodents. Deregulation of the HPA-axis can result in a

wide range of disorders, including mood disorders. Limbic areas express high levels of receptors sensitive to corticosteroids (CORT) and are especially affected by changes in CORT levels. We demonstrated earlier that repeated application of CORT results in immediate and long-lasting changes in spontaneous glutamate transmission in the basolateral amygdala (BLA), an area that regulates fear behavior. To study the effect of circadian fluctuations of CORT levels on glutamatergic neurotransmission in the BLA, we investigated spontaneous glutamate release in BLA slices of mice sacrificed at the start of the inactive phase and at the start of the active phase. To mimic in vivo exposure to ultradian glucocorticoid pulses, 'inactive phase slices' were exposed to increasing concentrations of CORT (3, 10, 30 and 100 nM, 1 hr between pulses). Active phase slices were exposed to decreasing concentrations of CORT (100, 30, 10 and 3 nM, 1 hr between pulses). Miniature excitatory postsynaptic currents (mEPSCs) were recorded in the presence of TTX and bicuculline. Results showed that the basal mEPSC frequency was increased in inactive phase slices over the course of the experiment (1.11±0.14 Hz, 2.28±0.38 Hz, $p<0.05$). The basal mEPSC frequency was reduced in active phase slices (1.63±0.20 Hz, 0.91±0.12 Hz, $p<0.05$). Furthermore, tone-cued fear conditioning experiments with similar groups of animals showed that mice at the start of the inactive phase show more freezing behavior, a measure of fear, than mice at the start of the active phase (63.92±3.18%, 38.46±4.53%, $p<0.05$). These data indicate that neuronal activity in the BLA is controlled by the pulsatile circadian rhythm in which glucocorticoids are released.

Title: Investigating frontostriatal circuit function in social interaction behavior and chronic social stress

Authors: ***B. S. HALL**, R. N. FETCHO, T. HUYNH, A. RAJADHYAKSHA, C. LISTON; Weill Cornell Med. Col., New York, NY

Abstract: Impairments in social functioning are a core component of many stress-related neuropsychiatric conditions including depression, schizophrenia and anxiety disorders. The underlying mechanisms that lead to social dysfunction in these conditions are not well understood, but are thought to involve the nucleus accumbens (NAc), a stress-sensitive area of the ventral striatum that regulates drives and motivation. The NAc integrates signals from a reward-processing network that includes the infralimbic (IL) region of the prefrontal cortex. The mechanisms by which IL-to-NAc projections influence social behavior and how they are altered by chronic stress have not been well defined. This work aims to investigate how projections from the IL modulate activity in the NAc and influence social interaction behavior in order to define circuit mechanisms by which these processes are altered by chronic stress. Using a rodent model of chronic stress (chronic social defeat stress) and fiber photometry in order to record from and manipulate specific neural populations and circuitry, we show how chronic stress affects NAc activity and IL-to-NAc signaling in the context of social interaction behavior. This work may elucidate mechanisms by which stress can lead to changes in reward circuitry that impact social interaction and lead to social dysfunction in psychiatric diseases.

Title: Localization of CRF-binding protein in GABAergic interneurons in the prefrontal cortex

Authors: *K. KETCHESIN, A. SEASHOLTZ;
Univ. of Michigan, Ann Arbor, MI

Abstract: Corticotropin releasing factor (CRF) is the key central nervous system regulator of the mammalian stress response. CRF mediates its primary effects through binding to CRF receptors, and dysregulation of the CRF system has been linked to alcohol addiction. The activity of CRF is also modulated by the CRF-binding protein (CRF-BP), a 37 kDa secreted glycoprotein that binds CRF with very high affinity and regulates CRF receptor activation. We have recently shown that

CRF-BP mRNA expression is significantly decreased in the medial prefrontal cortex (mPFC) after repeated cycles of binge drinking in mice. However, the neurotransmitter/neuropeptide phenotype of CRF-BP-expressing cells in the PFC is currently unknown. The goal of the current study was to characterize the expression of CRF-BP in excitatory and inhibitory neurons of the PFC. Dual in situ hybridization experiments were performed to determine the colocalization of CRF-BP mRNA expression with vesicular glutamate transporter (VGLUT) mRNA and glutamate decarboxylase (GAD) mRNA in the PFC of male C57BL/6 mice. CRF-BP mRNA was highly colocalized with GAD, but not VGLUT, in the PFC, suggesting a role in inhibitory GABA neurons. To further characterize the specific GABAergic interneuron subtype, dual in situ hybridization experiments were performed for CRF-BP mRNA and various neuropeptides, including cholecystokinin (CCK), somatostatin (SST), vasoactive intestinal peptide (VIP), and parvalbumin. There was a high degree of colocalization of CRF-BP with parvalbumin and SST in the PFC, while the degree of colocalization of CRF-BP with VIP and CCK was significantly lower. Overall, these results suggest that CRF-BP is primarily expressed in GABAergic interneurons of the PFC, specifically in parvalbumin and SST-expressing neurons. Previous studies suggest that CRF is primarily expressed in GABAergic interneurons, while CRF-R1 is mainly expressed in excitatory pyramidal neurons of the cortex. The expression patterns observed in the current study suggest that CRF-BP may be positioned to act locally in interneurons of the mPFC to regulate CRF receptor activity on pyramidal neurons, perhaps modulating the output of these neurons. Ongoing studies are investigating the colocalization of CRF-BP with CRF in the PFC. Together, these colocalization studies will provide a more comprehensive understanding of the role of CRF-BP in regulation of CRF activity within the circuits of the stress and reward systems.

Title: Subchronic heat stress exposure increases activity in hippocampus and amygdala reflected as anxiety-like behavior of young Wistar rats

Authors: J. C. AVILA SANDOVAL, L. V. CONTRERAS, E. U. FRANCO ANDRADE, *J. GUZMÁN MUÑIZ, O. P. GONZALEZ-PEREZ, N. A. MOY LÓPEZ;
Psychology/Lab Neurosci., Univ. of Colima, Colima, México, Mexico

Abstract: Climate change is a current topic of research not only by their environmental effects, but also to the possible influence of high environmental temperatures in humans, which have been related to anxious and violent behavior, suggesting an existent biological factor between heat-anxiety and the stress-modulated structures. However, the relationship between anxiety and hot weather is not fully understood, which leaded us to examine the effects of subchronic heat stress exposure in anxiety-like behavior and amygdala/hippocampus activity in young Wistar rats. In order to accomplish this aim, 30 days old experimental rats (10 males and 10 females) were exposed to heat (33±3°C) for 6 hours during 7 days, whereas control group (10 males and 10 females) in standard laboratory conditions (24±1°C), all of them was kept under 12:12h light/dark cycle with water and food *ad libitum*. Anxiety index and motor activity were evaluated with Elevated Plus Maze and Open Field test respectively, while (Heat Shock Protein 70) HSP70 *and c-fos* markers were quantified by immunohistochemistry in amygdala (central and medial) and hippocampus (CA2, CA3 and DG). Behavioral results showed an increment in anxiety index and motor activity only in experimental males ($t=2.71$; $df=18$; $p=0.01$). On the other hand, a significant expression of *c-fos* protein on CA2, CA3, DG and medial amygdala was found between groups ($t=8.69$; $df=48$; $p=<0.001$). Nevertheless, a marked difference in staining was detected only in female CA2 ($t=2.58$; $df=48$; $p=0.01$) where experimental females had less expression of HSP70 than control females; while experimental males also showed a decreased expression of HSP70, but only in CA3 and DG hipocampal areas ($t=2.58$; $df=48$; $p=0.01$). This findings suggest that heat stress exposure in early ages can lead to sex dependent modifications in *c-fos* and HSP70 expression in amygdala and hippocampus, which leads to anxiety circuitry changes and it could reflect as aggressive behavior and irritability in humans.

Title: Amygdala and prefrontal cortex activity varies with individual differences in the stress response

Authors: *T. R. OREM, M. D. WHEELOCK, N. G. HARNETT, K. H. WOOD, A. M. GOODMAN, S. MRUG, D. C. KNIGHT;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Introduction
Prior work has shown that the prefrontal cortex (PFC) and amygdala mediate the stress response (Ressler 2010; Quirk and Beer, 2006). However, the neural substrates that underlie individual variability in the emotional response to stress have not yet been determined. The present study examined the relationship between PFC – amygdala circuitry and the psychophysiological response (e.g. heart rate and skin conductance) to stress.
Methods
Heart rate (HR), skin conductance response (SCR), cortisol, and blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) were measured while participants completed the Montreal Imaging Stress Task (MIST). The MIST is a well-validated psychosocial stress task that includes Stress and Control conditions. HR, SCR, and cortisol were monitored as indices of the peripheral emotional response to stress.
Statistical Analyses
To assess the relationship between brain activity and psychophysiological reactivity, the differences between Control and Stress MIST conditions was calculated for HR and SCR. The difference between baseline and post-stress tasks was calculated for cortisol. These measures were then regressed on BOLD fMRI data using the AFNI software package (Cox, 1996).
Results
HR and SCR were greater during the Stress than Control condition, indicating a differential emotional response to stress was evoked by the task. Cortisol levels were higher at baseline than post-task and were therefore inconsistent with the typical cortisol response to stress. Differential BOLD fMRI was observed within the ventral PFC and amygdala. Further, differential activity within these brain regions varied with the peripheral emotional response (i.e. HR and SCR) to stress.
Discussion
These results are consistent with the view the ventral PFC and amygdala support processes that are important for the expression and regulation of emotion. Findings from the present study suggest that psychosocial stress affects PFC-amygdala circuitry, controls the peripheral expression of emotion, and may account for individual variability in the stress response.

Title: Lasting sex differences in chronic stress-induced patterns of fos and brain-derived neurotrophic factor expression in prelimbic cortex in response to a novel acute stressor

Authors: *K. M. MOENCH, C. L. WELLMAN;
Dept. of Psychological and Brain Science, Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Stress-related psychopathologies such as depression are associated with prefrontal cortex dysfunction, and are twice as likely to be diagnosed in women than men. Risk for stress-related disorders increases with the number of prior stressful life events. However, the neurobiological basis for increased vulnerability to multiple stressors in males and females has yet to be established. One possibility is that long-lasting alterations in factors that modulate prefrontal cortex activity, such as brain-derived neurotrophic factor (BDNF), could give rise to aberrant behavioral and neuroendocrine responses to subsequent stressors. Thus, we examined activity (via fos expression) and BDNF expression in prelimbic cortex (PL) of chronically stressed male and female rats in response to a novel stressor. Adult rats underwent chronic restraint stress (3h/day for 10 days) or were left unstressed (No Stress). Either one (Stressed) or 7 days later (Stress-Recovery), rats were exposed to a 30-minute elevated platform stressor. Rats were euthanized ~60 minutes after the cessation of the elevated platform stressor, and brains were removed and stained for fos and BDNF. Stereological estimates of fos-positive cells and relative luminosities of BDNF-expressing neurons were obtained for superficial and deep layers of PL. In response to a novel stressor, Stressed males had a decrease in fos expression in the superficial layers of PL compared to No Stress males, whereas Stressed females had increased fos expression throughout PL. For Stress-Recovery males, exposure to a novel stressor increased fos expression in the deep layers of PL, whereas fos expression in Stress-Recovery females was similar to No Stress females. Further, BDNF expression was increased in Stressed males, but not in Stress-Recovery males. In contrast, Stressed females showed little change in BDNF expression, whereas Stress-Recovery females showed an increase in expression. Thus, exposure to chronic stress alters the response of prelimbic cortex to novel stressors in in a sex-specific manner, and alterations in BDNF may contribute to this effect. Such chronic stress-induced changes in responses to subsequent stressors may contribute to the differential vulnerability of males and females to stress sensitive disorders.

Title: Targeting glucocorticoid receptor deletion to Dlx 5/6 interneurons results in impulsive behavior and a higher peak corticosterone release in female, but not male, mice

Authors: ***J. SCHEIMANN**, P. MAHBOD, R. L. MORANO, M. FITZGERALD, B. PACKARD, J. P. HERMAN;
Univ. of Cincinnati, Cincinnati, OH

Abstract: Dysfunction in the activation or cessation of the hypothalamic-pituitary-adrenocortical (HPA) axis stress response is linked to stress-related affective disorders. The glucocorticoid receptor (GR) is the target of corticosterone released as part of the HPA axis stress response, and inappropriate signaling by this receptor is believed to play a role in stress-related pathologies. Glucocorticoid receptors in the forebrain, including the PFC, have been shown to be integral for cessation of the HPA axis response. Our group has demonstrated that chronic stress depletes GR in the PFC, largely targeting interneurons. In these studies, we tested the role of forebrain interneurons in regulation of PFC-related behaviors. The DLX 5/6 homeobox genes are expressed in developing and mature interneurons that arise from the medial ganglionic eminence, and migrate to the forebrain in areas such as the cortex, prefrontal cortex, striatum, and hippocampus. In this experiment, we generated interneuron-specific GR knockout mice by breeding GRflox mice with transgenic mice overexpressing Cre recombinase behind a DLX5/6 promoter. Adult female DLX 5/6 Cre+: GR f/f mice had a higher peak corticosterone release after 30 minutes of acute restraint and showed a reduced latency of escape behavior in a test of behavioral inhibition (passive avoidance). DLX 5/6 Cre+: GR f/f females did not exhibit demonstrable deficits in forced swim test or open field. In contrast, adult male DLX 5/6 Cre+:GR f/f mice did not show any behavioral or hormonal phenotype. This study supports the crucial role of glucocorticoid receptor on interneurons in forebrain for control of the HPA axis, and suggests that deletion of the receptor in these regions may impair behavioral inhibition and HPA axis control. This study also suggest that males and females may develop different mechanisms for control of the HPA axis and behavior following genetic deletion of GR in forebrain interneurons. Title: Learned helplessness induced by maternal separation of an animal model of posttraumatic stress disorder using a shuttle box in rats and levels of brain-derived neurotrophic factor in the hippocampus and the medial prefrontal cortex

Authors: ***M. TANICHI**, H. TODA, S. ENOMOTO, K. SHIMIZU, M. NAGAMINE, M. UENOYAMA, M. NIBUYA, A. YOSHINO;
Natl. Def. Med. Col., Saitama, Japan

Abstract: OBJECTIVES: We have reported posttraumatic stress disorder (PTSD) model of rat using a shuttle box, in which rats exposed to inescapable footshocks (IS) corresponding to trauma 2 weeks before had the persistent behavioral alterations characterized by hypoactive and hyperarousal behaviors. Clinical studies have previously shown that exposure to stress during the postnatal development periods is associated with an elevated risk for PTSD. But we reported last year in this congress that maternal separation (MS), which is one of the most commonly used procedures for inducing the early life stress in rodents, increased learned helplessness (LH) behaviors of our PTSD model rats using a shuttle box, not PTSD like behaviors. In this study, we examined the influence of MS on our PTSD model regarding of the mRNA expression of brain-derived neurotrophic factor (BDNF) in the hippocampus and the medial prefrontal cortex (mPFC). METHODS: Timed pregnant Wistar rats were delivered on gestation day 14. On postnatal day (PND) 2, litter was assigned to MS or typical animal facility rearing groups. MS was taken place for 3 hours per day for 2 weeks from PND 2 and only male pups were used for the subsequent experiment. On 7 weeks old, the IS session corresponding to trauma was performed, and then 2 weeks after the IS, the avoidance/escape task trials were done. Detailed experimental procedures were described as previously (Sawamura et al, 2004). RESULTS: MS significantly worsened hypoactive behaviors counted as the number of moving to other chamber in the 5 minutes adaptation period ($p<0.05$) and LH behaviors counted as the number of failure to escape ($p<0.01$) and time to successful escape ($p<0.05$) in the avoidance/escape trials. But MS didn't affect to their hyperarousal behaviors. Levels of hippocampal BDNF mRNA didn't decreased by MS, but levels of mPFC BDNF mRNA decreased, especially BDNF exon IV

significantly. CONCLUSIONS: MS worsened not PTSD but LH behaviors in our PTSD model after 2 weeks since the IS, and decreased levels of BDNF mRNA not in the hippocampus but in the mPFC. Title: Role of infralimbic cortex in stress responding and extinction memory

Authors: *A. FRANCO-VILLANUEVA[1], R. L. MORANO[2], B. L. SMITH[2], P. MAHBOD[2], J. R. SCHEIMANN[2], B. A. PACKARD[2], B. MYERS[2], J. P. HERMAN[2];

Abstract: The medial prefrontal cortex (mPFC) is critical for emotional control and executive processing in adverse situations. Specifically, individuals suffering from fear or anxiety disorders present PFC hypofunction. In rodents, the mPFC is functionally segregated. Thus, the prelimbic cortex (PL) mediates fear expression and perseveration as well as normal inhibition of the hypothalamic-pituitary-adrenocortical (HPA) axis stress responses, whereas the infralimbic cortex (IL) promotes suppression of fear. Furthermore, chronic stress increases inhibitory synaptic drive to IL pyramidal cells in rats. We used chemogenetics to activate IL neurons in male Sprague-Dawley rats. After confirming the expression of the excitatory Designer Receptor Exclusively Activated by Designer Drugs (DREADD) and its functionality by immunofluorescence, we investigated the role of IL pyramidal neurons on HPA axis stress reactivity and in fear behavior. Chemogenetic activation of IL projection neurons does not affect corticosterone response to acute stress, but does have a lasting effect on fear conditioning one week later. A second IL activation during the extinction retrieval session appears to enhance extinction recall. However, rats expressing the DREADD showed decreased fear behavior on the conditioning day, and thus low levels of freezing during the extinction retrieval could be due to

impaired conditioning. These results suggest that IL engagement in conjunction with stress alters subsequent emotional responses in a glucocorticoid-independent manner.

Title: Ketamine increases prefrontal dendritic spine formation *In vivo* following chronic stress

Authors: ***M. H. MURDOCK**[1], Y. MENG[1], L. NELLISSEN[1], R. N. MODA[1,2], J. WITZTUM[1,3], C. LISTON[1,2];
[1]Brain and Mind Res. Inst., [2]Neurosci., [3]Physiology, Biophysics and Systems Biol., Weill Cornell Med. Col., New York, NY

Abstract: How ketamine exerts its fast-acting antidepressant effects in the living brain is incompletely understood. Previous work has shown that ketamine, an N-methyl-D-aspartic acid receptor antagonist, increases post-synaptic dendritic spine density in the rat prefrontal cortex. Spines are highly dynamic dendritic protrusions that undergo a constant remodeling process that is shaped by experience. How ketamine affects prefrontal cortical dendritic spine remodeling in the living brain is unknown. Here, we used two-photon microscopy to study the formation and elimination rates of dendritic spines in the frontal association and medial prefrontal cortex of mice expressing yellow fluorescent protein in a subset of layer V pyramidal cells. We used cranial windows or chronically-implanted microprisms to image the same dendritic arbors before and after 21 days of exposure to the murine stress hormone corticosterone. Chronic corticosterone exposure recapitulates an important element of chronic stress which may contribute to depression and other stress-related psychiatric illnesses. We determined that

chronic corticosterone exposure increased spine elimination rates and decreased spine formation rates compared to untreated mice. A single low dose of ketamine (10 mg/kg, intraperitoneal) increased 24-hour spine formation rates following chronic corticosterone exposure. Moreover, a fraction of these newly-formed spines appeared within a distance of 2 micrometers of spines eliminated during corticosterone treatment. These data suggest that ketamine's antidepressant effects are in part due to increased spine formation rates and the recovery of spines lost during chronic stress.

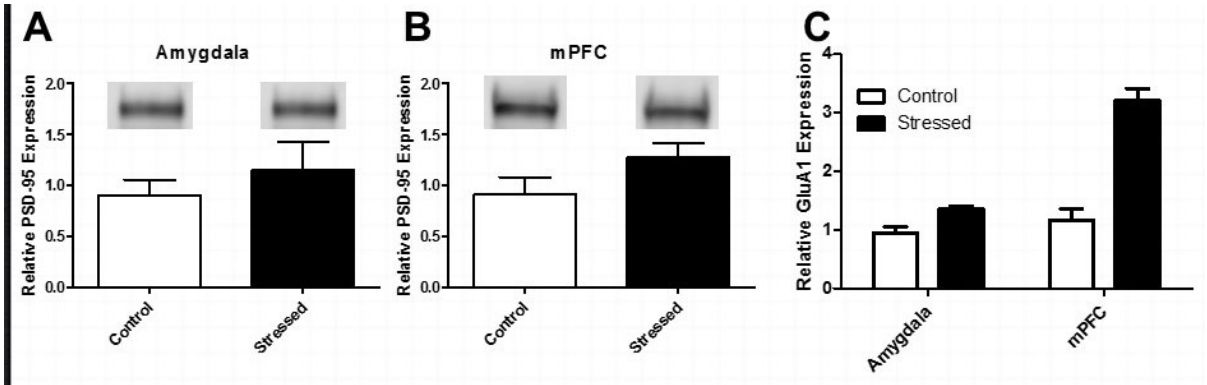
Title: Acute stress increases GluA1 expression in mPFC, but not the amygdala, in adult rats

Authors: ***N. B. KEELE**, M. L. MCREYNOLDS, L. C. ORNELAS;
Baylor Univ. Dept. of Psychology and Neurosci., Waco, TX

Abstract: Environmental stressors are significant antecedents to mood and anxiety disorders. Stress alters both the structure and function of key brain areas involved in emotion, including the medial prefrontal cortex (mPFC) and the amygdala. The amygdala is a critical brain area mediating learned fear/anxiety, and in general, the mPFC acts in a top-down manner to regulate amygdala activity. It is thought that exposure to stress alters amygdala - mPFC circuitry to predispose to stress-related disorders. However, the effects of stress exposure depend on the timing and duration of the stress, as well as the type of stressor, and the brain area under investigation. For example, stress reportedly increases amygdala volume, leading to exaggerated fear behavior. However, stress also causes dendritic atrophy and impairs function of the mPFC. In this project we seek to test the hypothesis that stress affects the synaptic organization differently in the amygdala than the mPFC, and these effects manifest as different anatomical and behavior responses to stress. In control experiments, adult rats with no history of early life stress were subjected to restraint stress (3 days, 1 hr/day). We used standard immunoblotting techniques to determine stress-related changes in PSD-95 and AMPA glutamate receptor 1 (GluA1) expression. Pilot results show that stress did not change PSD-95 expression in either the

mPFC or the amygdala. However GluA1 was increased in the mPFC but not in the amygdala. Increased GluA1 expression may indicate enhanced neural plasticity in the mPFC necessary to elicit adaptive responses to stress. A better understanding of the effects of stress on mPFC-amygdala circuitry may yield important new information regarding the neurobiological underpinnings of pathalogical anxiety.



Stress increases GluA1 expression in the mPFC but not the amygdala. 24 hrs after restraint stress (3 d, 2 hr/d), tissue samples were collected from the amygdala and the medial prefrontal cortex (mPFC) and used for immunoblotting. Postsynaptic density protein of 95kDa (PSD-95) expression was unchanged by stress (filled bars) in both the amygdala (A) and the mPFC (B). However, in these same samples (C), stress caused an increase in the expression of glutamate AMPA receptor subunit 1 (GluA1) in the mPFC (right) but not in the amygdala (left).

Title: Adrenalectomy ablates acute stress-induced Per1 mRNA in the paraventricular nucleus of the hypothalamus, but only attenuates stress-induced Per1 mRNA in the prefrontal cortex of male and female rats

Authors: *L. E. CHUN, J. CHRISTENSEN, E. R. WOODRUFF, S. J. MORTON, L. R. HINDS, R. L. SPENCER;
Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Properly entrained circadian rhythms optimize survival of an organism. Underlying these circadian rhythms are oscillating molecular clocks, which consists of core clock genes (*Bmal1, Per1, Per2*) whose expression is self-regulating and approximates a 24-hour period. Knockdown of clock genes in rodents leads to aberrant behavior. Thus, optimal health depends on the integrity of the molecular clock, which exists in the body's master clock, the suprachiasmatic nucleus of the hypothalamus (SCN), as well as extra-SCN brain and peripheral tissue. The SCN has few direct efferent projections. Glucocorticoids (CORT) are an ideal candidate for how the SCN entrains extra-SCN molecular clocks. CORT is secreted in a diurnal rhythm, glucocorticoid receptors are ubiquitously expressed (except in the SCN), and *Per1* has a functional glucocorticoid response element. In male rodents, administration of CORT or acute stress increases *Per1* mRNA in peripheral tissue and the paraventricular nucleus of the hypothalamus (PVN). If a diurnal peak in CORT is an entrainment factor for extra-SCN clocks, then untimely, stress-induced surges in CORT can compromise the integrity of the molecular clock. Sex differences exist in stress responsivity and prevalence of mood disorders associated with stress and disruptions in circadian rhythms. Thus, the objective of the present study was to examine whether 30 minutes of acute restraint stress can induce clock gene (*Per1, Per2, Bmal1*) and *C-fos* mRNA (in situ hybridization) in male and female Sprague Dawley rats, and how CORT and estradiol modulates these processes. Rats were housed on a 12:12 h light:dark cycle and received adrenalectomy (ADX) or SHAM surgeries. Female rats were ovariectomized and received estradiol benzoate (10 μg/kg, SC once every 4 days) or vehicle injections. Acute restraint stress rapidly and selectively induced *Per1* mRNA in the PVN and prefrontal cortex (PFC). In male rats this stress-induction was entirely dependent on CORT in the PVN, as ADX prevented stress-induced *Per1* mRNA. However, ADX only attenuated stress-induced *Per1* mRNA in the PFC of male and female rats. Estradiol replacement had no overall effect on *Per1* mRNA in the PFC, but it attenuated stress-induced *C-fos* mRNA in the PFC. These results suggest that regulation of Per1 expression may be the gateway by which stress affects the molecular clock. In addition the results indicate that there are regional differences in the extent to which stress-induced *Per1* mRNA depends on endogenous CORT. Future data analysis will examine *Per2* and *Bmal1* mRNA in the PFC, which may be more affected by estradiol manipulations.

Title: Effects of chronic social defeat stress on functional connectivity using awake rodent resting state fMRI

Authors: *R. N. FETCHO[1], Y. MENG[2], B. S. HALL[2], T. N. HUYNH[2], C. LISTON[2]; [2]Brain and Mind Res. Inst., [1]Weill Cornell Med. Col., New York, NY

Abstract: The development of resting state functional magnetic resonance imaging (rsfMRI) has provided a powerful tool for noninvasive investigation of circuit mechanisms underlying psychopathology. In humans, rsfMRI has identified a large number of abnormal functional properties in patients diagnosed with stress-related psychiatric disorders. However, interpretation of these results is difficult due to the subjective and heterogeneous nature of psychiatric diagnoses; the diversity of uncontrolled environmental factors impacting disease state; and the purely observational nature of human studies. Recently, rsfMRI has expanded into the realm of rodent research. The discovery of consistent functional networks in rodents, similar to humans, implicates rsfMRI as a promising cross-species technique. Rodent rsfMRI provides an unprecedented opportunity for investigating and manipulating pathological features of functional networks using tools that can be deployed in parallel human studies.
Modeling psychiatric disease in rodents is a difficult task; however, the ability to carefully control the induction of disease-like phenotypes via environmental factors is a major advantage of rodent models. Chronic social defeat stress (CSDS) induces a wide range of “depressive-like” behaviors including anhedonia, anxiety and social dysfunction. Through repeated exposure to and defeat by an aggressive partner, this protocol provides a chronic, naturalistic social stress. CSDS also leads to a variable stress response, with “susceptible” mice showing abnormal

behavioral phenotypes while “resilient” mice do not differ behaviorally from a non-stressed control group. This variability in stress response is interesting in the context of human psychiatric illness, in which an environmental stressor may prime one individual for disease while leaving another unscathed.
Utilizing awake mouse rsfMRI, this work aims to identify changes in functional connectivity associated with stress susceptibility and resilience. Using a within-subject design, mice first undergo rsfMRI to establish baseline non-stressed functional connectivity properties. Mice then enter the CSDS protocol, followed by a second rsfMRI assessment. By comparing functional connectivity in “susceptible” and “resilient” groups, we identify network features important in predicting stress susceptibility as well as network changes that occur in response to chronic stress that correlate with susceptible or resilient behaviors. These findings will facilitate efforts to identify predictors of stress resilience and stress-related pathology identified via rsfMRI in human clinical populations.

Title: Prolonged elevations in corticosterone induces regressive and enduring dendritic spine alterations in the medial prefrontal cortex

Authors: ***R. M. ANDERSON**, S. B. JOHNSON, R. GLANZ, S. A. ROMIG-MARTIN, J. J. RADLEY;
Dept. of Psychology, Program in Neurosci., Univ. of Iowa, Iowa City, IA

Abstract: The stress-responsive HPA axis plays a central role in promoting adaptations acutely, whereas adverse effects on physiology and behavior following chronic challenges may result from over-activity of this system. Elevations in adrenocortical hormones, the end-products of HPA activation, play roles in adaptive and maladaptive processes by targeting cognate receptors throughout limbic cortical networks to alter synaptic functioning. Work from our laboratory and others have shown that chronic stress leads to functionally- relevant regressive alterations in dendritic spine shape and number in pyramidal neurons in the medial prefrontal cortex (mPFC),

thus implicating a glucocorticoid-dependency for these effects. Here we examined the nature and temporal characteristics of prolonged glucocorticoid exposure on dendritic spine modifications in the mPFC. Rats were implanted with subcutaneous pellets of corticosterone (B) to provide for the continuous release over a 7-, 14-, 21-day period, and 21 days of exposure + 21-day washout. Plasma B measurements in clamped rats using radioimmunoassay revealed steroid levels that approximated the circadian mean (150 ng/ml) with respect to sham-pellet control rats. Animals were perfused and pyramidal neurons throughout all layers of prelimbic region (PL) of mPFC were selected for intracellular fluorescent dye-filling, followed by high-resolution 3D imaging and analysis of dendritic arborization and spine morphometry. Whereas no effects were observed following 7-day exposure, 14 days of B exposure decreased apical dendritic length (by 23%; $p < 0.05$) and spine density (by 13% for each; $p < 0.05$ for each). Thin spine subtypes showed the greatest degree of attrition throughout apical dendrites (by 12%, $p < 0.05$ for each). Follow-up population analyses of spine characteristics in rats receiving B for 2 weeks revealed decreases in spine volume across subtypes. After 21 days of B exposure, similar effects were observed as with 14-day treatment, although the effects of spine attrition extended to larger volume subtypes. Moreover, the chronicity of glucocorticoid-induced dendritic spine loss in PL was highlighted by the failure of these indices to normalize following a 21-day washout period. These results suggest that prolonged alterations in adrenocortical activity may be sufficient to induce enduring regressive structural alterations in mPFC, and may be relevant for understanding mechanisms of mPFC compromise in a variety of contexts whereby glucocorticoids become dysregulated, such as aging, chronic stress, and Cushings disease.

Title: Network analysis of frontal cortical microcircuit dynamics after chronic stress hormone exposure and ketamine treatment

Authors: *R. N. MODA[1,3], R. N. FETCHO[1,3], J. WITZTUM[2,3], M. H. MURDOCK[3], Y. MENG[3], C. LISTON[1,3];
[1]Neurosci., [2]Physiology, Biophysics and Systems Biol., Weill Cornell Med. Col., New York, NY; [3]Brain and Mind Res. Inst., New York, NY

Abstract: Chronic stress exposure has been shown to alter neuronal morphology within the prefrontal cortex (PFC), inducing changes such as dendritic retraction and spine loss. Additionally, clinical studies have shown that subanesthetic doses of ketamine, an NMDA antagonist, can act as a fast-acting antidepressant in treatment-resistant depressed patients. These effects may be mediated by a ketamine-induced increase in postsynaptic dendritic spine density in PFC pyramidal cells. How changes in synapse number and dendritic morphology affect PFC microcircuit function, however, has yet to be established.
In an effort to address this question, we investigated neural network dynamics in dorsal PFC microcircuits using two-photon calcium imaging. Adult mice were intrancranially injected in the prefrontal cortex with a pan-neuronal GCaMP-expressing AAV virus (driven by the hSyn promoter), and a borosilicate glass cranial window was chronically implanted in the skull for visualization of GCaMP-expressing cells. PFC microcircuit activity was quantified by two-photon calcium imaging before and after a chronic, 21-day exposure to high levels of corticosterone, the principal murine stress hormone, via corticosterone tablets that were implanted subcutaneously. The mice were then injected with a subanesthetic intraperitoneal dose of ketamine (10 mg/kg IP), and repeat imaging was performed 24 hours later from the same neural populations. PFC microcircuit activity and network properties were analyzed, and results suggest that chronic corticosterone exposure suppresses neuronal activity and alters functional connectivity in the PFC. Following a single injection of ketamine, these effects are partially rescued, with an increase in cell activity that is especially pronounced in highly connected, "hub-like" neurons. Further, analysis of graph theory metrics of PFC network connectivity suggests that ketamine also partially rescues corticosterone-induced deficits in network connectivity measures.

Title: Circuit-specific dendritic spine changes after controllable or uncontrollable stress in medial prefrontal cortex of male and female rats.

Authors: *T. GRUENE[1], M. V. BARATTA[3], S. D. DOLZANI[4], L. E. CHUN[3], S. F. MAIER[3], R. M. SHANSKY[2];

Abstract: The stressor controllability paradigm has been extensively used to demonstrate that control over stress leads to adaptive outcomes and blunts the effects of the stressor. In this paradigm rats are either exposed to escapable tailshock (ES), yoked inescapable tailshock (IS), or no stress. While IS leads to a variety of behavioral effects such as increased anxiety and social avoidance, ES animals are protected from these effects. Moreover, ES "immunizes" animals from the negative effects of future stressors. The protective and long term "immunizing" effects of behavioral control depend on the activation of prelimbic cortex (PL) neurons that project to the dorsal raphe nucleus (DRN). The foregoing suggests that DRN-projecting PL neurons undergo stable changes following ES, thus it is possible that ES leads to dendritic spine changes that support these stress-buffering effects. How ES and IS impacts dendritic morphology in the PL-to-DRN pathway is unknown. Here we investigate the possibility that ES induces distinct dendritic spine changes in a circuit-specific manner in both male and female rats. DRN-projecting PL neurons were labeled via fluorescent retrobead injections into the DRN. Then, rats were exposed to either ES, IS or no stress and were sacrificed 24 hours later for morphology analysis. Microinjections of fluorescent dye were targeted to retrobead labeled and unlabeled neighboring neurons. Dendritic segments were imaged in 3D using a confocal microscope and automated spine analysis was performed. In addition to overall spine density, spine type (mushroom or thin) density as well as spine head diameters were analyzed. By comparing morphology of DRN- to non DRN-projecting PL neurons, we are able to perform within-subject analyses to identify circuit-specific spine changes as well as investigate group differences in

spine density of labeled and unlabeled PL neurons. Additionally, we report analyses comparing dendritic spine effects in males and females to uncover possible sex-differences.

Title: Investigating the role of the paraventricular thalamic nucleus in regulating the stress response: potential molecular mechanisms

Authors: B. CORBETT[1], S. LUZ[1], *S. BHATNAGAR[2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: In the field of stress neurobiology, habituation is defined as a decreasing and learned response to a familiar stressor over time. Disrupted habituation is a signature of post-traumatic stress disorder (PTSD), causing devastating effects for those afflicted. Understanding the molecular and neural substrates underlying habituation may allow for improved therapies for PTSD patients. In rats, we model habituation using the repeated restraint paradigm. Repeated exposure to this moderately intense stressor increases the expression of immediate early genes in certain brain regions, induces the production of stress-related hormones, and elicits struggle behavior. All of these responses are highest on day 1 of restraint and attenuate over time. We have previously identified the posterior paraventricular thalamic nucleus (pPVT) as a crucial brain region that regulates habituation. However, the underlying molecular mechanisms and specific neural connections between the pPVT and other brain regions that mediate habituation are unknown. Using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), we investigating the role of the pPVT in regulating the stress response. We demonstrated that chemogenetic inhibition of the pPVT increased adrenocorticotropic hormone production on day 1 and day 5 in rats receiving injections of clozapine-N-oxide (CNO), the synthetic ligand for DREADDs, compared to controls. Further, chemogenetic inhibition of the pPVT attenuated corticosterone habituation as increased corticosterone levels were observed on day 5, but not day 1, in CNO-treated rats. We are currently investigating whether a subset of pPVT neurons that

project to the medial prefrontal cortex (mPFC), another brain region that negatively regulates the stress response, mediates habituation. We hypothesize that pPVT neurons, in particular those that project to the mPFC, play a critical role in stress habitation. Additionally, we investigated a potential mechanisms of neuronal habituation within the pPVT by assessing the expression of activity-regulated cytoskeleton-associated protein (Arc) in naïve rats. Arc is an immediate early gene that reduces excitatory synapse number. We found that Arc expression was increased in the pPVT on day 1, but not day 5 of restraint. We hypothesize that Arc-mediated restrictions in excitatory synapse number are a critical mechanism underlying habituation of the stress response. Our findings offer new insight into the role of the pPVT in mediating the stress response and are among the first to provide a possible molecular mechanism of stress habituation.

Abstract: By filtering relevant sensory inputs and initiating stress responses, the brain is an essential organ in stress coping and adaptation. However, exposure to chronic or repeated stress can lead to allostatic overload, where neuroendocrinal and behavioral reactions to stress become maladaptive. This work examines forebrain mechanisms involved in allostatic processes in teleost fishes. Plasma cortisol, forebrain serotonergic (5-HTergic) neurochemistry and mRNA

levels of corticotropin-releasing factor (CRF), CRF binding protein (CRFBP), CRF receptors (CRFR1 and CRFR2), mineralcorticoid receptor (MR), glucocorticoid receptors (GR1 and GR2), and 5-HT $_{1A}$ receptors (5-HT$_{1Aa}$ R and 5-HT$_{1Ab}$ R) were investigated at 1 h before and 0, 1 and 4 h after acute stress, in two groups of rainbow trout held in densities of 25 and 140 kg m^{-3} for 27 days. Generally, being held at 140 kg m^{-3} resulted in a less pronounced cortisol response. This effect was also reflected in lower forebrain 5-HTergic turnover, but not in mRNA levels in any of the investigated genes. This lends further support to allostatic load as a situation where fish cannot mount a proper cortisol in response to an acute stressor, and suggests that changes in forebrain 5-HT metabolism is involved in allostatic processes in fish. Independent of rearing densities, mRNA levels of 5-HT $_{1Aa}$ R and MR were down regulated 4 h post stress compared to values 1 h post stress, suggesting that these receptors are under feedback control and take part in the down regulation of the hypothalamic-pituitary-interrenal (HPI) axis after an acute stressor.

Title: Neurobiological findings related to Internet use disorders

Authors: ***S. ROH**[1], B. PARK[2], D. HAN[3];
[1]Dept. of Psychiatry, Hanyang Univ. Col. of Med., Seoul, Korea, Republic of; [2]Dept. of Neurol., Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Psychiatry, Chung-Ang Univ., Seoul, Korea, Republic of

Abstract: In the last ten years, numerous neurobiological studies have been conducted on Internet addiction or Internet use disorder. Various neurobiological research methods—such as magnetic resonance imaging; nuclear imaging modalities, including positron emission tomography and single photon emission computed tomography; molecular genetics; and neurophysiologic methods—have made it possible to discover structural or functional impairments in the brains of individuals with Internet use disorder. Specifically, Internet use disorder is associated with structural or functional impairment in the orbitofrontal cortex, dorsolateral prefrontal cortex, anterior cingulate cortex, and posterior cingulate cortex. These

regions are associated with the processing of reward, motivation, memory, and cognitive control. Early neurobiological research results in this area indicated that Internet use disorder shares many similarities with substance use disorders, including, to a certain extent, a shared pathophysiology. However, recent studies suggest that differences in biological and psychological markers exist between Internet use disorder and substance use disorders. Further research is required for a better understanding of the pathophysiology of Internet use disorders.

Title: Reducing alcohol cue reactivity in rats using retrieval+extinction

Authors: *R. U. COFRESI[1], S. M. LEWIS[1], K. M. TUITE[1], I. S. PARK[1], N. CHAUDHRI[2], H. J. LEE[1], M. H. MONFILS[1], R. A. GONZALES[1];

Abstract: Conditioned responses to alcohol-associated cues can hinder an indvidual's attempts to abstain from or moderate their drinking. Cue extinction protocols can reduce reactivity to alcohol cues, but their efficacy is limited. Here, we evaluated the potential of memory retrieval-enhanced cue extinction to reduce return of extinguished responses to alcohol-predictive cues relative to return of responses observed following standard cue extinction. To do this, we used our recently developed model of alcohol cue learning (presented by Cofresí et al, SfN 2015): a discrete trial procedure in which time-limited access to unsweetened alcohol (via retractable sipper) is contingent upon a visual cue (houselight illumination). We adapted the extinction phase in our model such that every day rats experienced context exposure (NORET) or isolated cue retrieval (RET) and following 1hr in homecage, a standard cue extinction session. Total exposure to cue and context within and across the 14 consecutive days was equated. RET and NORET groups were also matched on ingested ethanol doses across conditioning as well as levels of visual cue-conditioned anticipatory approach to the site of alcohol access and contact

with the alcohol access device (sipper). We tested for early spontaneous recovery of extinguished responses by giving a 4-trial extinction probe 48 hr after the last extinction session (SR test). We tested for reinstatement of extinguished responses using a second memory probe during which ethanol odor was present (RT test). We also evaluated response reacquisition rate by reintroducing cue-contingent alcohol access. Rats exhibited similarly low response likelihoods over the final 4 extinction trials, but differed over SR and RT test trials depending on NORET v. RET treatment. Approach and contact by NORET rats (n=14) decayed slowly over trials from initially high levels in both tests. In contrast, responses by RET rats (n=13) were initially low and either did not change or increased modestly before rapidly decaying across trials in both tests. In keeping with a protective effect of RET treatment against response return, RET rats (n=6) were also slower to reacquire responses to the cue relative to NORET rats (n=7). Our findings strongly suggest that isolated cue memory retrieval prior to cue extinction may enhance the efficacy of cue exposure therapy to reduce alcohol cue reactivity.

Title: A novel behavioral paradigm for assessing the role of behavioral pattern separation in ethanol relapse

Authors: ***P.-K. HUANG**[1], E. H.-J. WANG[1], E. MEJIA[2], L. K. QUINN[1], F. H. GAGE[2], A. A. CHIBA[1];
[1]Univ. of California San Diego, La Jolla, CA; [2]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: A major obstacle facing the problem of drug addiction is the resilient nature of drug relapse during protracted abstinence. Overcoming this obstacle requires a greater understanding of how certain drug-induced changes in the brain can produce an aberrant chronic relapsing state that is observed in drug addiction. Recent research examining the behavioral role of neurogenesis in the hippocampus enables new avenues for exploration that may provide important insights to

understanding the progression of drug relapse in addiction. The dentate gyrus and neurogenesis are thought to be important for discriminating between similarly encoded contexts, often referred to and demonstrated experimentally as behavioral pattern separation. Additionally, chronic consumption of addictive drugs across different drug classes has been widely shown to impair neurogenesis. However, the role that behavioral pattern separation plays in drug addiction has yet to be explored. This study tests the hypothesis that a gradual decline in neurogenesis from repeated drug consumption leads to impairments in the ability to discriminate between drug-paired contexts and other similar non-drug-paired contexts. With continual drug use, drug craving and relapse may be experienced in dissimilar contexts. Thus, a propensity for relapse may arise from the loss of specificity of the encoded associations between the affective properties of the drug and the contexts in which the drug was taken. This phenomenon of context overgeneralization, presumably due to the loss of ability to discriminate fine differences between contexts may reside at the heart of the observation of drug cravings and relapse gradually becoming more prevalent with the progression from recreational drug use to addiction. To test this hypothesis, this study implements a new behavioral paradigm to simultaneously assess discrimination of similar visual contextual memories (behavioral pattern separation) and preference for contexts associated with drug and natural rewards (relapse-like behavior) in chronic ethanol-drinking rats and non-ethanol controls.

Title: Neural mechanisms of memory system bias following withdrawal from cocaine.

Authors: *E. HARVEY[1], C. S. AHN[2], N. ANGELILIIS[2], P. J. KENNEDY[2];
[1]Psychology, [2]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Research in the field of learning and memory suggests that the brain is composed of multiple memory systems. Among these systems is the hippocampus (HC), which encodes information flexibly and supports behaviors that can be rapidly updated. Another system is the

dorsolateral striatum (DLS), which encodes information inflexibly and supports behaviors that are “hard-wired” (habits). During new learning, humans with a history of addictive drug use will show a bias towards learning and memory processes that are dependent upon the dorsolateral striatum (DLS), and deficits in hippocampal-dependent memory processing have been shown to predict poor treatment outcomes in stimulant users. Here we investigated the effects of prior cocaine exposure on performance in a dual solution cross-maze task that tests the use of flexible, HC-dependent versus inflexible, DLS-dependent learning strategies. We found that following 3 weeks of withdrawal from chronic cocaine, rats demonstrated a bias towards the use of a DLS-dependent learning strategy whereas drug naïve controls demonstrated learning dependent on the HC. This effect was reversed by peripheral treatment with a kappa opioid antagonist (JDTic) throughout withdrawal. Epigenetic mechanisms contribute to both maladaptive neuronal plasticity associated with drug exposure, and brain plasticity that is critical for memory formation. We further report that withdrawal from chronic cocaine is associated with an increase in global levels of permissive histone modifications within the DLS, and a reduction within the HC. These data suggest a molecular switch that may contribute to persistent changes in DLS and HC plasticity following repeated exposure to cocaine. Follow-up experiments are underway to investigate transcriptional adaptations mediating drug-induced memory system and behavioral bias and the effects of kappa opioid antagonism on these processes.

Title: Extinction of morphine place-preference and neuroplasticity transcript profile of the ventral striatum

Authors: *M. E. LLORET, F. MARTINEZ;
Univ. of Puerto Rico Med. Sci. Campus, San Juan, Puerto Rico

Abstract: Drug addiction has been associated with deficits in neural circuits that regulate extinction of addictive behaviors. Current available data correlate addiction to neuroplasticity changes in the reward circuit, however little is known about the cellular and molecular mechanisms for extinction learning. We used conditioned place preference (CPP) to identify differential expression of plasticity genes in the ventral striatum/nucleus accumbens (VS/Nac) of extinction-trained animals. Rats expressing morphine (5mg/kg) CPP were divided into 2 groups

receiving either forced or sham extinction training during 4 consecutive days. After the extinction test day the VS/Nac was isolated and differentially expressed genes were examined using RT² Profiler™ PCR array kit for plasticity genes. We identified two separate animal's subgroups: those that extinguished CPP (Extinction-CPP) and those still showing CPP (Persistent-CPP). As expected, extinction-untrained animals (Sham-Extinction) retained their morphine place preference. Real time RT-PCR analysis revealed differential gene expression for the extinction of morphine-seeking behavior. Notably, rats the Extinction-CPP group showed upregulation of Bdnf, Gria 4 and Reln transcripts. In the Persistent-CPP group, transcripts for Crem and Rheb were upregulated, while Tnfa was downregulated. On the other hand, Sham-Extinction rats showed a widespread modulation of synaptic plasticity genes including transcript upregulation of Camk2g, Ephb2, Grm8 and Ngfr, as well as mu and delta opioid receptors. Together, our data, allowed us to compare different phenotypes of extintion learning based on differential modulation of gene expression. It could also suggest that alteration of plasticity genes could alter extinction learning and/or vice versa. Future studies at the protein level in the reward system i.e. amygdala, prefrontal cortex and Hippocampus will be evaluated, as well as pharmacological studies to demonstrate the role of key molecular players (i.e. Bdnf and opioid receptors) regulating extinction behaviors.

Title: CB1 receptor decreased expression in the nucleus accumbens and prefrontal cortex prevents amphetamine-induced place preference conditioning in rats

Authors: ***D. PEREZ**[1], A. ROMANO-LOPEZ[1], A. RUIZ-CONTRERAS[2], M. MENDEZ-DIAZ[1], O. PROSPERO-GARCIA[1];
[1]Fac. of Medicin, [2]Fac. of Psychology, Univ. Nacional Autonoma De Mexico, Mexico City, Mexico

Abstract: An extensive literature suggests drugs of abuse-dependence is a learning process. Memory consolidation, including memory re-consolidation, requires protein synthesis. In this context, we decided to used chloramphenicol (CAP), a drug that inhibits bacterial but also mammalian protein synthesis to prevent amphetamine (amph)-seeking behavior. Twenty Wistar adult rats were subjected to amph (2mg/kg)-induced Conditioned Place Preference (CPP). Rats were divided into 2 groups (n=10). Amph+saline (veh) rats, received amph and were kept in one compartment of the chamber (30min). Once this period finished they received a subcutaneous injection of veh (0.5ml) and returned to their home-cage. Amph+CAP rats, were similarly treated with amph but instead of veh received CAP (150mg/kg). Once CPP was evaluated rats were killed and the prefrontal cortex (PFC) and the nucleus accumbens (NAcc) were isolated and prepared for CB1 receptor Western blot analysis. A vivarium (viv) reared group of rats (n=8) was added as control. Results indicated that rats receiving amph+veh developed CPP while increasing CB1R expression in the NAcc, with no changes in the PFC compared to viv-control. Rats receiving amph+CAP did not develop CPP while reducing CB1R expression in the PFC compared to both viv- and amph+veh-rats. Regarding CB1R in the NAcc, amph+CAP amount was similar to the amount of viv-control, sparing the increase detected in the amph+veh, suggesting CAP prevented the amph-induced CB1R increase. These results further support the notion that drug-dependence is a learning process that requires protein synthesis. In the case of amph-induced CPP includes an increase of CB1R in the NAcc that is prevented by protein synthesis inhibitor CAP.

Title: 17β-estradiol enhances intrinsic excitability of IL-mPFC neurons through a BDNF-dependent mechanism

Authors: *H. YOUSUF[1], D. MUELLER[2];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Ponce Hlth. Sci. University-School of Med., Ponce, PR

Abstract: Persistence of strong emotional memories can lead to the development of neuropsychiatric disorders such as posttraumatic stress disorder (PTSD) and drug addiction. Treatment of maladaptive memories can occur through extinction learning, which involves the formation of a new inhibitory memory and suppresses fear expression and drug seeking. (Mueller and Quirk, 2008; Quirk et al., 2006). The infralimbic medial prefrontal cortex (IL-mPFC) is critical for extinction of conditioned fear and dug seeking (Milad and Quirk, 2002; Otis et al., 2014). The potent estrogen, 17β-estradiol (E_2), has been shown to increase dendritic spine density and memory function. Behaviorally, E_2 enhances extinction of both conditioned fear and cocaine seeking (Twining et al., 2013; Graham and Milad, 2014). However, the cellular mechanisms by which E_2 enhances extinction remain unclear. Using patch-clamp electrophysiology, we tested whether E_2 alters intrinsic excitability in IL-mPFC neurons as intrinsic excitability promotes synaptic plasticity underlying memory formation. Brain slices were derived from female ovariectomized rats and recordings were obtained from layer V IL-mPFC pyramidal neurons. The minimum amount of current required to elicit a single action potential was used as a depolarizing step throughout the experiments. Bath-application of E_2 significantly increased excitability as compared to vehicle treatment in IL-mPFC neurons. Activity of E_2 is modulated via several signaling molecules, including brain-derived neurotrophic factor (BDNF). Therefore, we tested whether E_2-induced potentiation of intrinsic excitability in the IL-mPFC is mediated via BDNF signaling. Since, BDNF binds to its high-affinity tropomyosin receptor kinase B (TrkB), slices were incubated with a Trk receptor antagonist, K-252a, prior to bath-application of E_2. Patch-clamp recordings from IL-mPFC pyramidal neurons revealed that E_2-induced enhancement of intrinsic excitability was prevented in the presence of K-252a. Thus, E_2 enhances intrinsic excitability in a TrkB-dependent manner. Furthermore, this enhanced excitability may underlie E_2-induced facilitation of extinction of conditioned fear and drug seeking. These data indicate that optimizing E_2 levels and/or augmenting BDNF function could enhance therapeutic interventions to alleviate neuropsychiatric disorders such as PTSD and drug addiction.

Title: Expression of basic fibroblast growth factor (bFGF or FGF2) is regulated by extinction following cocaine self-administrtion

Authors: *M. HAFENBREIDEL[1], C. W. SMIES[1], D. MUELLER[2];
[1]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Ponce Hlth. Sci. University-School of Med., Ponce, PR

Abstract: Drug addiction is characterized by compulsive drug seeking and chronic relapse, which are maintained by drug-induced maladaptive plasticity. This plasticity is mediated, in part, by the actions of growth factors such as basic fibroblast growth factor (bFGF or FGF2). bFGF expression is increased following stimulant drug use in reward-related brain regions, including the medial prefrontal cortex (mPFC; Fumagalli et al., 2006; Hafenbreidel et al., 2015), and bFGF mediates drug-induced increases in dendritic length (Mueller et al., 2006) as well as amphetamine-induced sensitization (Flores et al., 2000). Moreover, addiction is maintained by cues associated with the drug, and therefore reducing cue reactivity through extinction could reduce relapse rates. We previously found that neutralizing bFGF in the infralimbic region of the mPFC (IL-mPFC) facilitates extinction following cocaine self-administration (Hafenbreidel et al., 2015). However, whether bFGF overexpression is sufficient to prolong extinction and what mechanisms underlie bFGF-induced resistance to extinction is unknown. Therefore, we first determined if bFGF overexpression would delay new learning. Extinction of sucrose self-administration does not alter bFGF expression in IL-mPFC (Hafenbreidel et al., 2015), so we overexpressed bFGF in this region by infusing bFGF prior to extinction. First, rats were trained to lever press for sucrose before undergoing extinction, which consisted of eight 90 min extinction sessions. Next, rats were infused with vehicle or bFGF into IL-mPFC prior to the first four extinction sessions. We found that bFGF-treated rats extinguished at the same rate as vehicle-treated rats, indicating that increasing infralimbic bFGF during extinction was not sufficient to prolong extinction. Thus, exogenous bFGF neither enhances nor impairs extinction of sucrose seeking. In contrast, we previously reported that extinction reverses drug-induced bFGF overexpression in IL-mPFC that occurs following self-administration (Hafenbreidel et al., 2015). Additionally, preliminary analyses suggest that extinction following cocaine self-administration also reduces bFGF protein expression in the nucleus accumbens and dorsal hippocampus, and ongoing investigations are examining the mechanisms underlying these effects. In summary, extinction reduces bFGF expression throughout reward-related circuitry, indicating that targeted reductions in bFGF expression could facilitate addiction treatment.

Title: Brain activation patterns associated with cue reactivity and craving in Internet gaming disorder: an fMRI study

Authors: *J.-E. JEONG;
Seoul St.mary's Hosp., Seoul, Korea, Republic of

Abstract: *Background and aims*: Extensive use of the Internet gaming has become widespread and problematic for the last two decades. This study aimed to investigate the brain activation pattern associated with cue reactivity and craving in Internet gaming disorder (IGD). *Methods: Participants* The sample included 23 healthy control (HC) males (age, 30.04 ± 5.17) and 25 males with the Internet gaming disorder (IGD) (age, 30.27 ± 5.27) were selected using IGD criteria which recently included in section III of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5). Both of the HC and IGD group had an experience of playing the same kinds of games. *Procedures* Before the fMRI scanning, the Internet gaming video was presented for 1 minute in order to maximize the craving response. The video was made of the highlights from the online videogame matches. The gaming craving was measured, by asking to the extent of urge to play the video game at this moment, using the 10 point visual analog scale after presentation of the video clip. During the fMRI scanning, participants viewed the stimulus that consisted of three sets of picture: gaming, mosaic, and landscapes. These pictures were arranged according to a block design. *Results*: In the results of perceived gaming craving, the participants with IGD recorded higher scores than with HC ($t=-2.0$, $df=47$, $p<.05$). In the fMRI results, the IGD group compared to HC revealed more activation on right dorsolateral prefrontal cortex (DLPFC), left occipital lobe, bilateral caudate nucleus, and right medial prefrontal cortex (MPFC) under gaming pictures (relative to mosaic pictures). On the other hand, brain activity within left ventrolateral prefrontal cortex (VLPFC) and anterior part of left prefrontal cortex was decreased in IGD group compared to HC under gaming pictures (relative to landscapes pictures). *Conclusions*: In this study, we could demonstrate the different cerebral activation between normal Internet game users and people with IGD during watching cue-induced gaming pictures. In the fMRI results of the gaming condition, the IGD group compared with HC showed more activation in DLPFC and left occipital cortex, related to regulation of craving and processing the visual information. In addition, activation in caudate nucleus, which is involved in reward circuit, would be associated with the subjective experience of gaming craving. On the other hand, IGD group compared with HC showed deactivation in VLPFC, which have been reported as the important area of the cognitive reappraisal and emotion regulation.

Title: Involvement of histone deacetylase 3 in extinction of reward-seeking behaviors

Authors: *L. N. HITCHCOCK[1], T. M. NAVIS[1], M. A. WOOD[2], K. M. LATTAL[1]; [1]Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Neurobio. & Behavior, Univ. of California-Irvine, Irvine, CA

Abstract: Substance use disorder is a chronic, often relapsing disease that leads to a loss of behavioral inhibition and compulsive drug-seeking. Cues that are paired with acquisition of drug-seeking are thought to influence subsequent extinction (animal model of exposure-based therapy) and relapse-like behavior, both in humans and animals. Our previous work has implicated the dorsal hippocampus for developing and retrieving memories in a drug-seeking context. By inactivating the dorsal hippocampus, we found that extinction was impaired in a contextual learning paradigm (cocaine-induced conditioned place preference). At the molecular level, the epigenetic enzyme histone deacetylase 3 (HDAC3), has been shown to be a negative regulator of cocaine-associated learning and memory. Here, we further investigate this hippocampus-based extinction model and determine whether inhibition of HDAC3 can enhance extinction after cocaine self-administration. Extended extinction did not eliminate contextual renewal or cue-induced reinstatement, but a systemic injection of an HDAC3 inhibitor caused persistent extinction and weakened renewal and cue-induced reinstatement. We examined the generality of these findings by assessing effects of a viral point mutation of HDAC3 in the dorsal hippocampus during acquisition and extinction of responding for natural rewards (food pellets). In this experiment, the HDAC3 point mutant led to faster acquisition and faster extinction learning. Together, these findings support the idea that HDAC3 is involved in acquisition and extinction of reward-seeking behaviors.

Title: Inhibition of hippocampal nonmuscle myosin II disrupts the reconsolidation of methamphetamine-associated memory

Authors: ***S. B. BRIGGS**, E. J. YOUNG, A. M. BLOUIN, G. RUMBAUGH, C. A. MILLER; Neurosci., The Scripps Res. Institute-Fl Campus, Jupiter, FL

Abstract: Persistent, drug-associated memories are an underlying core feature of substance use disorder (SUD). These memories are trigged by numerous and often abstract environmental cues, making them difficult to predict and treat. Dendritic spines, which are thought to contribute to the encoding and storage of memory, undergo actin-dependent changes that are critical to long-term memory. We recently reported that the actin cytoskeleton that supports methamphetamine (METH)-associated memories, but not other amygdala (AMY)- dependent memories, continuously cycles, presenting a new and unique therapeutic target for METH abuse that is both selective and retrieval-independent. Moreover, disrupting actin polymerization with a single, intra-AMY or systemic administration of Blebbistatin (Blebb), a nonmuscle myosin II inhibitor, abolishes METH seeking, with a concomitant decrease in AMY spine density, providing a potential therapeutic target. Presently, we sought to understand if the mechanism by which Blebb disrupts METH-associated memory is unique to the AMY. To test this, male mice received Blebb infusions into other regions of the circuit supporting drug-associated memories, the prefrontal (PFC), nucleus accumbens (NAc) or the hippocampus (Hipp), immediately before METH conditioned place preference testing. Contrary to our AMY results, Bebb injections into these regions did not result in an immediate disruption of drug seeking, suggesting that the actin cytoskeleton in the PFC, NAc and Hipp is stable after METH exposure. Furthermore, unlike in the AMY, the METH-associated increase in HPC spine density was unchanged by Blebb treatment. However, METH-associated memory was disrupted when animals were tested a second time (24 hours) after intra-HPC infusion, suggesting an effect on reconsolidation. Indeed,

Blebb disrupted METH-associated memory when delivered into the HPC immediately after a brief memory recall session (5 mins), but not a full test session (15 mins), suggesting a brief time window for disruption of reconsolidation-based actin dynamics. Taken together these results build upon our previous work on nonmuscle myosin II, shedding light on a second mechanism by which Blebb functions to disrupt drug-associated memory. This suggests that, if combined with retrieval, nonmuscle myosin II inhibition may prove to be a powerful therapeutic approach by disrupting storage of the portion of METH-associated memory trace stored in the AMY (no retrieval required) and reconsolidation of the portion of the memory trace stored in the HPC.

Title: Delayed protein expression in the mPFC in a critical time window is necessary for late consolidation of cocaine incubation

Authors: *C. CHEN;
The Sixth Hosp. of Peking Univ., Beijing City, China

Abstract: Introduction: One of the challenges of cocaine addiction is the incubation in which relapse to drug use can occur after prolonged withdrawal. Although several brain regions and molecular mechanisms were involved in this process, the underlying mnemonic mechanisms are still unknown. Long-term memory persistence requires a late protein synthesis-dependent phase, even many hours after memory acquisition. BDNF is a crucial protein synthesis product that has emerged as a potent molecular mediator for synaptic plasticity. Here we explored whether delayed BDNF expression during the time window of late consolidation in mPFC regulate cocaine incubation **Methods:** Rats tested the double-wave of protein synthesis expression after 10 d self-administration (SA) training. Rats were harvested brain at 7 different time points after last training for expression analysis including 0.5 h, 1 h, 9 h, 12 h, 18 h, 24 h and 36 h. We detected brain activity after SA training by analyzing c-fos expression in several brain regions, including prelimbic cortex (PrL), infralimbic cortex (IL), basolateral amygdale (BLA) and central amygdala (CeA). Then, we explored the effects of microinjection of the protein synthesis inhibitor anisomycin in target brain region on drug craving after 30 d withdrawal. Next, we will regulate BDNF-TrkB-ERK signaling pathway activity to further confirm whether this pathway

plays a crucial role in the late consolidation of cocaine craving. **Results:** Our preliminary experiment showed the early and late protein expression waves in PrL and IL after 10 d SA training. In the PrL, the peak of c-fos expression presented on 0.5 h, 1 h and 18 h after last SA training and only 0.5 h and 24 h were found in IL. In the BLA, only the early wave of protein expression was existed, and no significant difference was found in CeA. Cocaine incubation was sensitive to protein synthesis inhibition at 18 h after the last SA training in the PrL, and the active nosepokes were decreased in 30 d withdrawal test but not 2 d withdrawal test. **Conclusion:** These results indicate that delayed protein expression in a critical time window is involved in late consolidation of cocaine incubation.

Title: Epigenetic regulation of the FosB gene in hippocampal-dependent behaviors

Authors: *P. A. GAJEWSKI[1], A. L. EAGLE[2], E. A. HELLER[3], I. MAZE[4], A. J. ROBISON[2]; [1]Genet., [2]Physiol., Michigan State Univ., East Lansing, MI; [3]Pharmacol., Univ. of Pennsylvania, Pennsylvania, PA; [4]Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Drug addiction results in part from maladaptive learning, including the formation of strong associations between the drug and the environment and circumstances of its use. However, the patterns of gene regulation critical for this learning remain unknown. Consolidation of explicit memories occurs through synaptic plasticity in the hippocampus, and some of the molecular mechanisms of this process are well characterized, but epigenetic regulation underlying changes in hippocampal gene expression and the distribution of gene expression through the hippocampus is poorly understood. The transcription factor ΔFosB is an important arbitrator of activity-dependent gene expression, and our group has recently demonstrated that its expression in hippocampus is critical for learning. Previous studies demonstrate that drugs of abuse also upregulate ΔFosB in hippocampus, but the mechanism of its induction by cocaine in hippocampus and its role in hippocampus-dependent cocaine responses is unknown. We are currently determining whether the expression pattern of ΔFosB differs throughout hippocampal subregions in response to cocaine-related learning behaviors, as it

appears to be uniquely induced in the CA1 subregions in response to spatial learning. Furthermore, we use chromatin immunoprecipitation to demonstrate that dimethylation of lysine 9 at histone H3, a repressive histone modification, is decreased at the *FosB* gene promoter in hippocampus after chronic exposure to cocaine and general learning. We show that locus specific modification of this histone mark in dorsal hippocampus is sufficient to impair learning and memory. Experiments are ongoing to determine whether these locus-specific histone modifications impact drug-related behaviors, as well. These findings collectively suggest that specific salient stimuli, such as formation of drug-environment associations, induce epigenetic changes in the hippocampal *FosB* gene promoter that regulate ΔFosB induction, which in turn may control the transcription of genes that underlie hippocampal cell function, plasticity, and cocaine-related learning.

Title: Increasing CS duration facilitates extinction and blunts context-specific sensitization in mice

Authors: *A. S. RAUHUT, J. BRITTON, A. YOUNG;
Psychology, Dickinson Col., Carlisle, PA

Abstract: Associative learning processes have been proposed to contribute to behavioral sensitization; however, previous research has shown that extinction does not alter expression of behavioral sensitization in rodents. The duration of conditioned stimulus (CS) exposure has been shown to be an important variable in determining the rate and robustness of extinction in the Pavlovian conditioning literature. Thus, the present experiment examined the effect of varying the CS duration on the rate of extinction of conditioned hyperactivity and the subsequent expression of behavioral sensitization in mice. The experiment consisted on 3 phases: acquisition, extinction and test for behavioral sensitization. During acquisition, male, Swiss Webster mice (n = 6/group) received an injection (subcutaneous, s.c.) of methamphetamine (1.0

mg/kg; paired) or vehicle (saline; unpaired) on 4 alternating, 30-minute locomotor activity sessions (Chamber Days). On the 4 intervening sessions (Home Cage Days), paired and unpaired mice received vehicle or methamphetamine, respectively, in their home cages. Following the acquisition phase, the extinction phase began and lasted 8 sessions. At this time, paired and unpaired mice received an injection of vehicle and placed in the locomotor activity chambers for either 30 or 120 minutes. Two control groups (Paired-Rest and Unpaired-Rest) were included that did not undergo extinction and remained in their home cages for the entirety of this phase. The test for behavioral sensitization occurred 24 hours after the last extinction session. All mice received an injection of a challenge methamphetamine dose (0.5 mg/kg) and tested for a 120-minute period in the locomotor activity chambers. It was found that paired mice that received 120-minute extinction sessions extinguished faster and showed a less robust sensitization response to methamphetamine compared to paired mice that underwent only 30-minute extinction sessions. These results add further support for the role of associative learning processes in behavioral sensitization and suggest that factors (e.g., CS duration) that promote extinction may alter the expression of behavioral sensitization.

Title: *In vivo* calcium imaging to assess the role of prelimbic cortex neuronal ensembles in encoding reinstatement of palatable food seeking in rats.

Authors: *R. MADANGOPAL, D. CAPRIOLI, B. LIANG, G. BARBERA, B. T. HOPE, Y. SHAHAM, D.-T. LIN;
Natl. Inst. On Drug Abuse IRP, Baltimore, MD

Abstract: Background & rationale: *In vivo* imaging in awake behaving rats provides a dynamic, spatio-temporal view of task-related ensemble activity during the course of learning. Previous studies using the rat reinstatement model have implicated the prelimbic cortex in relapse to palatable food-seeking induced by non-contingent pellet priming. However, the underlying neuronal ensemble activity in the prelimbic cortex that encodes pellet priming-induced reinstatement is unknown.
Technique: We developed a miniature epifluorescent microscope for imaging calcium dynamics in awake behaving rats. We also optimized protocols for implantation and coupling with gradient

index (GRIN) lenses for long-term imaging in prelimbic cortex of awake behaving rats.
Behavioral procedure: We trained rats that were food restricted to 75% *ad lib* feeding level to lever press for a palatable food pellet reward (fixed ratio 1 schedule; 1 pellet reward delivered after presentation of a 10s discrete cue) in a modified trial-based design (60 trials/session; 60-s lever availability/trial; variable inter-trial interval). Next, we extinguished the rats' lever-pressing in the presence of the discrete cue. We then tested the rats under extinction conditions for pellet priming-induced reinstatement of palatable food seeking.
Results: We observed reliable food self-administration and extinction of food-reinforced responding in the trial-based procedure. We also observed robust pellet-primed reinstatement under extinction conditions.
Ongoing studies: We are currently recording task-specific *in vivo* neuronal activity in prelimbic cortex during our trial-based task to identify and monitor neuronal ensembles that encode food-seeking behavior.

Title: Genetic depletion of D2 receptors in dopamine neurons increases locomotor sensitivity to cocaine and impairs reversal learning in mice

Authors: J. LINDEN[1], A. S. JAMES[1], C. MCDANIEL[2], C. GOODMAN[2], *J. D. JENTSCH[1]; [1]Binghamton Univ., Binghamton, NY; [2]Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Neuroimaging studies in rodents and non-human and human primates have all revealed that relatively low striatal dopamine D2-like receptor binding potential is associated with poor impulse control and with vulnerability for addiction-related behaviors. These studies cannot, however, disambiguate the roles for various pools of D2 receptors found in the striatum (e.g., those expressed on medium spiny striatopallidal neurons vs. on dopamine-releasing nerve terminals) in these behavioral outcomes. To clarify the role of the latter pool - namely, D2

autoreceptors - we studied mice carrying a conditional DRD2 gene, with or without Cre-recombinase expressed under the transcriptional control of the dopamine transporter gene locus (DAT-DRD2flox, N=19 and WT-DRD2flox, N=21). These mice were tested for response to cocaine in locomotor activity chambers, and spatial reversal learning was assessed in operant boxes. As predicted, compared to WT-DRD2flox mice, DAT-DRD2flox animals demonstrated heightened sensitivity to the locomotor stimulating effect of cocaine (10 mg/kg, i.p.), confirming previous research using a similar genetic model. In the spatial reversal learning task, DAT-DRD2flox mice were slower to reach a learning criterion, committed higher numbers of anticipatory responses and had difficulty sustaining a prolonged nose poke response, all measurements related to defective response inhibition. Rate of learning of the initial discrimination and latencies to collect rewards, to initiate trials and to produce a response were unaffected by genetic deletion of D2 autoreceptors, discarding possible motor and motivational factors. Together, these findings confirm the role of D2 autoreceptors in reversal learning and suggest a broader involvement in behavioral inhibition mechanisms.

Title: Suppression of 50kHz ultrasonic vocalizations in rats as a sensitive measure of memory in cocaine-induced conditioned place preference

Authors: *P. S. KUDVA, K.-A. REYES, B. SORG;
Neurosci., Washington State Univ., Vancouver, WA

Abstract: Reconsolidation of a memory is the process of reactivating a memory and then re-stabilizing it, thereby strengthening it. When a memory is reactivated, it can be disrupted using specific pharmacological agents that weaken it. Rats emit ultrasonic vocalizations (USVs) in response to various stimuli, and the emission of frequency-modulated 50kHz USVs (FM50 USVs) is believed to be associated with positive affective states. Here we examined the impact

of the alpha-1 adrenergic antagonist, prazosin, on the ability to disrupt the reconsolidation of memories associated with cocaine in a cocaine-induced conditioned place preference (CPP) task. We tested the hypothesis that USVs would be suppressed after disruption of reconsolidation by prazosin, and that this affective measure would be a more sensitive indicator of memory than traditional CPP (motor) behavior. During CPP training, rats were confined to one side of the CPP box and received an IP injection of either cocaine or saline on alternating days for eight days. On the CPP Test day, rats were allowed open access to both sides of the box without any injection. Rats demonstrated increased FM50 USVs on the cocaine- vs. saline-paired side. Their memory was then reactivated the next day by confinement in the cocaine-paired chamber for 15 min followed an IP injection of prazosin or vehicle. The following day, rats were allowed open access to both sides of the box. While CPP behavior was reduced in prazosin-treated rats, FM 50 USVs USVs were still elevated on the cocaine-paired side equal to that of vehicle controls. In addition, a separate cohort of rats that did not demonstrate significant CPP behavior on the CPP Test day still demonstrated higher FM50 USVs on the cocaine-paired side. These results indicate that FM50 USVs may be a more sensitive indicator of memory than CPP behavior.

Title: Cerebellar and medial prefrontal deactivations effects on the acquisition of cocaine-induced preference conditioning

Authors: ***I. GIL MIRAVET**[1], M. CARBO GAS[1], J. MORENO RIUS[1], F. E. OLUCHA BORDONAU[2], M. MIQUEL[1];
[1]Psychobiology, [2]Anat. and Embryology, Univ. Jaume I, Castellon, Spain

Abstract: The cerebellum has traditionally been overlooked in addiction research, despite growing evidences that suggest a role for it in many of the brain functions affected in addicts. Recent studies have demonstrated that the cerebellum mediates the consolidation of emotional

memories; the development of reward-induced learning; and the persistence of procedural memory. Moreover, clinical data suggest that lesions and pathological conditions might reorganize functions of the prefrontal-cerebellar circuitry. Recently, we have found two cerebellar hallmark signatures of conditioned preference for cocaine: an increase in cFOS expression in cells at the apex of the granular layer and stronger expression of the perineuronal nets (PNNs) surrounding Golgi interneurons in the same region. In the present study, we analysed the effect produced by the impairment of these prefronto-cerebellar networks in the acquisition of cocaine-induced preference conditioning. We evaluated the effects of different mPFC and cerebellar deactivations in rats before starting the conditioning training to acquiring preference towards an olfactory stimulus paired with cocaine. Two groups of rats were subjected before training to a temporary prelimbic or infralimbic inactivation by lidocaine. Other two groups were treated with quinolinic acid for a permanent lesion in two different regions of the posterior cerebellar vermis. In this work, we report that either the inactivation of infralimbic cortex or the lesion of the cerebellar apex of the vermis significantly increased the percentage of animals acquiring conditioned preference for cocaine. Therefore, our findings showed that the development of cocaine-induced conditioned preference is promoted when activity in either the infralimbic cortex or the apex of the posterior vermis decreases. A simultaneous inactivation of both sites prevented this effect. Opposite results were found after either prelimbic impairment or ventral cerebellar lesion. The results suggest that the mPFC cortex and cerebellum work together on the acquisition of drug-related emotional memories. To study the anatomical network behind this process retrograde and anterograde tracers were injected in the same site of cerebellar cortex and mPrf cortex where lesions were placed.

Title: The role of ghrelin in morphine and methamphetamine induced conditioned place preference in rats

Authors: *M. SUSTKOVA[1], T. HAVLICKOVA[1], N. PUSHKINA[2], C. CHARALAMBOUS[2], M. LAPKA[1];
[1]Dep Pharmacol. Third Fac. of Med. Charles Univ. in Prague, Charles Univ. In Prague, Praha 10, Czech Republic; [2]Dep Addictology, First Fac. Med. Charles Univ., Prague 2, Czech Republic

Abstract: Aims: An increasing number of studies over the past few years have demonstrated ghrelin´s participation in alcohol, cocaine and nicotine abuse. However, the role of ghrelin in opioid and methamphetamine effects has rarely been examined. The aim of the present study in rats was to ascertain whether a ghrelin antagonist (JMV2959) was able to inhibit morphine induced and methamphetamine induced conditioned place preference (CPP) and also to prevent the methamphetamine-induced place conditioning process. Methods: In the biased CPP model, rats were conditioned for 8 days with morphine (10 mg/kg s.c.) or methamphetamine (5 mg/kg i.p.). On the experimental day, JMV2959 (3 and 6 mg/kg i.p.) or saline were administered 20 min before testing. In another experiment JMV2959 (3 and 6 mg/kg i.p.) was administered always together with methamphetamine during the conditioning process. There were 14 rats in each group of morphine and 8 rats in groups of methamphetamine experiments. Results: One way ANOVA followed by Holm Shidak test revealed significant and dose dependent reduction of morphine-induced as well as methamphetamine induced CPP after acute JMV2959 pretreatment (3 and 6 mg/kg). Pretreatment with JMV2959 (3 and 6 mg/kg) during the conditioning process significantly and dose-dependently reduced the methamphetamine induced CPP. Conclusion: Ghrelin secretagogue receptors (GHS R1A) appear to be significantly involved in the morphine induced and methamphetamine induced conditioning associated with the reward processing.

Title: Activity-dependent transcriptional regulation of hippocampal projections in fear/anxiety and cocaine reward

Authors: *A. L. EAGLE[1], C. E. MANNING[1], P. A. GAJEWSKI[1], R. ACHARGUI[1], L. A. GRON[1], F. M. BOYCE[2], R. L. NEVE[3], A. J. ROBISON[1];

Abstract: Drug seeking, a hallmark of addiction, is mediated by neurobiological adaptations in the reward circuitry of the brain. In particular dysfunctional regulation of reward regions, like nucleus accumbens (NAc), promotes the development of drug addiction, and evidence suggests this is mediated by direct glutamatergic projections from ventral hippocampus (vHPC) to NAc. In addition, the vHPC is important for regulating fear and anxiety behavior via direct projections to the amygdala (Amy). These projection neurons may also undergo significant functional adaptations after learning, stress, or exposure to drugs of abuse, such as cocaine, that may depend, in part, from activity-dependent alterations in gene expression. However, the mechanisms underlying vHPC projection-specific changes in gene expression are not understood. ΔFosB, a truncated splice product of the *FOSB* gene, is a *chronic* activity-dependent transcription factor that we have recently demonstrated is critical for hippocampus-dependent learning. We therefore sought to determine the role of ΔFosB in vHPC projections to NAc and Amy and subsequent drug seeking (e.g. drug reward) and fear/anxiety behaviors. To this end, we developed a novel dual-viral CRISPR-Cas9 technique to selectively silence the *FOSB* gene in vHPC projections to NAc or Amy in adult mice. We first demonstrate here that non-specific ΔFosB inhibition in the ventral HPC (vHPC) impairs cocaine conditioned place preference (CPP), which measures the expression of drug reward, and avoidant learning, both of which are known to be mediated by the function of NAc and Amy, respectively. Additionally these same behaviors induce ΔFosB in vHPC neurons in a projection-specific manner. We then examined the effects of selective silencing of *FOSB* in specific vHPC projections on these same behaviors. We found that *FOSB* in vHPC-NAc projections is critical for the expression of cocaine CPP, but not avoidant learning. Conversely, *FOSB* KO in vHPC-Amy projections impaired avoidant learning and reduced anxiety-like behavior, but did not affect expression of cocaine CPP. These findings suggest that ΔFosB regulates projection-specific vHPC neuron functional adaptations via changes in gene expression, thereby driving cocaine-dependent behaviors and stress-evoked behaviors, such as fear & anxiety. Furthermore, they suggest that ΔFosB in vHPC projections may be important in drug addiction and stress-related psychiatric disorders, such as posttraumatic stress disorder and depression, serving as a viable target for drug development for these disorders.

Title: Identifying functional alterations in neuronal ensembles of medial prefrontal cortex activated during food self-administration in rats

Authors: *L. R. WHITAKER, B. L. WARREN, T. C. HARTE, J. M. BOSSERT, K. B. MCPHERSON, J. BEIDEL, Y. SHAHAM, A. BONCI, B. T. HOPE;
Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Learned associations between environmental stimuli and rewards drive goal-directed learning and motivated behavior. These associations are thought to be encoded by specific patterns of sparsely distributed neurons called neuronal ensembles that are determined by selective activation of reward-predictive stimuli. The question remains as to how neurons in these ensembles are functionally altered during learning, and which of these changes encode learned associations. The objectives of our study were to identify ensembles of neurons strongly activated during food self-administration, and then to determine functional alterations specific to these neuronal ensembles. Training took place over a period of 10 days. During each training session, rats were allowed to lever press for food pellets in the self-administration chambers for one hour. Rats formed an association between lever pressing and food reward over the course of ten days of training. Immunohistochemical analysis was performed on days 1, 3 and 10 of training. Preliminary data show induction of Fos expression on training day 1 that diminishes by day 10. Additionally, whole cell recordings were performed in *Fos-GFP* transgenic rats on days 1 and 10 of training to identify functional alterations that contribute to operant learning. In these rats, strong neuronal activation activates the *Fos* promoter and drives expression of GFP. No changes in intrinsic excitability were observed in FosGFP+ neurons over the course of training. However, there was a decrease in excitability in the FosGFP- neurons from day 1 to day 10 of training. Future studies will identify the mechanism underlying this alteration in membrane excitability following operant learning. This work was supported by NIDA Intramural Research Program.

Title: Fos expression in the infralimbic cortex following extinction of cocaine seeking.

Authors: *B. L. WARREN, M. P. MENDOZA, F. SOTO, D. CAPRIOLI, M. VENNIRO, L. R. WHITAKER, R. MADANGOPAL, Y. SHAHAM, B. T. HOPE;
Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Background: We recently found that Fos-expressing neuronal ensembles in the infralimbic cortex encode operant extinction of food seeking. Here we tested whether this finding generalize to extinction of operant cocaine seeking.
Methods: We trained Long-Evans rats to lever press for infusions of cocaine for 14 days days (3 h/day; 1.0 mg/kg/infusion on days 1-7 and 0.5 mg/kg/infusion on days 8-14). We subsequently exposed rats to 0, 2, or 7 daily extinction sessions (3 h/day) to assess Fos expression at three different time points following extinction training. The next day, we exposed all rats to a short 15 min test under non-reinforced conditions to induce Fos. We then assessed Fos immunoreactivity in the infralimbic cortex.
Results: Rats increased their lever pressing for cocaine infusions over the course of self-administration training. Furthermore, rats doubled their lever pressing when the dose of cocaine per infusion was cut in half. On test day, rats decreased their lever pressing following both 2 and 7 prior extinction sessions. We found maximal Fos expression in the infralimbic cortex of rats exposed to 2 prior extinction sessions.
Conclusions: Increased Fos expression in the infralimbic cortex suggests that neuronal ensemble activity in this area encode extinction of cocaine seeking. We currently test this hypothesis using the Daun02 inactivation procedure.

Title: The addictive potential of artificial sweeteners

Authors: *L. A. BECKER, W. MILLER, V. DEERE, N. BEDI, K. MAYES, K. SHEETS; Psychology, Univ. of Evansville, Evansville, IN

Abstract: This study explored the potential for artificial sweetener addiction in comparison to the potential for sugar addiction, using rats as an animal model. Research focused on adolescent rats, such that artificial sweetener addiction might be correlated with the rise in obesity among teenagers (Fowler et al., 2008; Ogden et al., 2012). Rats were exposed to one of six conditions, with four groups having a sweetener added to their water supply that varied in type and concentration: 10% sucrose, 30% sucrose, 0.4% sucralose, and 0.8% saccharin. An additional group served as a negative control (water) and a final group acted as a positive control (water), given daily intraperitoneal injections of 1.6 mg/kg nicotine, allowing for the contrasting of sweetener addiction to nicotine addiction. Addiction was achieved via food and water deprivation 12 hours daily for a period of eight weeks, thereby inducing bingeing and withdrawal behaviors. This addiction was then quantified by measuring withdrawal symptoms brought on by the injection of naloxone, an opioid antagonist, prior to a series of three tests: open field, elevated-plus maze, and Porsalt forced swim. Rats in the artificial sweetener conditions spent less time in the center of the open field than rats in the sugar condition and rats in either condition swam a lesser distance than negative control rats in the Porsalt forced swim test. These data support that artificial sweeteners are at least equally as addictive as sugar, but that neither sweeteners are as addictive as nicotine. Thus, it is hypothesized that increased consumption of artificial sweeteners is correlated with the rise in teenage obesity.

Title: Oral self-administration of caffeine in rats.

Authors: *C. A. BRADLEY, E. A. WILLIAMS, M. I. PALMATIER;
East Tennessee State Univ., Johnson City, TN

Abstract: Caffeine is the most consumed psychoactive drug in the world and functions as a reinforcer in humans, but no previously published study has established reliable caffeine self-administration in non-humans. However, our laboratory has found that caffeine is a robust 'reinforcement enhancer' - it increases responding for non-drug reinforcers such as sucrose and saccharin. We have recently leveraged this effect to establish intravenous self-administration caffeine. When rats earned caffeine infusions and a reinforcing taste stimulus (0.2% saccharin) for making an operant response, they increased their responding relative to a group receiving the taste stimulus alone. The objective of the present studies was to establish a more veridical model in which oral caffeine is consumed in a vehicle that also contained the non-drug reinforcer. Because of the potent bitter taste of caffeine, we predicted that a masking stimulus (decaffeinated coffee, 0.5% w/v) would enhance oral caffeine intake at higher concentrations. Forty rats were shaped to lever press for 0.1 ml presentations of saccharin (0.2% w/v) in a liquid dipper under a progressive ratio (PR) schedule of reinforcement. Rats were subsequently assigned to one of two drug conditions: vehicle alone (-) or caffeine included in the vehicle (+), and one of three vehicle conditions: saccharin alone (S+ or S-), saccharin with decaffeinated coffee (SD+ or SD-), or water (W+ or W-). After initial acquisition with a moderate concentration of caffeine (2.5 mg/ml) additional concentrations were tested (3.5, 5.0, and 7.0 mg/ml) to describe the relationship between caffeine dose and operant behavior. All sessions ended after rats reached a 20 minute breaking point (20 min with no further reinforcement earned). The S- and DS- groups did not differ in their motivation to obtain the vehicle solutions, indicating no difference in reinforcing effects of the vehicles. However, caffeine robustly increased responding in the S+ and DS+ groups, confirming that oral caffeine is self-administered by rodents. Decaffeinated coffee did not enhance responding at any concentration, suggesting that a masking flavor is not needed to establish or promote oral caffeine intake. The effects of caffeine were also dose-dependent, with peak concentrations between 2.5 and 3.5 mg/ml. Oral caffeine in water (W+) reduced intake relative to the vehicle control (W-).These findings are the first to clearly establish that caffeine is self-administered orally in concentrations that do not have primary reinforcing effects in rodents.

Title: DeltaFosB expression in the hippocampus regulates behavior in the social defeat model of depression

Authors: ***C. MANNING**, A. L. EAGLE, P. A. GAJEWSKI, M. MAZEI-ROBISON, A. ROBISON;
Michigan State Univ., East Lansing, MI

Abstract: Stressful and traumatic experiences can contribute to mood disorders in some individuals while others are resilient. Though we know that the hippocampus plays a crucial role in stress responses, it is unknown how changes in hippocampal function, particularly at the level of gene expression, may drive resilience to stress. We have recently described a critical role for hippocampal expression of the transcription factor ΔFosB, encoded by the *FosB* gene, in general learning, but its role in hippocampal control of stress responses is unknown. The mouse chronic social defeat stress (CSDS) model of depression has both pharmacological and face validity, and has the added advantage of generating both susceptible and resilient animals, and we have therefore used this model to investigate the role of hippocampal ΔFosB in stress resilience. Here we show that animals with *FosB* developmental knockout (KO) restricted to the dentate gyrus and CA3 subregions of the hippocampus show both increased susceptibility to stress and reduced rates of antidepressant-induced neurogenesis. Moreover, using a novel dual-virus CRISPR system, we show that silencing of the *FosB* gene in adulthood in specific hippocampal cells projecting to nucleus accumbens increases susceptibility to CSDS. This result provides a molecular mechanism for recent reports that glutamatergic hippocampal afferents to nucleus accumbens regulate susceptibility to CSDS, and acute stimulation in these projections result in a susceptible phenotype (Bagot 2015). Our data also implicate ΔFosB in regulating cellular excitability, as overexpression of ΔFosB in these CA1 projection neurons results in reduced

excitability and irregular action potentials. Taken together, these data suggest that ΔFosB expression in response to stress regulates hippocampal cells projecting to NAc to promote resilience. We are currently investigating potential downstream targets of ΔFosB in the hippocampus and ΔFosB's role in hippocampal neurogenesis.

Title: Assessing acid-sensing ion channels in instrumental learning behavior

Authors: *S. M. ALAM[1], A. GHOBBEH[1], R. J. TAUGHER[1], R. FAN[1], R. T. LALUMIERE[2], J. A. WEMMIE[1];

Abstract: Acid-sensing ion channel-1A (ASIC1A) is a proton-gated cation channel activated by extracellular acidosis. ASIC1A is expressed throughout the brain including the nucleus accumbens and amygdala, is localized to dendritic spines, and has been implicated in learning, memory, and synaptic plasticity. Recent data suggest roles for ASIC1A in cocaine- and morphine-seeking behaviors including operant drug self-administration. These observations motivated us to test whether ASIC1A is involved in instrumental learning to non-drug rewards. We trained *Asic1a*$^{+/+}$ and *Asic1a*$^{-/-}$ mice to press a lever for various rewards in an operant behavioral task. We then assessed motivation using fixed-ratio 1 and progressive ratio reinforcement paradigms. In both paradigms, *Asic1a*$^{-/-}$ mice performed normally, suggesting normal task acquisition and motivation. We next removed the reward to test extinction learning. Both *Asic1a*$^{+/+}$ and *Asic1a*$^{-/-}$ mice extinguished normally. These data suggest that ASIC1A disruption does not cause deficits in instrumental reward learning. Furthermore, the previously identified role of ASIC1A in reward behavior may be specific to drugs of abuse.

Title: Withdrawal from alcohol induces transient microstructure changes in grey and white matter structures in the rodent prefrontal cortex

Authors: *S. S. SOMKUWAR[1,2], E. VILLALPANDO[3], M. SCADENG[3], M. FANNON[2], C. MANDYAM, 92129[2];
[1]San Diego, CA; [2]Veterans Affairs San Diego Hlth. Syst., San Diego, CA; [3]Univ. of San Diego, San Diego, CA

Abstract: White matter abnormalities are observed in heavy consumers of alcohol. Recent morpho-anatomical studies also reveal decreases in grey matter volume in the frontal lobe of individuals addicted to alcohol. Diffusion tensor imaging (DTI) is a magnetic resonance imaging technique that reveals valuable information regarding microstructural architecture of the brain, as such, decreased fractional anisotropy (FA) is associated with demyelination or dysmyelination. The current study investigated temporal changes in DTI measures during protracted abstinence from alcohol in a rat model of alcohol addiction. Adult male rats were subject to seven weeks of chronic intermittent ethanol exposure (CIE) paradigm where rats breathed air containing alcohol vapor for 14 hours/day that produced blood alcohol levels of 150-250 mg/dl. DTI was conducted 24 hours, 7 days, 21 days or 42 days after cessation of the seven-week CIE procedure in isoflurane anesthetized CIE rats, and in age-matched alcohol-naïve controls (n=4/group). FA and mean diffusivity (MD) were measured in specific regions of interest (ROIs) in the prefrontal cortex, specifically, in infralimbic, prelimbic, anterior cingulate and motor cortices and in the corpus callosum. FA and MD values, expressed as % of control, at various time-points after cessation of CIE were compared in the individual ROIs using separate one-way ANOVAs. In the corpus callosum, prelimbic and infralimbic cortices, FA was decreased at 21 days compared to 24 hours post CIE, and was increased at 42 days compared to 21 days; no other differences were revealed between the various time-points. In the anterior cingulate and motor cortices, FA was

decreased at 7 days and 21 days compared to 24 hours and was increased at 42 days compared to 7 days post CIE. In corpus callosum as well as in anterior cingulate, prelimbic and infralimbic cortices, MD was decreased at 21 days compared to 24 hours post CIE, no other differences were revealed in MD in these regions. In contrast, MD was decreased at 7 days, 21 days as well as 42 days post CIE compared to 24 hour time-point in the motor cortex. Thus, evidence of transient demyelination was observed in both the grey and white matter regions of the prefrontal cortex of rats withdrawn from CIE. Brain region differences were noted in the persistence of these changes, such that more permanent myelin loss was revealed in the motor cortex compared to the other regions. Taken together, the results in the rat model are consistent with observations from human imaging studies, thereby providing validation for a translationally important model to study causal link between excessive alcohol intake and prefrontal myelin neuropathology.

Title: Distinct neural processes for appetitive and informational rewards

Authors: *E. S. BROMBERG-MARTIN[1,2], J. MEREL[1,2], T. C. BLANCHARD[3,4], B. Y. HAYDEN[4];
[1]Columbia Univ., New York, NY; [2]Kavli Inst. for Brain Sci., New York, NY; [3]Harvard Univ., Cambridge, MA; [4]Univ. of Rochester, Rochester, NY

Abstract: When we are uncertain about future rewards, we often have a strong desire to seek out informative sensory cues that will tell us what our future holds. This information seeking behavior is common in our everyday lives, but is not accounted for by current theories of reinforcement learning and decision making. In fact, we often seek information even when it has no 'objective' value in terms of gathering rewards, as if the information has an intrinsic, 'subjective' value of its own. Here we test two major proposals that have been put forward to explain information seeking. According to the two-process theory, the brain has two distinct motivational processes: one for valuing primary rewards (such as food and water) and one for valuing information about those rewards. According to the single-process theory, however, both

behaviors stem from a single process tied to primary rewards; information seeking is explained as a mere side-effect of suboptimal, nonlinear distortions in learning of cue values. We present neural and behavioral evidence for the two-process theory. We gave monkeys a choice between gambles that differed in two dimensions: the amount of water reward at stake, and the chance to see informative cues that indicated the gamble's outcome several seconds in advance of reward delivery. Behaviorally, we show that monkeys assign high value to information, paying more than 20% of their water reward in exchange for informative cues. We show using theory and model-fitting that their behavior is better explained by two-process than one-process models. Neurally, we recorded from cells in the orbitofrontal cortex (OFC) which have been hypothesized to represent the subjective value of choice alternatives. Indeed, OFC neurons signaled the water reward and cue informativeness of each gamble. However, strikingly, OFC neurons signaled water and informativeness in uncorrelated manners, resembling the distinct processes in two-process models. Thus, our data suggest that information-seeking is not merely a side-effect of seeking primary rewards; the brain appears to value information in its own right.

Title: Seeking information in a social reward donation task

Authors: *J. A. JOINER[1], S. W. C. CHANG[2];
[1]Psychology, [2]Psychology, Neurobio., Yale Univ., New Haven, CT

Abstract: Both primary reinforcers, such as food, and more abstract reinforcers, such as information, strongly influence our behaviors. Like humans, non-human primates find information about upcoming rewards to be reinforcing regardless of whether or not that information influences their tangible reward outcomes (Bromberg-Martin & Hikosaka, 2011). However, whether or not monkeys find reward information about others similarly reinforcing has yet to be explored. While we know that rhesus macaques are curious about the value of own

rewards, we do not know if they are also curious about the reward values of others and if their information seeking behavior captures the underlying preferences they have about the rewards at stake during social interactions.
To explore social curiosity and how it is related to social reward sharing preferences, we utilize a modified version of the juice donation game in which an actor monkey chooses to allocate juice to himself, another monkey, both himself and the other monkey, or no one at all. Critically, after choosing any of these options, but prior to the reward delivery, the monkeys were presented with an opportunity to reveal the magnitude of the upcoming reward in each of the different reward scenarios at a specified cost. They were able to either opt in or opt out of seeking the reward value information by fixating on an occluder for different lengths of time in order to uncover a reward magnitude cue indicating the size of the upcoming reward. The amount of effort required to uncover the reward magnitude cue was systematically varied (0.3 – 1.4s) to examine the relative valuation factoring into the cost and benefit associated with revealing the information across social contexts.
Preliminary results show that revealing the non-contingent information about the upcoming reward value critically depended on the effort required, such that the monkeys seek information more when the cost is low. Monkeys also developed information seeking preferences in line with their underlying social reward sharing preferences, such that a prosocial preference was associated with seeking the information about other-relevant reward value and an antisocial preference was associated with seeking the information about other-irrelevant reward value. Notably, with a prosocial preference, preferentially seeking the information about the donated value over the wasted value was specific to when the effort required was high. These results indicate that curiosity about others is determined by the information cost, suggesting that social curiosity in monkeys is controlled by the tradeoff between cost and benefit of obtaining the information.

Title: Social information foraging obeys the marginal value theorem in rhesus macaques

Authors: *C. TURRIN[1], N. FAGAN[1], O. DAL MONTE[1], S. W. C. CHANG[2];
[1]Psychology, [2]Psychology and Neurobio., Yale Univ., New Haven, CT

Abstract: Like food, water and other essential resources, animals aggregate in clumped distributions based on specific landscape and biotic features of an environment. It has been demonstrated across a variety of taxa that animals forage for patchily distributed resources according to an energy-maximizing strategy, balancing the tradeoff between the benefits of obtaining energetic gain and the costs of searching. For social species, seeking out conspecifics and effectively attending to and interpreting the social signals of others are critical to reproduction and survival. However, it remains unknown how animals forage for social information. To determine whether social information foraging behavior resembles nonsocial resource foraging behavior, we investigated how rhesus macaques (*Macaca mulatta*) forage for social emotions of conspecific faces. Monkeys completed a virtual social foraging task in which they explored environments containing patches of social information. While foraging, monkeys could explore and exploit specific social information by selecting targets mapped onto emotional valence of conspecific faces that were revealed upon selection. Monkeys could also choose to leave the current patch for a new patch at any time by selecting a travel bar, which indicated randomly varied travel delay length (time to a new patch). Monkeys had a consistent preference for negative-valence targets, selecting them substantially more and earlier within a given environment, suggesting an intrinsically greater informational value of negative-valence images relative to positive-valence images. Looking behavior at facial regions of interest (ROIs: whole face, eyes, mouth) differed significantly for negative- and positive-valence images. Furthermore, between-subject differences in looking time within ROIs reflected differences in social information gathering strategies or social reward valuation by the social status of foragers. We used the Marginal Value Theorem (MVT; Charnov, 1976, Theor Popul Biol), an optimality model that describes the behavior of an animal foraging among patches of resources, to assess whether monkeys foraged for social information using an optimal strategy. Patch residence times during social foraging increased with longer travel delay times, which is consistent with MVT. Our results indicate that social information foraging obeys MVT, suggesting that some of the neural computations used for nonsocial resource foraging (Hayden et al., 2011, Nat Neurosci) may underlie decisions concerning the tradeoff between the benefits of obtaining social information and the search costs.

Title: In economic choices between bundles of goods monkeys satisfy basic assumptions of revealed preference theory

Authors: *A. PASTOR-BERNIER, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: HYPOTHESIS This study assesses trading behavior in non-human primates using formal concepts of revealed preference theory in economics. We investigated how rhesus monkeys handle rewards in a manner that presages the use of bundles in human economic choices. Are their choices compatible with the notion of giving up one good in order to obtain another good? Does this behavior satisfy basic properties of revealed preference theory? GOAL We studied choices between bundles of two juices that allowed the animals to give up some quantity of one in order to gain one unit of the other without a change in overall utility. The bundles contained a common juice (blackcurrant) and one of several other juices such as grape, strawberry, water, blackcurrant juice itself, apple squash, lemon juice, yoghurt, salt (NaCl) solution, and combinations with monosodium glutamate (MSG) and inosine monophosphate (IMP). The different quantities of the two bundle goods combining to the same utility can be graphed as indifference curves, which are didactically a central concept in microeconomics. METHOD Monkeys chose between two bundles by touching specific stimuli on a touch-sensitive monitor. Each bundle contained the same two juices (e.g. blackcurrant and grape) whose quantity was indicated by the height of a bar within a vertical rectangle. One bundle was composed of a fixed quantity of each juice (reference). The other bundle (variable) had a specifically set quantity of grape juice and a quantity of blackcurrant juice that was varied psychophysically to determine choice indifference between the two bundles (50%±5%). Then we increased the quantity of grape juice by one unit (0.1 ml) in the variable bundle and determined psychophysically the quantity of blackcurrant juice that was necessary for regaining choice indifference against the unchanged reference bundle. In this way, we tested how much blackcurrant juice the animal was ready to give up in order to gain one additional unit of grape juice (‘marginal rate of substitution’) without changing overall utility. RESULTS We established at total of 52,500 indifference points in 11 and 4 different bundles in monkeys A and B, respectively (about 3,500 indifference points per bundle type and indifference map per animal). We determined empirically maps of indifference curves with different utility levels and derived the marginal rate of substitution of several juices against blackcurrant juice. Choices made along the indifference curves were internally consistent, transitive and satisfied GARP (Generalized Axiom of Revealed Preferences)

Title: Dynamic integration of reward parameters into economic decision variables by single neurons in the monkey amygdala

Authors: *F. GRABENHORST[1], R. BAEZ-MENDOZA[2], W. SCHULTZ[1];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Neurosurg., Harvard Med. Sch., Boston, MA

Abstract: Recent neurophysiological data suggest a role for the primate amygdala in economic decisions, beyond its known functions in fear and reward. A fundamental process in economic decision-making is the formation of a decision variable, based on the integration of different reward parameters. Here we tested whether individual amygdala neurons extract information about two principal reward parameters—probability and magnitude—from sequential visual cues, and integrate this information into economic decision parameters, including expected reward value and reward (variance) risk. We recorded the activity of 483 amygdala neurons while two monkeys viewed sequential stimuli that signaled separately the probability and magnitude of upcoming liquid rewards. On each trial, probability and magnitude cues were drawn randomly from a set of 15 combinations, thus requiring flexible, dynamic integration. Sequential, non-overlapping cue presentation separated the influence of probability and magnitude information on neuronal responses and allowed us to test their integration over the timecourse of single trials. Behavioral data confirmed accurate reward expectation based on probability and magnitude cues and choice sensitivity to expected value and risk. During sequential presentation of probability and magnitude cues, a significant number of amygdala neurons encoded the cued reward parameter (probability: 105/483 neurons, 22%; magnitude: 125/483 neurons, 26%). Over sequential cue phases, about half of the neurons with initial probability encoding subsequently encoded reward magnitude (and vice versa). Thus, individual neurons processed both probability and magnitude dynamically over time, consistent with potential integration of these reward parameters. As soon as probability and magnitude cues had been shown, a substantial number of neurons (95/483, 20%) encoded either the expected value or risk of the upcoming reward outcome. Crucially, these parameters were not explicitly cued but had to be computed internally based on cued probability and magnitude information. Some of these neurons seemed to explicitly reflect this internal computation, as they showed dynamic

coding transitions that linked initial probability and magnitude signals with subsequent expected value or risk signals. These data suggest that individual amygdala neurons flexibly and dynamically integrate basic reward parameters into economic decision variables.

Title: Eliciting values with the Becker De-Groot-Marschak method (BDM) in non-human primates.

Authors: *A. AL-MOHAMMAD, W. SCHULTZ;
Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Objectives
Current methods of estimating economic (reward) value in animals require repeated choices - thus, values are inferred over the course of many trials. We sought to bring one of experimental economics' most powerful tools of value estimation, providing trial-by-trial value estimates, to research in non-human primates: the Becker De-Groot Marschak method (BDM).
In the BDM, subjects bid for a reward against a computer. If the subject's bid is higher than the computer's then they receive the reward and pay an amount equal to the computer's bid. If the subject's bid is lower than the computer's, then they pay nothing but do not receive the reward. Hence, the BDM is strategically equivalent to a 'second-price' auction, and given few assumptions regarding the subjects' preferences, the optimal strategy is to bid one's true value.
Method
Macaque (rhesus) monkeys were trained in a BDM analogue. They learnt that the area of a bar stimulus on a computer display represented a given volume of juice A (the 'currency' with which to bid), and that a second fractal stimulus represented a given volume of juice B (the reward to bid for).
Monkeys used a joystick to move a red marker across the bar stimulus, its resting location indicating their bid. A second, green, marker appeared to indicate the computer's bid. In the event of a winning bid, an area from the bottom of the bar to the computer's bid was occluded, indicating the volume of 'currency' juice that had been paid - the animal then received the

remaining currency (corresponding to the un-occluded area of the bar), and the reward (indicated by the fractal). In the event of a losing bid, the fractal disappeared (as the reward had not been won), and the animal received all of the 'currency' juice available for that trial, as no 'payment' had been made.
We compared each animal's BDM valuation using an equivalent binary choice task, which estimated subjective values for the various rewards used in the BDM (juice B) in units of the currency used in the BDM (juice A) - thereby checking the validity of values elicited in the BDM.

Results

Data from two animals suggests that the BDM can produce ranking of rewards by order of preference, in both continuous and discrete versions of the task, and with several reward and currency combinations.
Whilst rankings were the same in the BDM and binary choice tasks, absolute values elicited in the two tasks differed. We altered the distribution of computer bids to increase the costs of sub-optimal bidding and observed more consistent bidding following this manipulation. Control tests confirmed that reward value is the main driver of bids in the first monkey, and are currently being tested in the second monkey.

Title: Investigating the role of the prefrontal cortex in central amygdala-induced risky decision-making

Authors: *R. TOM[1], M. J. F. ROBINSON[2];
[2]Neurosci. & Behavior; Psychology, [1]Wesleyan Univ., Middletown, CT

Abstract: Addiction is characterized by a focused, intense pursuit of one reward above all others, even despite a risk of adverse consequences. The compulsive pursuit of reward has been shown to involve structures in the mesolimbic dopaminergic pathway of the brain. The central amygdala (CeA) plays a role in this pathway, and optogenetic stimulation (ChR2) of this area has previously been shown to assign an increased value to the reward with which it is paired (Robinson et al., 2014).
Our current research shows that rats will continue to pursue CeA stimulation-paired reward, even

when associated with a risk of foot shock. This behavior is thought to come from excessive motivation for disadvantageous reward, and an inability to restrain this motivation. One proposition is that while the CeA may be responsible for the former, the prefrontal cortex (PFC) is critical for the latter, as evidenced by studies showing that drug addiction can cause a reduction in PFC gray matter volume as well as hypoactivity of PFC neurons (Chen et al., 2013). If loss of inhibitory control in the ChR2-CeA rats is in part due to decreased functioning in the PFC, then a restoration of PFC activity should decrease risk-taking behavior (Chen et al., 2013). Here, we investigated this both through amphetamine administration as well as stimulation mediated by designer receptors exclusively activated by designer drugs (DREADDs). Rats are initially trained on an operant task in which they can choose to press either of two levers: one delivering a sucrose pellet, and the other delivering a sucrose pellet and laser stimulation of the CeA. After establishing a >95% preference for the laser-paired reward, conditions are changed such that the lever that previously delivered a sucrose pellet + CeA laser stimulation, is now also associated with a probabilistic risk of foot shock. Animals are then tested with and without stimulation of the PFC (via amphetamine or DREADDs) to demonstrate the impact of PFC stimulation on CeA-driven risky decision-making. These experiments will provide further insight into the role of the CeA in risky decision-making, and the potential moderation of these decisions by the PFC.

Title: Primed cues and optogenetic inhibition of the frontal cortex generate shifts in risky decision-making

Authors: *C. FREELAND[1], A. AHUJA[2], F. G. AYRES[2], M. J. F. ROBINSON[3];
[1]Biol. and Psychology Dept., [3]Neurosci. & Behavior and Psychology Dept., [2]Wesleyan Univ., Middletown, CT

Abstract: Adaptive decision-making involves successfully weighing potential benefits against negative consequences when picking between risky and safe choices. However when the underlying neural systems become skewed to favor risky outcomes, this can lead to unhealthy behaviors and even addiction. Both past memories and internal neural mechanisms affect our ability to make rational decisions in the moment. Previous research has shown that human participants primed with cues previously paired with large risky wins are more likely to choose the riskier option. Imaging studies have also shown that the frontal cortex, particularly the anterior insular cortex (AIC) and orbitofrontal cortex (OFC), are implicated in risky decision-making. Yet little is known about how decisions are made moment-to-moment especially in the face of uncertainty and risk. In this study, we examined how priming with either win and loss cues and activity in specific brain regions influence risky decision-making. First, rats were trained on an operant task that required them to choose between a risky option that offered a large but uncertain (50%) reward and a safe option that offered a small but certain (100%) reward. Each possible outcome (small safe win, large risky win and risky loss) was accompanied by one of three distinct auditory cues. After training, rats completed a testing phase in which the auditory cues preceded (primed) each choice trial but were not predictive of the reward outcome. We found that rats chose the risky option significantly more often following primed win cues and less often following loss cues. Additionally, female rats appeared to be more sensitive to primed cues than males. Next, to pinpoint the role of the AIC and OFC in the decision-making process, we utilized the temporal sensitivity afforded by optogenetics to inhibit these structures at brief specific time points. Following the same operant training regimen, optogenetic inhibition was administered during the task in three possible ways (pre-choice, post-choice following risky win trials and post-choice following risky loss trials) at each site on separate testing days. Our findings suggest that inhibiting the AIC either prior to choice, or post-choice on risky win trials, significantly shifted risky preference. This suggests that the AIC may be involved in decision-making ‘in the moment’ by tracking win outcomes. Together these results begin to uncover the interplay of environmental cues and neural systems that affect our choices under conditions of uncertainty and risk.

Title: Optogenetic modulation of desire and dread motivations in the nucleus accumbens shell

Authors: *S. L. COLE, N. A. MOSTOVOI, K. C. BERRIDGE;
Univ. of Michigan, Ann Arbor, MI

Abstract: The nucleus accumbens (NAc) shell is famous for reward, but also can generate fearful behaviors following an anatomical 'desire-dread' rostrocaudal pattern. This is revealed by microinjections that relatively inhibit NAc neurons (e.g., DNQX). Here, we tested whether neuronal inhibition is crucial, by using optogenetic *depolarization* to combat DNQX-inhibition at the same NAc site. Our results suggest this is possible: channelrhodopsin (ChR2) depolarization of NAc neurons reduced eating behavior elicited by DNQX microinjection at the same site in rostral shell. Further, laser ChR2 depolarization had to overlap with microinjection site to reduce DNQX-induced eating. Finally, we are testing whether optogenetic inhibition via halorhodopsin is sufficient by itself in rostral shell to induce eating behavior. Preliminary results suggest the answer is yes: in a laser stimulation-bound fashion, laser *hyperpolarization* induces intense bouts of eating. Together, these findings demonstrate that NAc hyperpolarization is both necessary for DNQX-mediated motivation and sufficient to produce intense motivated behavior.

Title: Disgust and brain areas activated by pharmacologic inhibition of the posterior ventral pallidum

Authors: *K. URSTADT, H. A. KHAN, N. M. RABAH, K. C. BERRIDGE;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Pathologically excessive disgust can induce negative affect and emotional distress in certain psychiatric disorders, driving research to understand the neural substrates of disgust. The posterior lateral ventral pallidum (plVP) is the only brain area wherein lesions produce pathological disgust, thereby converting normal liking of sucrose to disgusted gapes. However, few other disgust generators in the brain have been identified; these may be disinhibited by plVP inhibition. We highlighted activation of such disgust generator candidates via c-fos immunohistochemistry. We also observed how plVP inhibition alters multiple behaviors. A muscimol and baclofen cocktail (MB) or vehicle was injected directly into the plVP of adult male and female Sprague-Dawley rats. MB treatment strongly increased c-fos expression in posterior accumbens shell, lateral hypothalamus, supramammilary nucleus, substantia nigra, parabrachial nucleus, and paraventricular thalamus. MB treatment also induced gaping, flailing, and hyperkinetic treading responses to oral sucrose solution, suppression of palatable M&M intake, increased social avoidance, and increased bedding treading and head burying behaviors. These data suggest that the plVP regulates an assortment of disgust and avoidance responses, and does so through multiple downstream brain regions that could serve as generators of disgust. Future studies will probe the plVP further with inhibitory DREADD and optogenetic techniques.

Title: Central amygdala controls choice and amplifies 'wanting' for sucrose and cocaine without altering 'liking'

Authors: *S. M. WARLOW[1], D. C. CASTRO[2], E. E. NAFFZIGER[1], K. C. BERRIDGE[1]; [1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Anesthesiol., Washington Univ. in St. Louis, St. Louis, MO

Abstract: We have previously found that optogenetic stimulation of central amygdala (CeA) but not basolateral amygdala can powerfully bias a rat's choice and increase their motivation for one sucrose reward over another. However, it is unknown how CeA stimulation is generating such a strong bias. One possibility is that the outcome of sucrose is being enhanced. In other words, CeA stimulation is making the sucrose more 'liked'. We tested this possibility by using a taste reactivity test, which assesses the hedonic impact of various tests. We infused a 1% sucrose solution into the mouths of rats via intraoral cannulas while also delivering optogenetic CeA stimulation or not (baseline). We observed no changes in positive (or negative) affective orofacial reactions in response to sucrose in the presence of laser stimulation. This indicates that CeA stimulation was not enhancing incentive motivation by making the sucrose more 'liked', and instead selectively making the sucrose more 'wanted', or desired in the same rats. Further, when pairing CeA stimulation with earning one cocaine infusion (0.3mg/kg/infusion) vs. an identical infusion not paired with laser, rats intensely bias their choice and display increased motivation for CeA-paired cocaine. We additionally observed for the first time numerous consummatory bite, nibble, and sniff actions directed only at the CS nose port delivering CeA stimulation with cocaine. Since CeA stimulation is capable of biasing and enhancing incentive motivation, we next asked whether CeA stimulation could control which reward gets 'wanted' most. We arbitrarily paired CeA stimulation with earning either a sugar pellet or a cocaine infusion (0.3mg/kg/infusion), and gave rats a choice between the two rewards in the same session. We are also exploring the role of CeA subdivisions in enhancing and biasing incentive motivation. We selectively stimulated either medial or lateral portions of CeA during an operant task where rats chose between a laser-paired sucrose and an identical sucrose not paired with laser. These experiments have the potential to highlight specific central amygdala circuitry capable of generating focused desire for reward in an addictive-type fashion.

Title: Optogenetic stimulation of the medial amygdala biases choice and enhances motivation for sucrose

Authors: *E. E. NAFFZIGER, S. M. WARLOW, K. C. BERRIDGE;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: It has previously been shown that optogenetic stimulation of the central nucleus of the amygdala (CeA) can powerfully bias choice and enhance motivation for the delivery of a laser-paired sucrose pellet over delivery of an identical sucrose pellet. These findings were confined to the CeA, as similar photostimulation of the basolateral amygdala failed to elicit a bias for the sucrose pellet paired with laser stimulation. However, whether the medial nucleus of the amygdala (MeA), which shares several neuroanatomical similarities with the CeA, would similarly alter choice is unknown. We report novel data indicating that the MeA, comparable to the CeA, is capable of biasing choice and enhancing motivation for a sucrose reward that has been paired with MeA photostimulation. Preliminary evidence suggests that photoexcitation of the MeA by itself may be sufficient to establish self-stimulation behavior in at least some individuals. Together this data indicates that while the MeA is also capable of focusing choice and enhancing motivation for a sucrose reward, it may be doing so via somewhat different psychological mechanisms than the CeA.

Title: Optogenetic stimulation of the median raphe nucleus produces anxiety-like behavior

Authors: *A. R. ABELA[1], C. J. BROWNE[1,2], A. D. LÊ[1], P. J. FLETCHER[1];
[1]Psychology, CAMH, Toronto, ON, Canada; [2]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: There is a large body of evidence indicating that serotonin (5-hydroxytryptamine; 5-HT) neurons originating in the midbrain raphe nuclei contribute to the regulation of stress and anxiety. In laboratory animals, anxiety-like behavior is assessed using tests of approach-avoidance conflict in an innately fear-provoking context (e.g., a rodent's preference for a safe, closed space over a vulnerable, open space). Pharmacological and genetic manipulations that impair the action of the serotonin transporter in rodents (thereby enhancing 5-HT activity) induce avoidance of open spaces (Olivier et al., Neuroscience, 2008; Drapier et al., Behav Brain Res, 2007). A similar anxiogenic response is produced by lesions of the median raphe nucleus (MRN)—a major source of 5-HT output to the rest of the brain (Andrade and Graeff, Pharm, Biochem and Behav, 2001). However, pharmacological manipulations often produce non-selective receptor activity at other targets, or in the case of genetic knock-out animals, there is the possibility of compensatory mechanisms that occur during development. We examined whether optogenetic stimulation of 5-HT neurons originating in the MRN modulated the expression of anxiety-like behavior in three approach-avoidance contexts: 1) the elevated-plus maze, 2) novelty-suppressed feeding, and 3) the open-field test. The optogenetic construct was created through expression of channel rhodopsin (ChR2) under the control of a serotonergic cre-driver, using a cross-breeding procedure of two mouse lines. Ai32 mice, which express ChR2 in response to cre recombinase through excision of an upstream floxed-STOP cassette, were crossed with ePet-cre mice producing ChR2 expression restricted to 5-HT neurons. A chronically implanted optical fiber enabled delivery of 10 ms pulses of 10 mW blue light to the MRN. Optogenetic stimulation of the MRN at 4 Hz for 3 min caused animals to avoid the open arms of the elevated-plus maze, a behavior that was not observed in other periods absent of stimulation. Continuous optogenetic stimulation increased the latency at which animals investigated and consumed food in a novel context, but not when the context was familiar. In the open field test, optogenetic stimulation of the MRN had no effect on the amount of time spent in the centre, the distance travelled or the average speed of the animals. These results demonstrate that 5-HT output from the MRN rapidly regulates the expression of anxiety-like behaviors, in contexts that innately illicit fear and approach-avoidance conflict. Future studies will examine how 5-HT output from the MRN interacts with specific downstream structures to produce these changes in behavior.

Title: Effects of pharmacological, genetic, and optogenetic enhancement of serotonin activity on responding for a primary reinforcer

Authors: *C. BROWNE[1,3], X. JI[3], P. J. FLETCHER[1,2,3];
[1]Psychology, [2]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [3]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Serotonin (5-hydroxytryptamine; 5-HT) neurons originating in the midbrain raphe nuclei innervate virtually the entire brain and have been implicated in the control of many behavioural processes. A large body of evidence suggests that reward-related behaviours are particularly sensitive to changes in 5-HT activity. Manipulations that increase 5-HT typically reduce behaviours such as operant responding for primary reinforcers, while these behaviours are potentiated following decreases in 5-HT activity. While the mechanism of this serotonergic inhibition of motivated behaviour is unknown, it is hypothesized to involve 5-HT neurons in the dorsal raphe nucleus (DRN) that densely innervate brain regions involved in reward processing. In these experiments, we first examined the effects of acute or chronically elevated whole-brain 5-HT on lever pressing for the primary reinforcer saccharin (0.2%, 0.1 ml) on an RR4 schedule of reinforcement in mice. Acute blockade of the serotonin transporter (SERT) with 10 mg/kg of the selective 5-HT reuptake inhibitor citalopram significantly reduced responding for saccharin. Similarly, mice with a constitutive genetic deletion of the SERT (SERT-KO), which chronically elevates extracellular 5-HT, made fewer responses for saccharin compared to wild-type littermates. Next, we examined whether optogenetic activation of DRN 5-HT neurons could recapitulate the inhibitory effects elevated 5-HT on responding for saccharin. To generate this optogentic construct, Ai32 mice which express ChR2 through cre-mediated excision of an upstream floxed-STOP cassette were crossed with the serotonergic cre-driver line ePet-cre. A chronically implanted optical fiber enabled delivery of 10 ms pulses of 10 mW blue light to the DRN. Photostimulation of the DRN had no effect on responding for saccharin at a range of different frequencies (1, 5, 10, 20 Hz). However, when 10 Hz DRN stimulation was coupled with a subthreshold dose of 5 mg/kg citalopram, a significant reduction in responding for saccharin compared to citalopram-treated control mice was observed. Temporal analysis of the test sessions found that this effect was largely due to the combination of citalopram and DRN

photostimulation changing the overall pattern of behaviour. Together, these results implicate DRN 5-HT output in the control of incentive motivation, but suggest that these effects may be dependent upon an interaction between SERT function and levels of extracellular 5-HT, as opposed to frequency modulation of DRN 5-HT neurons.

Title: Serotonin exerts tonic inhibitory control over mesolimbic dopamine release and dopamine-dependent behaviour through the 5-HT_{2C} receptor.

Authors: ***C. HARVEY-LEWIS**[1], C. J. BROWNE[1,2], T. JI[1], G. A. HIGGINS[3,4], P. J. FLETCHER[1,2,3];
[1]Biopyschology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Pyschology, [3]Pharmacol., Univ. of Toronto, Toronto, ON, Canada; [4]Intervivo Solutions, Toronto, ON, Canada

Abstract: The serotonin 2C (5-HT_{2C}) receptor system is hypothesized to influence reward-related processes through modulatory control of the mesolimbic dopamine (DA) system. Previous studies have shown that 5-HT_{2C} receptor agonists decrease mesolimbic DA activity and dopamine-dependent behaviors. Similar studies have shown that 5-HT_{2C} antagonists can increase mesolimbic DA release, but it is unknown whether this has any direct influence on behaviour. Here we confirm the effects of the 5-HT_{2C} antagonist, SB242084, on nucleus accumbens DA release and investigate the effect of SB242084 on two dopaminergic-dependent behaviors - responding for a conditioned reinforcer (CRf) and locomotor activity. For microdialysis experiments, one group of mice received guide cannula implants above the nucleus accumbens, through which a dialysis probe was inserted into the accumbens one week later. In chronically anesthetized mice, dialysate samples were collected prior to, and following, an IP injection of 0.5mg/kg SB242084 or vehicle and analyzed online using high performance liquid chromatography. Two additional groups of mice were used for behavioral experiments. One group of mice received 5 days of habituation to locomotor chambers. Following training, animals were treated with SB242084(0-1mg/kg) 20min prior to locomotor testing. The other group of

mice was given 14d of Pavlovian conditioning during which a CS was paired with the delivery of 0.1ml 0.2% saccharin. Subsequently, mice were given the opportunity to lever press for the presentation of the CS (now a CRf) without saccharin. Animals were given SB242084 (0-1mg/kg) 20-min prior to tests on this task. In a second series of tests, this group of animals received the broad-spectrum DA receptor antagonist flupenthixol (0.25mg/kg) prior to SB242084 (0.5mg/kg) and were then allowed to respond for a CRf. We found that SB242084 caused approximately a 20% increase in nucleus accumbens dopamine concentration when compared to preinjection baseline. Behaviorally, SB242084 caused significant increases locomotor activity and CRf-directed responding. In addition, treatment with a silent dose of flupenthixol blocked the SB242084 induced increases in responding for a CRf. Together, these results provide support the ability of serotonin to tonically suppress mesolimbic DA activity and DA-dependent motivated behavior through the 5-HT_{2C} receptor.

Title: Contribution of nucleus accumbens core cholinergic interneurons to cue-motivated behavior

Authors: *A. L. COLLINS[1], T. J. AITKEN[1], S. B. OSTLUND[2], K. WASSUM[1,2];
[1]UCLA, Los Angeles, CA; [2]UCI, Irvine, CA

Abstract: Environmental reward-predictive stimuli provide a major source of motivation for reward-seeking behaviors. Considerable evidence has implicated the nucleus accumbens core (NAc) and dopamine signaling therein in cue-motivated behavior, but relatively little is known about how other striatal neuromodulatory systems contribute. Our recent data suggest that the NAc cholinergic system may also critically modulate cue-motivated behavior, possibly through terminally modulating dopamine release. Cholinergic interneurons (CINs) provide the main source of acetylcholine to the striatum, and their activity has been shown to be elevated in

situations that discourage vigorous reward seeking and depressed in response to reward-predictive cues, which encourage reward seeking. These data suggest that NAc CIN activity may gate the expression of cue-motivated behavior, having a suppressive effect when elevated and a permissive effect when depressed. To test this, we examined the causal role of CIN activity in cue-motivated behavior using the Pavlovian-to-instrumental transfer (PIT) task designed to assess the motivating influence of a reward-predictive cue (CS+) over an independently-trained instrumental action. CIN activity was optically stimulated concurrent with CS+ presentation and this was compared to the influence of CIN stimulation unpaired with CS+ presentation. Findings that CIN stimulation blunts CS+-invigorated reward seeking will provide causal support the above hypothesis.

Title: Contribution of nucleus accumbens core cholinergic interneuron tonic activity to cue-motivated behavior

Authors: ***T. AITKEN**[1], A. L. COLLINS[1], S. B. OSTLUND[2], K. M. WASSUM[1,2]; [1]Psychology, UCLA, Los Angeles, CA; [2]UCI, Irvine, CA

Abstract: Environmental reward-predictive stimuli provide a major source of motivation for reward-seeking behaviors. Considerable evidence has implicated the nucleus accumbens core (NAc) and dopamine signaling therein in cue-motivated behavior, but relatively little is known about how other neuromodulatory systems contribute. Our recent data suggest that the NAc cholinergic system may also critically modulate cue-motivated behavior, possibly through terminally modulating dopamine release. Cholinergic interneurons (CINs) provide the primary source of acetylcholine acting at these receptors and activity of these neurons has been shown to correlate with the presentation of reward-predictive stimuli, motivated behavior, and satiety. Therefore, here we examined the function of these NAc CINs in cue-motivated behavior using a

Pavlovian-to-Instrumental transfer (PIT) task designed to assess the motivating influence of a food-predictive cue over an independently-trained, instrumental, food-seeking action. Inhibitory DREADDs were used to inactivate NAc CINs during a PIT test while rats were either hungry or sated. Preliminary data indicate that attenuation of NAc CIN activity augmented cue-induced invigoration of reward seeking, suggesting that NAc CIN activity may gate the expression of cue-motivated behavior. Follow-up tests are exploring additional functions of the NAc CINs in motivated behavior and are examining a possible dopaminergic mechanism for this effect.

Title: Estrous cycle phase modulates cue-triggered motivation for food in obesity-prone but not in obesity-resistant rats

Authors: *Y. ALONSO CARABALLO[1], C. R. FERRARIO[2];
[1]Neurosci. Grad. Program, [2]Dept. of Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: In females, naturally occurring alterations in estradiol influence food intake and food preference. However, how the cycle alters motivation for food is poorly understood. Furthermore, weight gain disrupts the reproductive cycle and is associated with enhanced motivation for and consumption of sugary, fatty foods, particularly in obesity-susceptible individuals. Here, we determined how food intake and motivation for food vary across the estrous cycle in female obesity-prone vs. obesity-resistant rats. Rats were housed in reverse light/dark conditions, weight was measured daily, and vaginal lavage was used to determine estrous cycle phase. Home cage food intake was measured for 13 days in singly housed females (Lab Diet 5001). Changes in motivation across the cycle were examined in a separate set of pair housed females using Pavlovian conditioned approach procedures. Specifically, rats were trained to associate one auditory cue (CS+; 2 min) with sucrose delivery (45 mg pellets; TestDiet) whereas a second cue (CS-; 2 min) was never paired with sucrose (5 sessions, 1 session/d). Rats

were then repeatedly tested for conditioned approach, a measure of motivation, at each stage of the cycle. The test consisted of 4 presentations of the CS+ and CS- in the absence of sucrose. We found that daily home cage chow consumption and body weight were greater in female obesity-prone vs. obesity-resistant rats. Estrous cyclicity was similar between groups. In addition, home cage food intake during estrus decreased in all rats. When motivation was examined, we found that the estrous cycle modulates conditioned approach behavior in obesity-prone but not obesity-resistant rats. Specifically, the magnitude of approach to the CS+ was reduced in proestrus and estrus compared to diestrus in obesity-prone rats, but remained stable across the cycle in obesity-resistant rats. This was somewhat surprising given that home cage food intake and weight decreased during estrus in both groups. Furthermore, when comparisons were made between obesity-prone and -resistant groups, we found that the magnitude of approach behavior during the CS+ tended to be higher in obesity-prone vs obesity-resistant rats. This difference was most pronounced during proestrus and metestrus, when motivation was highest in obesity-prone rats. In rats and humans, enhanced motivational responses to stimuli paired with food predict subsequent weight gain. The data here suggest that motivation for and consumption of food is enhanced in female obesity-prone rats, and that the ability of naturally occurring changes in hormonal levels to modulate motivation is also enhanced relative to obesity-resistant rats.

Title: Calcium-permeable AMPA receptors in the nucleus accumbens mediate cue-triggered food-seeking in obesity-prone rats.

Authors: *R. C. DERMAN[1], C. R. FERRARIO[2];
[2]Pharmacol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Studies in humans and rats show that obesity-susceptible individuals are more sensitive to the motivational impact of stimuli associated with food (i.e., conditioned stimuli). Using Pavlovian-to-instrumental transfer (PIT), a classic measure of the motivational strength of

conditioned stimuli (CS), we found that selectively bred obesity-prone (OP) rats exhibit enhanced PIT relative to obesity-resistant (OR) rats. The expression of PIT relies on activation of the NAc and AMPARs provide the main source of excitation to the NAc. Here, we measured NAc AMPAR subunit expression after initial training and the effect of intra-NAc AMPAR blockade on the expression of PIT. Male OP and OR rats learned to press a lever to earn food pellets (Bioserv). Next, in Pavlovian training, they learned to discriminate between an auditory CS+ that was always paired with food and a CS- that was never paired with food. A set of untrained control rats were handled daily. After training or control handling, NAc tissue was collected and cross-linked with BS^3 enabling the comparison of surface vs. intracellular proteins. Thus, these data provide a "snapshot" of AMPAR expression corresponding to the time when PIT testing would normally occur. For intra-NAc infusion studies, rats were trained as described above. Following training they were surgically implanted with bilateral guide cannulae aimed at the NAc core. Rats were given 2 additional instrumental and Pavlovian training sessions before PIT testing. Rats were tested repeatedly after intra-NAc infusion of vehicle, Naspm (20ug/0.5ul) a selective antagonist of calcium-permeable AMPARs (CP-AMPAR), or the general AMPAR antagonist CNQX (0.5ug/ul), in a counter-balanced design. During PIT testing, pellet delivery was omitted, levers were continuously available, and each CS was presented 4 times. We found that training increased NAc surface vs intracellular GluA1 expression in OP, but not OR rats. No changes were found in GluA2 expression in either group. An increase in GluA1 without changes in GluA2 suggests an increase in CP-AMPARs, as these receptors lack the GluA2 subunit. During PIT testing, we found that CNQX produced a general reduction in lever pressing in OR rats, but did not disrupt the selective invigoration of lever pressing by the CS+ (i.e., PIT), while CNQX had no effect in OP rats. In contrast, Naspm eliminated PIT in OP rats, but had only modestly effects in OR rats. Together, our data show that training selectively increases NAc CP-AMPARs in OP but not OR rats and that NAc core CP-AMPARs selectively mediate the expression of PIT, a form of cue-triggered motivation. Finally, effects of CP-AMPAR blockade were more pronounced in OP rats.

Title: Representation of contextual information in cortico-basal ganglia circuits during motor timing

Authors: *E. HOSSEINI[1], J. WANG[2], M. JAZAYERI[1,2];
[1]Brain and Cognitive Sci., [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Humans and animals can flexibly adjust their motor plans based on behavioral context. The cortico-basal ganglia circuits have been implicated in controlling context-dependent motor planning. However, the representation of behavioral context across these circuits is not well understood. To address this question, we recorded neural activity from multiple nodes of the circuit including the dorsal medial frontal cortex (dMFC), caudate (Cd) and central/motor thalamus (Thal) in rhesus monkeys trained to produce time intervals in a context-dependent manner. The behavioral task, which we refer to as the Cue-Set-Go (CSG) task, consists of four randomly interleaved trial types in which the animal produces either a "Short" (800 ms) or a "Long" (1500 ms) interval by either a saccade or a manual button press (2 Intervals x 2 Effectors). Each trial begins with the "Cue" period when the animal fixates on a central spot and places a hand on a button. The color and shape of the fixation point provide information about the Interval and Effector, respectively. After a variable delay, a "Set" flash around the fixation point cues the animal to initiate timing. The animal receives reward for initiating the movement with the correct effector and producing an interval that is close to the desired interval. The reinforcement schedule is adjusted throughout the session so that the animal receives reward on approximately half of the trials, and the magnitude of the reward increases with accuracy. Animals were able to perform the task and switch between contexts on a trial-by-trial basis.
We focused our analysis on the representation of the behavioral context. Our initial analysis revealed idiosyncratic selectivity patterns at the level of single neurons in all three areas with no discernible tuning for Effector or Interval. However, there were overall biases in the representation of Interval and/or Effector at the population level that were similar across areas, despite the diverse selectivity patterns of individual neurons. A hierarchical clustering analysis at the population level provided further evidence for the similarity of context representation across areas. Using dimensionality reduction techniques, we found that the two contextual axes (Interval and Effector) were represented in nearly orthogonal subspaces in the caudate, but not in other areas. This observation suggests that the caudate might play a unique role in maximizing the distance between possibly confusable contexts.

Title: Scalar dynamics in neural activity during timing

Authors: *J. WANG, E. HOSSEINI, M. JAZAYERI;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Human can produce different time intervals in a range of behaviors such as speech production, playing music and sports. Converging evidence suggests an important role for the cortico-basal ganglia circuits in motor timing. However, the coding principles by which these circuits support timing behavior is not known. To address this question, we performed electrophysiology experiments in monkeys trained to perform a motor timing tasks, which we refer to as the Cue-Set-Go (CSG) task. The CSG task consists of four randomly interleaved trial types in which the animal produces either a “Short” (800 ms) or a “Long” (1500 ms) interval by either a saccade or a button press. To initiate a trial, the animal is required to fixate a central spot and place a hand on a button. After a variable delay, a “Set” flash cues the animal to start timing. The animal has to initiate a motor response (Go) around the desired interval with the correct effector to receive reward. Animals were able to switch between Effector and Interval on a trial-by-trial basis. Average production intervals were close to the desired intervals and the variability for both effectors scaled with the interval duration (i.e., scalar variability).
We recorded neural activity in multiple nodes of the cortico-basal ganglia circuits including the dorsomedial frontal cortex (dMFC), the putative target of dMFC in the caudate, and the putative target of basal ganglia in the central thalamus. We analyzed neural activity associated with the production interval between Set and Go. In all three areas, individual neurons had heterogeneous responses and were strongly modulated by elapsed time. Remarkably, the response profiles of many neurons were similar after compressing or stretching the time axis to match the produced interval. We refer to this property as scalar dynamics. Dimensionality reduction of response profiles provided additional evidence for scalar dynamics at the population level, in particular in dMFC and the caudate. The scalar dynamics might be the key factor driving the scalar variability in timing behavior. Moreover, the ability to scale the neural responses on a trial-by-trial basis

puts important constraints on the architecture and mechanisms of cortico-basal ganglia circuits involved in timing.

Title: Amount of training affects CS-evoked neural activation pattern: Implication for a shift in nature of associatively-activated event representation over the course of conditioning

Authors: *H.-Y. KOH[1,2], H.-J. KIM[1,2];
[1]Korea Inst. of Sci. & Technol., Seoul, Korea, Republic of; [2]Dept. of Neurosci., Korea Univ. of Sci. and Technol. (UST), Daejon, Korea, Republic of

Abstract: In associative learning, a conditioned stimulus (CS) comes to activate an internal representation of the unconditioned stimulus (US) with which it is paired, and this representation can serve for acquisition of new learning about US. CS (odor)-evoked representation of a US (sugar) can substitute for the actual US itself in the acquisition of an aversion to that US, which is called representation-mediated taste aversion (RMTA). In our previous study using mice, we have shown that RMTA occurs only transiently in the early stage of the initial CS-US conditioning, and CS-nausea pairing can no longer establish an aversion to the US later with extended initial conditioning. It is proposed that the nature of CS-evoked US representation changes over the course of training, in that CS-evoked US representation contains the sensory component available for RMTA learning with a minimal initial training, but no longer does with an extended initial training. Here, we report an evidence for this change of nature of CS-evoked US representation by showing differential patterns of CS-evoked neural activation in brain regions (e.g. insular cortex, IC; nucleus accumbens, NAcc, etc.) using c-Fos immunohistochemistry. In the minimal training condition, rewarded odor (+Odor) induced significantly higher level of c-Fos expression than unrewarded odor (-Odor) in IC, which includes gustatory cortex, and also in NAcc, which is involved in motivation processing. In the extended training condition, +Odor induced significantly higher level of c-Fos expression than -Odor in NAcc, but not in IC. These results suggest that CS-evoked US representation contains both the perceptual and motivational components with a minimal training, and becomes less

perceptual with an extended training. This study would contribute greatly to better understanding of associatively-activated event representation in the field of learning theory.

Title: Decreased excitability of dorsomedial and dorsolateral striatum (by NBQX) undermines normal goal-directed decision making, but not interval timing, in a reward devaluation peak timing task

Authors: *R. I. CAAMANO-TUBIO, N. BALISOK, A. R. DELAMATER;
Brooklyn Col., Brooklyn, NY

Abstract: Prior research implicates the dorsal striatum in interval-timing. The dorsomedial (DMS) and dorsolateral (DLS) striatum have also been shown to play a role in goal-directed and habitual behavior, respectively. The present study examined the role of DMS and DLS in the expression of goal-directed responding on a peak interval timing task. Rats were trained to lever press for qualitatively different food pellet rewards in the presence of different discriminative stimuli (60 s tone, 60 s houselight). A single lever press 20 s after stimulus onset produced a sweet pellet in the presence of one of these stimuli, but a non-sweetened grain pellet in the presence of the other stimulus. Training continued on this task until responding on non-reinforced probe trials revealed a temporally organized pattern of responding across the trial with response rate peaking at approximately 20 s (the time of anticipated reward). Rats then received selective reward devaluation training in which one of the reinforcing outcomes was presented non-contingently (in the absence of the lever or stimuli) in sessions that ended in an injection of the emetic LiCl. The other reinforcing outcome was equally exposed on other sessions, but not paired with LiCl injection. Finally, rats were tested under extinction conditions for lever press responding in the presence of the two discriminative stimuli (one of which now signaled the devalued outcome). Prior to test sessions, two different groups of rats received either intra-DMS or DLS infusions. Each rat received a bilateral infusion of AMPA-receptor antagonist NBQX (0.1 ug delivered in 0.3 ul) and saline in a counterbalance order. We observed that saline-infused rats displayed temporally organized responding in the presence of the stimuli, with responding

peaking shortly after the anticipated time of food delivery; however, responding was lower in the presence of the stimulus signaling the devalued food reward. NBQX administered to either the DMS or DLS disrupted goal-oriented responding, but had minimal impact on the temporal organization of responding across the trial. In particular, NBQX in the DMS eliminated the difference in responding in the presence of the stimulus signaling the valued and devalued rewards. NBQX in the DLS, paradoxically, increased responding in the presence of the stimulus signaling the devalued reward relative to the other stimulus. We observed a similar pattern of results for conditioned magazine approach. These results do not support a significant role for the dorsal striatum in the expression of interval timing, but they do confirm prior results suggesting that it plays a role in goal-directed responding.

Title: Neural coding for distinct sets of reward-predictive cues in the rat ventral striatum

Authors: *J. GMAZ, J. E. CARMICHAEL, M. A. A. VAN DER MEER;
Dartmouth Col., Hanover, NH

Abstract: Background: Adaptive behavior requires learning associations between rewards and the stimuli that predict them, and using this information to guide decisions. These associations are encoded by neurons in the ventral striatum (vStr), which change their firing after presentation of reward-predictive cues in a manner that predicts the vigor and direction of subsequent actions. Natural environments typically contain multiple reward-predictive stimuli, which may span multiple sensory modalities and/or distinct anatomical inputs to the vStr. Moreover, the informativeness of these cues may be context-dependent. How do the currently relevant cues gain control of a final common motivational path? In particular, does the same population of neurons in the vStr encode reward regardless of which cue predicted it, or are there dedicated populations of reward-predictive neurons for each cue?
Behavioral task: To address this issue, we recorded the activity of multiple single neurons in the

vStr as rats performed a task that switches between different sets of reward-predictive cues. Specifically, we trained rats (n = 5) to run on a square track containing four possible reward locations. The presence or absence of sucrose water reward at each upcoming site was signaled by the identity of either a visual or auditory cue, trained in separate blocks (visual cue block: C+ ◊ reward, C- ◊ no reward; auditory cue block: A+ ◊ reward, A- ◊ no reward). After rats discriminated behaviorally between the cues, they were implanted with multielectrode arrays in the vStr, and we recorded from single units during performance of the task.
Neural data: We sought to determine first, what aspects of vStr activity discriminated between the rewarded cues C+ and A+, and second, how such discrimination related to encoding of reward. The principal components of ensemble neural activity around the time of cue presentation were broadly similar during the visual and auditory cues; nevertheless, a substantial proportion of cue-responsive neurons (~30%) distinguished between C+ and A+. A partially overlapping set of neurons distinguished between rewarded and unrewarded cues (~20%). Finally, a subset of neurons exhibited location-specific firing patterns, even though the task contained no such associations.
Conclusion: These data suggest that at vStr activity reflects a mixture of cue identity and reward outcomes, encoded in partially overlapping populations, such that information about both can be extracted from the population as a whole. This arrangement may allow for flexibility in the decoding of multiple motivationally relevant signals in a context-dependent manner.

Title: Kappa opioid receptors modulate input interactions in the ventral striatum

Authors: *J. M. BROOKS[1], P. O'DONNELL[2];
[1]Pfizer Res. Technol. Ctr., Cambridge, MA; [2]Pfizer Inc, Cambridge, MA

Abstract: Kappa opioid receptors (KOR) are highly enriched within the ventral striatum (VS) and are thought to modulate striatal neurotransmission. KOR activation inhibits local glutamatergic transmission via a presynaptic site of action, suggesting excitatory inputs to the VS are regulated by KOR. The VS receives glutamatergic input from multiple brain regions, including the prefrontal cortex (PFC) and hippocampus (HP), and individual medium spiny neurons (MSNs) serve as the site of convergence for these diverse inputs. Recent data indicates

competition can arise between these inputs. Previous data show robust PFC stimulation leads to a reduction in ongoing HP-evoked MSN responses, in part, through the recruitment of local inhibitory mechanisms in the VS. Here we explored the role of KOR activation in cortical suppression of competing excitatory synaptic inputs on VS MSNs. Whole-cell recordings were performed from rats receiving bilateral HP injections of a viral vector expressing channelrhodopsin 2 (ChR2) under the CamKinase II promoter. Input interactions were assed in MSNs through electrical stimulation of PFC fiber tracts and light stimulation of HP inputs expressing ChR2. Optogenetically-evoked HP EPSPs were greatly attenuated after a short latency (50 ms) following burst-like PFC stimulation (5 pulses, 20 Hz, 0.1-0.5 mA) and the magnitude of this suppression was partially reversed following bath application of picrotoxin (100 uM), but not saclofen (2 uM). As the reduction is not complete, we assessed the role KOR signaling. Although KORs are localized to the VS, their cellular distribution is not well understood. To determine whether KORs selectively modulate VS inputs, we examined the effect of KOR activation on HP and PFC- evoked EPSPs in MSNs. Superfusion of the KOR agonist U69593 decreased HP and PFC EPSP amplitudes, indicating KORs do not decrease excitatory neurotransmission in the VS in an input-selective manner. We next examined whether blockade of KOR signaling would impact PFC-induced suppression. Indeed, we found that bath application of the KOR antagonist norBNI (100 nM) decreased the magnitude of PFC-induced suppression of HP responses in a manner similar to that observed following GABA-A receptor blockade. Co-administration of norBNI and PTX blocked the suppressive effect of robust PFC stimulation on HP inputs to the VS. These findings confirm and extend our assertion that shifts in VS neuronal activity involve local suppression of competing afferents converging on the same MSN. Furthermore, these data indicate PFC-driven heterosynaptic suppression involves co-activation of local inhibitory mechanisms and opioid peptide signaling.

Title: Neural dynamics of cortical and basal ganglia circuits during dynamic decision-making

Authors: *P. E. CISEK[1], D. THURA[2], J.-F. CABANA[1], A. FEGHALY[1];
[2]Neurosci., [1]Univ. of Montreal, Montreal, QC, Canada

Abstract: How does the brain make decisions in a dynamic and constantly changing world? We have previously shown (Thura & Cisek, 2014, 2016) that when monkeys perform a task in which relevant sensory information for action selection varies over time and they are free to respond at any moment, neurons in dorsal premotor (PMd) and primary motor cortex (M1) continuously reflect the evolution of sensory information along with a context-dependent signal related to the growing urgency to respond. Approximately 280ms prior to movement onset, the activity of these cells reflects the resolution of a competition between the choices, implicating them in the process of volitional commitment. Here, we examine the interactions between PMd/M1 and two sources of input, from the dorsolateral prefrontal cortex (dlPFC) and from the external and internal globus pallidus (GPe/GPi). We analyze data by plotting the dynamical state of the system as a trajectory through a high-dimensional neural space defined by the activity of each recorded neuron. We then use Principal Components Analysis to reduce this high-D space into a lower-dimensional projection and examine how neural trajectories in different cortical and subcortical regions evolve over time in different conditions. We found that the strongest components identified by PCA are functionally interpretable, corresponding to (in order): the transition from deciding-to-acting, the sensory evidence, the urgency signal, and the monkey's speed-accuracy tradeoff policy. During deliberation, the neural state of PMd/M1 evolves on a 2-dimensional "decision manifold" defined by orthogonal directions roughly corresponding to sensory evidence and urgency, and then rapidly falls off this surface at the moment of commitment into trajectories specific to each target choice. In PFC, activity is primarily confined to a narrower manifold extended primarily along the evidence dimension. In sharp contrast to the cortical dynamics, activity in the GPe and GPi does not reflect deliberation and is instead confined to the urgency dimension, just until the putative moment of commitment, at which time it also falls into the choice-dependent attractors. These results suggest that the process of deliberation unfolds primarily in the cortical regions, driven by evidence from dlPFC and a non-specific urgency signal from GPi, until a critical point is reached in cortex, engaging tuning in the cortico-striatal loop and confirming the volitional commitment to the movement choice.

Title: Feature-specific reward prediction errors during reinforcement learning across nonhuman primate fronto-striatal circuits

Authors: *M. OEMISCH, S. WESTENDORFF, T. WOMELSDORF;
Dept. of Biol., York Univ., Toronto, ON, Canada

Abstract: When only one stimulus feature among many predicts reward, it becomes pivotal for an agent to learn feature-specific reward predictions. This depends on updating existing predictions with signals reflecting the discrepancy of predicted and actually experienced reward outcomes. These prediction error (PE) signals are encoded in the firing of neurons across multiple areas of the fronto-striatal system, among others.
An unresolved question is where PEs are encoded that are not only indicating a general error, but are uniquely informative about the feature giving rise to the prediction error. Such feature specificity of PE signals could enhance learning efficiency in reinforcement learning models by allowing a more selective value-updating of synaptic weight.
To test the possibility of feature-specific signaling of PEs we recorded neuronal spiking activity across multiple areas of the macaque fronto-striatal system during a reversal learning task. In this task a monkey was presented with two moving grating stimuli that differed in color, location, and motion direction. The animal was rewarded for reporting the motion of the stimulus with the reward-associated color. The reward-associated color was reversed uncued between blocks. This setting allowed tracking the learning of feature-outcome associations independent from action- and location-outcome associations. To test for feature-specific and unspecific PE signals we extracted positive PEs as those outcome signals following rare correct outcomes during reversal learning. Negative PEs were identified as the rare erroneous outcomes after learning at stable performance. PE signals were identified as feature-specific when they were selectively larger for e.g. a specific rewarded color.
We found neurons encoding PE signals across all fronto-striatal areas. More neurons encoded positive than negative PEs, and the largest proportions of PE encoding neurons were in the striatum and lateral PFC. Importantly, a substantial proportion of PE signals was feature-specific; this proportion was larger in medial and lateral PFC compared to striatum and emerged earliest in lateral PFC compared to ventral striatum.
These findings suggest that prefrontal PE signaling encodes the specific features that led to an unexpected outcome, while striatal neurons encode a more general PE signal. These results illustrate that neurons encoding PEs carry dissociable content about the feature origin of this

error. We speculate that differently feature-tuned PE signals enhance the speed of learning by facilitating selective credit assignment during the updating of feature value predictions during goal-directed behavior.

Title: DREADD-mediated manipulation of the indirect pathway of the dorsomedial striatum disrupts flexible updating

Authors: ***K. DELEVICH**, L. WILBRECHT, L.-H. TAI, S. VEDULA, Y. ZHANG;
UC Berkeley, Berkeley, CA

Abstract: Successful goal-directed behavior requires the ability to flexibly select actions that result in reward and avoid actions that result in no reward, or worse, punishment. A lack of flexibility and insensitivity to negative outcomes is characteristic of multiple psychiatric disorders. The dorsal medial striatum (DMS) is thought play a critical role in supporting flexible behavior in response to negative and positive feedback. Previous data from our lab and others implicate the activity of D2 receptor-expressing medium spiny neurons (MSNs) of the DMS in action selection (Tai et al., 2015) avoidance behavior (Kravitz et al., 2012; Lee, Tai et al., 2015), and responses to negative feedback (Cox et al. 2015). To further investigate the role of D2 MSNs of the DMS in behavioral flexibility we employed the chemogenetic tool hM4Di to selectively inhibit D2 MSNs in the DMS in an odor based 4-choice reversal task (Johnson et al., 2011; 2016). Male D2-Cre mice were bilaterally injected into the DMS with 0.5 uL DIO-hM4Di or DIO-mCherry and after three weeks for recovery and viral expression were trained to find a reward in 1 out of 4 scented bowls. CNO (1 mg/kg) was then given the next day, just prior to a recall and reversal test where the contingency was changed to a new odor. The D2-Cre DIO-hM4Di group showed greater perseveration compared to DIO-mCherry controls, searching more frequently in the previously rewarded odor and taking more trials to begin exploring alternate

odor choices. These data suggest that activity in the DMS indirect pathway MSNs impacts the efficiency of flexible updating.

Title: How do the subregions of striatum encode different value memories? - Brain-wide inputs to tail of caudate-putamen in rodent

Authors: *H. JIANG[1,2], H. Z. KIM[1,2], H. F. KIM[1,2];
[1]Ctr. for Neurosci. Imaging Res., Inst. For Basic Science(Ibs), Suwon-si, Korea, Republic of;
[2]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Different subregions of striatum are involved in different value-coding and behaviors in primate and rodent systems (Kim & Hikosaka, 2013; Yin & Knowlton, 2006). Head and tail of caudate nucleus (CDh & CDt) is one of the good examples: fast neuronal plasticity and adaptive behavior by CDh vs. slow neuronal plasticity but long-lasting behavior such as habit by CDt. Then, which mechanism makes these differences? One hypothesis is that different brain inputs to CDh and CDt generate these plasticity differences. Indeed we previously found separate dopaminergic inputs to CDh and CDt (Kim et al., 2014), but their brain-wide inputs remain a question. Here we first identify the whole inputs to tail of caudate-putamen (tCPu) using rodent system.
To examine the brain-wide inputs, rhodamine-conjugated retrobead was injected into the tCPu of rat brain using stereotaxic coordinates. The tCPu Inputs from several brain systems were identified. First we found strong inputs from limbic system to tCPu; neurons in the entorhinal and perirhinal cortices strongly project to tCPu, and amygdala also has less but significant number of projecting neurons to tCPu. In the insular cortex neurons were labeled across wide regions of the structure, indicating their converging inputs to the tCPu. In visual system we found a few input from primary visual cortex; instead, neurons in the secondary visual cortex more strongly innervate tCPu. Similarly, in motor system we found more inputs from the secondary motor cortex to tCPu than the primary motor cortex. In the substantia nigra pars compacta (SNc), dopamine neurons in caudal-lateral region of SNc were mainly labeled, indicating the selective input of value information to tCPu as previously reported in primate and

rodent systems (Kim et al., 2014; Manegas et al., 2015).
Our data show limbic, insular, visual, motor and value inputs to tCPu in rodent system (please also see brain-wide inputs in macaque monkey by Griggs et al., 2016 SfN poster). Comparing the brain-wide inputs to head and tail of CPu would give a critical answer for understanding the mechanism of neuronal plasticity and behavioral differences in the CPu subregions.

Title: Direct and indirect pathways in basal ganglia signaling opposite reward values: anatomical study

Authors: *H. AMITA[1], H. F. KIM[3,4], W. GRIGGS[1], A. GHAZIZADEH[1], O. HIKOSAKA[1,2]; [1]Lab. Sensorimotor Research, NEI, NIH, Bethesda, MD; [2]Intramural Res. Program, NIDA, NIH, Baltimore, MD; [3]Dep. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of; [4]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of

Abstract: Striatal output neurons project to the output area of the basal ganglia (e.g., substantia nigra pars reticulata, SNr) directly (i.e. direct pathway), or indirectly (i.e. indirect pathway) through globus pallidus externus (GPe) and subthalamic nucleus (STN). This scheme has suggested that the direct and indirect pathways are separate and carry different signals. However, this hypothesis has not been tested systematically. In fact, some striatal neurons project to both SNr and GPe in rats, thus raising a question about the separate circuit scheme. No relevant data are available in primates.
To answer this question, we performed anatomical experiments in 2 steps. In Experiment 1, we chose one striatal area (caudate tail, CDt) and determined its exact targets within SNr and GPe. For this, we injected a tracer (CTB555) in CDt. We found anterograde labeled axon terminals that were localized in caudal-dorsal-lateral SNr (cdlSNr) and caudal-ventral GPe (cvGPe). In Experiment 2, we determined whether individual CDt neurons project to cdlSNr or cvGPe, or both. For this, we injected different tracers into cdlSNr (Fast Blue) and cvGPe (CTB555). We found retrograde labeled neurons that were localized in CDt and caudal-ventral putamen (cvPut)

from both cdlSNr and cvGPe. However, very few neurons in CDt and cvPut were double-labeled. These results indicate that direct and indirect pathways from CDt and cvPut are largely separate.
Experiment 2 also revealed an unexpected feature of the indirect pathway. It has been shown that STN is mutually connected with GPe and thus acts as a key station of the indirect pathway. Our results were different from this scheme. After CTB555 injection in cvGPe, we found neither anterograde labeled axon terminals nor retrograde labeled neurons in STN. Instead, anterograde labeled axon terminals were heavily localized in cdlSNr. These results suggest that the direct and indirect pathways of CDt send signals to the same output station (i.e. cdlSNr). The indirect pathway is detoured only through cvGPe, but not STN.
The anatomical separation of the direct and indirect pathways of CDt and cvPut would allow them to send completely different signals to the same basal ganglia output (cdlSNr). Indeed, our behavioral and electrophysiological experiments (poster by Kim, Amita and Hikosaka) found that both of these pathways carry reward value signals, but in opposite directions: Direct pathway - Positive, Indirect pathway - Negative.

Title: Direct and indirect pathways in basal ganglia signaling opposite reward values: electrophysiological study

Authors: *H. F. KIM[1,2], H. AMITA[3], M. YASUDA[4], O. HIKOSAKA[3,5];
[1]Dept. of Biomed. engineering, Sungkyunkwan Univ., Suwon / Gyeonggi-Do, Korea, Republic of; [2]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of; [3]Lab. Sensorimotor Res., NEI, NIH, Bethesda, MD; [4]Dept. of Physiol., Kansai medical Univ., Hirakata, Japan; [5]Intramural Res. Program, NIDA, NIH, Baltimore, MD

Abstract: Neurons in the tail of caudate nucleus (CDt) in macaque monkeys encode stable reward values of visual objects and guide visual habit (Kim & Hikosaka, 2013). CDt neurons project to caudal-ventral region of globus pallidus externus (cvGPe) in indirect pathway and to caudal-dorsal-lateral region of substantia nigra pars reticulata (cdlSNr) in direct pathway (2016 SfN poster by Amita, Kim and Hikosaka). We hypothesized that different stable reward values

are separately processed in the indirect and direct pathway.
To test this hypothesis, we used electrophysiological methods. First, we electrically stimulated CDt while recording single neuronal activity in their target structures, GPe and SNr. 20 among 28 GPe neurons showed inhibitory responses, and the inhibited neurons were localized in cvGPe. CDt microstimulation also induced inhibitions in cdlSNr neurons (Yasuda & Hikosaka, 2015). These data indicate that CDt has inhibitory connections to both cvGPe and to cdlSNr. We then electrically stimulated cvGPe while recording neuronal activity in cdlSNr. cvGPe microstimulation induced inhibitions in cdlSNr neurons (n = 14), showing the inhibitory connection from cvGPe to cdlSNr. To further study the connection, we stimulated cdlSNr while recording single neuronal activity in cvGPe. We found that cvGPe neurons (n = 13) were activated antidromically. These results indicate that cvGPe neurons have monosynaptic connections to cdlSNr neurons.
Our data show two inhibitory pathways which would be involved in visual habit: direct pathway (CDtcvSNr) and indirect pathway (CDtcvGPecdlSNr). These two pathways were anatomically confirmed by our tracer study (2016 SfN poster by Amita, Kim and Hikosaka). Which value information is encoded in each pathway? We recorded activity of single cvGPe neurons while high- and low-valued fractal objects were presented. The fractal objects were learned over 4 days, and thus the monkeys developed a habitual preference of gazing without any reward outcome. Among 134 visual responsive neurons, 58 neurons differentially responded to previously learned objects. Notably, cvGPe neurons were mainly inhibited by low-valued objects. In contrast, cdlSNr neurons were mainly inhibited by high-valued objects (Yasuda & Hikosaka, 2015).
Our data indicate that opposite stable values are processed through indirect and direct pathways: (-) value in CDt Inhibit cvGPe Disinhibit cdlSNr vs. (+) value in CDt Inhibit cdlSNr. Consequently, neurons in superior colliculus (SC) are inhibited by low-valued object and disinhibited by high-valued objects, causing habitual saccades to high-valued objects.

Title: Different inputs to caudate head and tail for different types of reward values

Authors: W. GRIGGS[1], H. F. KIM[2,3], A. GHAZIZADEH[1], *O. HIKOSAKA[1,4];
[1]Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD; [2]Dep. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of; [3]Ctr. for Neurosci. Imaging Res., IBS, Suwon, Korea, Republic of; [4]Intramural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Anatomically distinct pathways originating from the caudate head (CDh) and caudate tail (CDt) encode flexible- and stable-valued memories respectively (Hikosaka et al., Annu Rev Neurosci 2014), but the inputs to these value-coding areas are not well understood. To identify these inputs, we first located flexible and stable value-coding areas in CDh and CDt of two rhesus macaque monkeys by showing them fractal objects with different amounts of reward reversibly or consistently. We then injected different retrograde tracers into these areas: Diamidino Yellow into CDh and CTB555 into caudal CDt of both monkeys, and CTB488 and Fast Blue into rostral CDt of monkey Z and S respectively. We found that CDh and CDt receive differential inputs from several subcortical and cortical areas including amygdala, claustrum, thalamic nuclei, presubiculum, insula, superior temporal sulcus (STS), and area TE. Within the amygdala, there are strong projections from the basal lateral nucleus to CDt, but no projections to CDh. The claustrum also projects to CDt, but not to CDh. Within the thalamus, the paraventricular and medial dorsal nuclei project to CDh while the pulvinar nucleus projects to CDt. There are projections from the parafascicular nucleus to both CDh and CDt, but the projecting areas are spatially distinct. Near the hippocampus, there are strong projections from the pre- and para-subiculum to CDt, but no projections to CDh. Within the cortical regions, there are projections from the insula to CDh, but not to CDt. Within the STS, there are projections to CDh and CDt, but they originate from different cortical layers and spatially distinct subregions. We also found strong projections from areas TE and TEO, including scene-coding areas, to CDt, with weak projections to CDh. So far, we found no neuron projecting to both CDh and CDt. Our data indicate that CDh and CDt constitute anatomically separate circuits, both for their outputs and inputs. Their outputs (aiming at the superior colliculus through the substantia nigra pars reticulata) encode strong, but distinct, value memories. It is likely that many of their inputs (shown in this study) also encode value memories (see companion abstract, Ghazizadeh et al.). Understanding the role of each of these input areas is important for understanding how value memories are created and stored.

Title: Pathway-specific coding of action and value in the dorsomedial striatum

Authors: *C. H. DONAHUE[1], M. LIU[2], A. C. KREITZER[2];
[1]Neurosci., [2]The Gladstone Inst., San Francisco, CA

Abstract: The basal ganglia play a critical role in action selection and reinforcement learning, and have been shown to represent action values which may help guide decision making. The striatum contains two intermingled classes of projection neurons, the direct and indirect pathway medium spiny neurons (dMSNs and iMSNs), that exert opposing effects on downstream structures. While the role of the direct and indirect pathways in facilitating and suppressing action are well known, the pathway-specific contributions to reinforcement learning are much less understood. To address this question, we trained mice to perform a value-based dynamic foraging task in a three-port chamber. The animals were trained to initiate a trial in the center port and to make a choice with a nose poke to the left or right port. The ports were baited with different probabilities of reward delivery (either 60% or 15%) to elicit matching behavior. The location of the port associated with high reward probability underwent frequent un-signaled reversals so that the animals had to learn by integrating their recent history of actions and outcomes.

We imaged pathway-specific activity in the dorsomedial striatum through the use of a genetically encoded calcium indicator (GCaMP6m) with a head-mounted microscope while the animals performed the task. As has been shown previously, analysis of bulk fluorescence showed that both dMSNs and iMSNs selectively responded when the animals made movements that were contralateral to the recording site. Contralaterally-directed movements from the side port towards the center port (during the trial reinitiation period) were associated with significantly stronger activity than movements from the center towards the side ports (during the decision period). Single-cell responses during trial reinitiation revealed this was due to distinct subpopulations of dMSNs and iMSNs that selectively combined information about the most recent action and outcome. A significantly larger population of dMSNs were active following evidence that the contralateral port was of higher value, while iMSNs were more active following evidence that the ipsilateral port was of higher value. These results provide evidence that the direct and indirect pathways play opposing roles in value-based learning.

Title: Different population of primate caudate neurons is involved in decision making under different emotional context.

Authors: *Y. UEDA, K. NAKAMURA;
Kansai Med. Univ., Osaka, Japan

Abstract: Neuronal mechanisms of decision making have been investigated for reward-oriented behavior, mostly choice of reward vs. no reward, and the basal ganglia (BG) have been implicated in the process. However, choice of a reward against a punishment or no-reward against punishment (avoidance) also occurs. We hypothesized that such inclusion of an aversive option creates specific emotional context, referred as stress or anxiety, and that distinct neuronal circuit may be comprised. To address this issue, we designed a behavioral paradigm in which animals made choice under different emotional context. Two monkeys (*Macaca fascicularis* and *Macaca mulatta*) were conditioned for three fractal images, with a juice (R), a neutral tone (T), or an aversive airpuff (A). After fixating on a central fixation point (FP, 1000 ms), a pair of images (R-T, R-A, T-A) appeared in the left and right of the FP. The monkeys chose one of the images by eye movements to obtain a reward and/or to avoid a punishment. The same image pair was repeated up to 30 trials as a block while the side of the images changed randomly, which allowed the animals to predict the specific pair before its presentation. Block-based comparison revealed significantly more frequent suboptimal choices for pairs with ‘A’ (R-A, T-A) than that without ‘A’ (R-T). Low nasal temperature for the pairs with ‘A’ indicated sympathetic dominance. Trial-based analyses also showed sympathetic dominance; higher heart rate before target presentation, for following suboptimum choices. Thus, inclusion of ‘A’ induced emotional changes, assessed objectively by the autonomic responses, and impaired the decision process. To investigate the neuronal substrate of decision making when an aversive outcome was possible, we measured neuronal activity of the caudate, an input channel of the BG for this task in the same animals. During the FP period where emotional context was known during the preparation for the choice, 198 out of 374 (53%) neurons exhibited differential activity depending on the pair type. Among them, 70 showed stronger activity for the pairs with 'R' (R-T, R-A) than those without 'R' (T-A), consistent with the hypothesis that the striatum is involved in reward-dependent modulation in action. However, 85 showed stronger activity for the pairs with 'A' than

those without 'A' suggesting aversive-context encoding. The aversive-context preferred activity did not simply encode ‘punishment’ because their activity was higher for trials with optimum choices than those with suboptimum choices. These results suggest that different subsets of primate caudate neurons are recruited in decision making under different emotional context.

Title: Unilateral naris occlusion suppresses gamma oscillations in ventral but not dorsal limbic structures in the rat

Authors: *J. E. CARMICHAEL[1], J. Y. KHOKHAR[2], A. I. GREEN[2], M. A. A. VAN DER MEER[1];
[1]Psychology and Brain Sci., Dartmouth Col., Hanover, NH; [2]Psychiatry, Geisel Sch. of Med. at Dartmouth, Hanover, NH

Abstract: Oscillations in the local field potential (LFP) are thought to reflect aspects of information processing, such as the gating or binding information from anatomically distant regions. In the rodent limbic system, interconnected regions such as the prelimbic frontal cortex (PL), orbitofrontal cortex (OFC), ventral striatum (vStr), and cingulate cortex (CG), show coherent oscillations and spike-field relationships in various frequency bands, which may mediate the flow of information between these areas.
Most of these areas are anatomically proximal to the piriform cortex (PC) and olfactory bulb (OB), which are located on the ventrolateral side of the rat brain, and show strong gamma-band oscillations. Our previous work has shown that inactivation of the OB/PC by unilateral naris occlusion abolishes gamma oscillations in the ipsilateral vStr LFP. This result suggests that gamma oscillations seen in the vStr LFP are actually volume-conducted from OB/PC, a conclusion further supported by clear gradients in gamma power that increase towards the ventrolateral vStr (Carmichael et al. 2015). Other structures adjacent to the OB/PC, such as the

OFC, also display gamma oscillations, suggesting that the gamma oscillations seen in the OFC field potential may contain contributions from the OB/PC, and raises the question of how far into adjacent structures OB/PC oscillations continue to shape the field potential.
We recorded local field potentials from rats (n = 4) implanted with electrodes in OFC, vStr, PL, and CG, as they underwent reversible unilateral naris occlusions. Both the vStr and OFC showed strong suppression in gamma power only when the ipsilateral naris was blocked, suggesting that local gamma oscillations in these structures are likely volume-conducted from the adjacent OB/PC. In contrast, the PL and CG instead showed similar gamma power during pre/post occlusion as well as contra-/ipsilateral occlusions.
Thus, gamma oscillations seen in brain regions adjacent to the OB/PC are likely not generated locally; however, the influence of OB/PC gamma does not extend to more distal, yet anatomically connected, areas such as PL and CG. This result does not imply that these volume-conducted components of the field potential are unimportant or uninformative; neurons in the vStr and OFC show striking phase-locking to gamma-band oscillations in the LFP. Rather, this emerging view of gamma oscillations in ventro-lateral limbic circuits highlights the importance of the PC common input as a major influence, perhaps excluding the possibility that areas such as vStr and OFC can control oscillations in their LFP.

Title: Biologically plausible learning in recurrent neural networks

Authors: *T. MICONI;
The Neurosciences Inst., La Jolla, CA

Abstract: Recurrent neural networks exhibit complex dynamics, reminiscent of cortical activity in higher areas during behavioral tasks. However, existing methods for training such networks are either biologically implausible, or require a real-time continuous error signal to guide the

learning process. This is in contrast with most behavioral tasks, which only provide time-sparse, delayed rewards. Here we introduce a biologically plausible learning algorithm, that can train chaotic recurrent networks based solely on delayed, phasic reward signals at the end of each trial. The method requires no dedicated feedback or readout networks: the entire network connectivity is subject to learning based on exploratory perturbations, and the network's output is read from one arbitrarily chosen network cell. We apply this method to learn three different tasks: a delayed nonmatch-to-sample task (requiring memory maintenance and non-linear selectivities); a selective attention task, in which the network learns to flexibly attend to one of two concurrent input streams while ignoring the other; and a motor control task using a bio-mechanical model of the human arm, with 4 degrees of freedom actuated by 16 independent muscles, to produce reaching movements toward instructed targets, showing that the algorithm can learn to coordinate multiple outputs. The trained networks exhibit complex dynamics previously observed in animal cortex, such as dynamic encoding and maintenance of task features, switching from stimulus-specific to response-specific representations, and selective integration of relevant input streams. We conclude that recurrent neural networks, trained with reward-modulated Hebbian learning, offer a plausible model of cortical dynamics during both learning and performance of flexible behavior.

Title: Investigating the ascending and descending prefrontal-midbrain projections using optogenetics: Implications for the regulation of motivation for sustained effort.

Authors: *A. HARATIKIA[1], B. CARACHEO[1], N. GORELOVA[1], K. DEISSEROTH[2], J. K. SEAMANS[1];
[1]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [2]Dept. of Bioengineering, Dept. of Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Dopamine (DA) neurons of the ventral tegmental area (VTA) exert critical modulatory effects on target neurons in the prefrontal cortex (PFC). In a reciprocal manner, DA neurons are themselves targeted by glutamate projections from PFC neurons. While the function of this reciprocal pathway is not known, we hypothesized that events signaling effort may be encoded by the PFC neurons that project to the VTA and that the activation of VTA neurons may in turn release DA in the PFC which maintains attention during long bouts of sustained effort. The present study investigated the effects of optogenetic manipulations of VTA-PFC or PFC-VTA pathways during a modified progressive ratio (PR) task. In the first experiment, TH::Cre rats received VTA injections of a viral vector containing the Cre-inducible ChR2 gene. They were then implanted with optic fibers in the PFC and trained on a PR task where the required number of lever presses increased by 2 on each iteration and the rats were given as many chances as they desired to complete a ratio, so long as they responded at least once within a 2min. interval. If they did not respond within the 2min., this was taken as the breakpoint. We found that tonic 3Hz optic pulses within the PFC extended the breakpoint and made rats more willing to make subsequent attempts after a failure. These effects were reproduced by injections of amphetamine into the PFC. In contrast, phasic stimulation (5 x 20Hz) of the PFC either at the time of the lever presses or at the completion of a ratio, had no effect. A second series of experiments focused on the PFC-VTA pathway. Normal rats received PFC injections of a viral vector carrying ChR2 gene to produce pyramidal cell type specific expression under the control of the CAMKII promotor. These rats were then implanted with a tetrode array in the PFC for multiple single unit recordings as well as optic fibers in the VTA. In this case, VTA light pulses were not used to modify behavior but as a means to antidromically identify PFC-VTA projecting neurons. A subgroup of PFC neurons identified as projecting neurons responded in a relatively continuous manner during lever press bouts and stopped firing when a ratio was completed and

the lever retracted. Finally, a separate group of rats received PFC injections of a viral vector carrying the inhibitory opsin eNpHr3.0. In these animals, tonic light pulses in the VTA reduced break points. The results are therefore consistent with the hypothesis that subpopulations of PFC-VTA projection neurons are activated by prolonged efforts and these neurons may activate the VTA-PFC pathway and release DA in the forebrain which in turn serves to increase the propensity to sustain effort, especially after failure.

Abstract: Addiction may arise in part from dysregulated activity of ventral tegmental area dopaminergic (TH^{VTA}) neurons, as well as from more global maladaptation in neurocircuit function. The direct consequences of dopamine signaling are largely restricted to brain regions that contain appreciable presynaptic fibers that release dopamine, as well as postsynaptic dopamine receptors. However, dopaminergic signaling may also indirectly influence the activity in multiple brain regions, some of which may receive little to no direct dopamine input. Here, we studied how *in vivo* modulation of TH^{VTA} neurons altered brain-wide activity patterns using optogenetics coupled with fMRI. To target DA neurons within the midbrain, tyrosine hydroxylase (TH)-Cre adult Long Evans rats were microinjected into the ventral tegmental area (VTA) with a Cre-inducible adeno-associated virus carrying the gene encoding channelrhodopsin-2 (ChR2), a light-gated cation channel fused to an enhanced yellow fluorescent protein (EYFP) (TH^{VTA}::ChR2 rats) or only EYFP (TH^{VTA}::control rats). Chronic optical fibers were stereotactically implanted bilaterally above the VTA to selectively activate

DA neurons within this region. fMRI experiments were performed 5-6 weeks after surgery. Single shot, single sampled GE-EPI sequences (BW= 300 kHz, TR= 1000 ms, TE= 8.107 ms, 80x80 matrix, FOV= 2.56 x 2.56 cm2, slice thickness= 1 mm) were acquired using a Bruker 9.4T MR scanner and home-made surface coil. Applying a standard generalized linear model (GLM) analysis approach, our results indicate that selective optogenetic stimulation of TH^{VTA} neurons enhanced cerebral blood volume (CBV) signals in striatal target regions in a dopamine receptor dependent fashion. However, brain-wide voxel-based principal component analysis (PCA) of the same dataset revealed that dopaminergic modulation activates several additional anatomically distinct regions throughout the brain, not typically associated with dopamine release events. Furthermore, explicit pairing of TH^{VTA} neuronal activation with a forepaw stimulus of a particular frequency expanded the sensory representation of that stimulus, not exclusively within the somatosensory cortices, but brain-wide. These data suggest that VTA dopaminergic neuronal activity has immediate global consequences, and can remodel brain-wide neuronal activity patterns alone or in the presence of a sensory stimulus.

Title: Input-specific mechanisms of drug-evoked plasticity in the mesolimbic dopamine system

Authors: *J. W. DE JONG, S. A. AFJEI, J. R. PECK, I. CERNIAUSKAS, V. HAN, S. LAMMEL;
Mol. and Cell Biol., UC Berkeley, Berkeley, CA

Abstract: Drugs of abuse can hijack synaptic plasticity mechanisms in brain circuits that are central to reward processing. One of the most well established synaptic modifications caused by *in vivo* administration of drugs of abuse is an increase in the strength of excitatory synapses onto

ventral tegmental area (VTA) dopamine (DA) neurons. We have previously shown that a single injection of cocaine induces a strong and long-lasting (>21 days) potentiation of excitatory synapses onto Ih-lacking VTA DA neurons projecting to the medial shell of the nucleus accumbens (DA→mShell). However, the anatomical origin of the inputs to this population of neurons which undergo synaptic potentiation following cocaine administration is largely unknown. Two prominent inputs to the VTA, which have been associated with reward-related behaviors, arise from the lateral hypothalamus (LH) and dorsal raphe (DR). Thus, we hypothesized that *in vivo* cocaine exposure will induce synaptic adaptations in one or both of these pathways. By combining optogenetics with synaptic electrophysiology, we found that light stimulation of LH and DR terminals in the VTA induced robust excitatory postsynaptic currents (EPSCs) in DA→mShell neurons. We next assessed the synaptic strength of each pathway by measuring the relative contributions of AMPA receptors (AMPARs) and NMDA receptors (NMDARs). We found that a single *in vivo* injection of cocaine (15 mg/kg, IP) increased the synaptic strength of DR inputs in a small proportion of DA→mShell neurons when assessed 24 hours later. However, a robust increase in the AMPAR/NMDAR ratio of DR inputs to DA→mShell neurons was observed following 5 consecutive days of cocaine treatment. In addition, we found that the rectification index (RI) of the AMPAR current was significantly increased, suggesting an increase in GluR2-lacking AMPARs, which show a characteristic inwardly rectifying current at positive potentials. Surprisingly, however, when stimulating LH inputs to DA→mShell neurons, a single injection of cocaine induced a significant decrease in the AMPAR/NMDAR ratio and no change in the RI. Collectively, these results suggest that opposing forms of drug-evoked plasticity in distinct VTA afferent pathways may contribute to the reorganization of neural circuitry during early stages of drug addiction.

Title: Dissecting lateral habenula circuits underlying depression-related behaviors

Authors: I. CERNIAUSKAS, J. W. DE JONG, N. SUNKARA, J. R. PECK, *S. LAMMEL; Mol. and Cell Biol., UC Berkeley, Berkeley, CA

Abstract: Recent research has indicated that the lateral habenula (LHb) may be a key region in the pathophysiology of depression. It has been shown that LHb neurons are hyperactive in depression-like states, and LHb lesions in rodents have led to a reduction of depression-related behaviors. However, little is known about the circuit and synaptic mechanisms that contribute to the hyperactivity of LHb neurons in depression-like states. Using a combination of anatomical tracing techniques, optogenetics and electrophysiology, we investigated afferent inputs to a specific subpopulation of LHb neurons which project to the ventral tegmental area (LHb→VTA). We found that chronic mild stress (CMS) induced depression-like behaviors in adult mice accompanied by significant increases in the firing rate of LHb→VTA neurons as revealed by whole-cell patch clamp recordings in acute brain slices. Next we employed a transsynaptic rabies virus strategy to further dissect the global input connectivity of this subpopulation. We found that major excitatory inputs to LHb→VTA neurons arise from the lateral hypothalamus (LH), entopeduncular nucleus (EP) and the VTA itself. These findings raise the possibility that synaptic changes in VTA, EP and/or LH excitatory inputs may drive hyperactivity of LHb→VTA neurons in depression-like states. To further characterize the synaptic properties of these inputs, we expressed channelrhodopsin-2 in the VTA, EP or LH and injected fluorescent RetroBeads into the VTA. We then recorded light-evoked excitatory postsynaptic currents by illuminating terminals from identified inputs to LHb→VTA neurons. Our results demonstrate that excitatory transmission of VTA and EP inputs to LHb→VTA neurons mainly relies on the presence of AMPA receptors and a relatively small NMDA receptor component. In contrast, LH inputs exhibit a more pronounced synaptic NMDA receptor component. We are currently investigating whether CMS leads to input-specific synaptic alterations of VTA, EP and LH afferents to LHb→VTA neurons. The identification of specific inputs that drive hyperactivity of LHb→VTA neurons and the underlying synaptic mechanisms will reveal important insights into the pathophysiology of depression, which may lead to novel circuit-specific therapeutic interventions.

Title: Responses of VTA/SNc neurons to stimulus novelty

Authors: J. MORRENS, J. NOUTEL, *S. HAESLER;
Neuroelectronics Res. Flanders, Leuven, Belgium

Abstract: The ability to discriminate novel from familiar sensory stimuli is a fundamental feature of the central nervous system. When humans or animals detect novel stimuli in their environment, they respond with distinct orienting and exploratory behaviors. Novel stimuli familiarize after a few exposures suggesting a very rapid form of memory formation. Disturbances in novelty processing are associated with numerous human pathological conditions including schizophrenia and autism, which highlights the clinical relevance of understanding the circuit mechanisms underlying novelty detection and familiarization. A candidate circuit implicated in novelty processing resides in the two dopaminergic midbrain structures substantia nigra pars compacta (SNc) and ventral tegmental area (VTA). Compared to the evidence linking dopamine with reinforcement learning, knowledge about the role of dopamine neurons in novelty processing is sparse. Human and animal suggest activation of midbrain dopamine neurons by stimulus novelty, but the response properties of dopamine single-units have yet to be systematically investigated under experimental conditions, in which stimulus novelty is manipulated selectively. Here, we used a recently developed novel behavioral paradigm to investigate the firing properties of optogenetically identified DA neurons to stimulus novelty. To relate novelty responses of dopamine neurons to their well-described responses to reward and punishment, we also recorded them in a reward/punishment task in the same behavioral session after animals have completed the novelty task. We compared response dynamics between neural and behavioral responses. Moreover, we compared responses between dopamine neurons in the SNc and VTA. Given that both structures differ considerably in their projection targets and electrophysiological properties, our results have implications for where novelty signals are broadcasted. In our ongoing work, we use optogenetic techniques to investigate the causal contribution of dopamine neurons to novelty processing.

Title: Projection to the rostromedial tegmental nucleus from the lateral preoptic area and ventral pallidum probed with Fos immunoreactivity following administration of amphetamine

Authors: *D. S. ZAHM, Y. TAN, K. P. PARSLEY;
Pharmacol. and Physiological Sci., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: The rostromedial tegmental nucleus (RMTg), a part of the medial mesopontine reticular formation comprising exclusively GABAergic neurons that project densely onto midbrain dopamine neurons, is widely acknowledged as a negative modulator of mesotelencephalic dopamine neuron activity in response to reward omission and aversion (Neuron 61:786-800, 2009; JCN 519:1143-1164, 2011; J Neurosci 31:11457-11471, 2011). Alternatively, infusion of the $GABA_A$ receptor agonist muscimol into the RMTg produces robust locomotor activation (Neuropsychopharmacol 40:676-87, 2015) and lesions of the RMTg facilitate motor learning (Neuropsychopharmacol 39:2788-98, 2014). Injection of anterograde tracer into the transition between the lateral preoptic area and caudomedial ventral pallidum (LPO-VP) produces dense anterograde labeling in the RMTg (Soc Neurosci Abstr 79.09, 2011) and infusion of $GABA_A$ antagonists, such as picrotoxin or bicuculline, centered on LPO-VP produce robust locomotor activation (Brain Struct Funct 219:511-526, 2014). These observations support a hypothesis that stimulation of LPO-VP inhibits the RMTg, which relieves midbrain dopaminergic neurons from RMTg-mediated inhibition. Consistent with this idea, we speculate that LPO-VP may also be activated (and RMTg in turn inhibited) in conditions of increased extracellular concentration of dopamine in the accumbens by inhibition of LPO-projecting ventral striatal GABAergic dopamine D2 receptor-expressing 'indirect pathway'-type medium spiny neurons, which are reported to be inhibited by dopamine (e.g., JPET 251:833-9, 1991; J Neurosci 14:7735-46, 1994). To address this possibility, we injected the retrograde tracer cholera toxin β subunit (Ctβ) into the RMTg of rats and after a week injected them with D-amphetamine (1 mg/kg) 2 hours prior to anesthetizing them, perfusing them with buffered aldehydes, sectioning the brains and processing the sections with antibodies against Ctβ and the immediate-early gene product, Fos. Retrogradely labeled neurons with and without Fos-expression were mapped with Neurolucida in sections containing LPO-VP. We consistently observed a small population (< 1% of retrogradely labeled) of small (10-15 μm) double-labeled neurons. Large, 'principal' projecting neurons were almost never double-labeled. Whereas, the results of the

experiment do not obviously support our hypothesis, we do identify a small population of 'activated' RMTg-projecting small neurons in LPO-VP. Small numbers of small neurons, e.g., the RMTg itself, can exert profound inhibition. Whether these, or other neurons not expressing Fos, are GABAergic and do remains to be determined.

Title: Neural circuitry driving rostromedial tegmental nucleus (RMTg) responses to aversive stimuli

Authors: *H. LI, M. EID, N. PULLMANN, J. THOMPSON, T. C. JHOU;
Med. Univ. of South Carolina, Charleston, SC

Abstract: The rostromedial tegmental nucleus (RMTg) is a GABAergic nucleus that sends strong inhibitory projections to DA neurons, and acts as a "braking" system for DA neurons. RMTg neurons are activated by aversive stimuli and by cues that predict aversive outcomes, while inactivation or lesions of the RMTg greatly reduce many behavioral responses to these stimuli. The RMTg is known to receive a wide range of afferents, but it is not known how these afferents modulate RMTg responses to aversive stimuli or cues. Furthermore, it is not known whether different types of aversive stimuli or cues activate the RMTg by different pathways. Using *in vivo* electrophysiology we found that RMTg neurons were activated by a variety of aversive stimuli including footshock, loud tone, bright light and LiCl injection. By using rabies tracing, we identified a di-synaptic pathway from the entopeduncular nucleus (EPN) to the RMTg via the lateral habenula (LHb). We found that footshock and/or cocaine injections induced cFos expression in LHb-projecting EPN neurons, while unilateral EPN lesions blocked the stimulus-induced cFos increases in the ipsilateral LHb and RMTg. *In vivo* electrophysiology recording indicated that a large portion of EPN and LHb neurons exhibited activation by shock predictive cues and inhibition by cues predicting rewarding sugar pellets. Temporal inactivation of the EPN or LHb with GABA agonists reduced activation to shocks in RMTg neurons. Moreover, both RMTg and EPN neurons showed bi-phasic responses to cocaine, i.e. a reduced firing rate during roughly the first 10 mins and augmented firing rate during the subsequent 10

mins. This result is consistent with the immediate rewarding and delayed aversive effects of cocaine. Additionally, bilateral EPN inactivation blocked the acquisition of avoidance responses to cocaine on a runway test.

Title: Effects of chemogenetic manipulations of prelimbic inputs to the paraventricular nucleus of the thalamus on dopamine release in the nucleus accumbens of sign-trackers and goal-trackers.

Authors: *P. CAMPUS[1], Y. KIM[2], A. PARSEGIAN[1], I. R. COVELO[1], S. M. FERGUSON[3], M. SARTER[2], S. B. FLAGEL[1];
[1]Psychiatry, Univ. of Michigan Dept. of Psychiatry, Ann Arbor, MI; [2]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI; [3]Dept. of Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: Conditioned stimuli (CS) associated with rewards can acquire not only predictive value, but also incentive motivational value. When a cue is attributed with incentive motivational value or incentive salience, it gains the ability to control behavior, leading in some cases to maladaptive outcomes. However, individuals vary considerably in the extent to which they attribute motivational value to CS. In a Pavlovian Conditioned Approach (PCA) task, in which the presentation of a lever is immediately followed by the delivery of a food reward, some rats preferentially approach the lever (sign-trackers, STs) while others approach the food cup (goal-trackers, GTs). Importantly, while the lever is a predictor for both STs and GTs, only for STs does it become an "incentive stimulus". It has been previously shown that the sign-tracking response is dopamine (DA) dependent, but the goal-tracking response is not. Further, when the discrete cue previously paired with food is presented, it engages different neural circuitry in sign-trackers vs. goal-trackers, suggesting that while STs rely primarily on subcortical mechanisms, GTs utilize more cortical engagement. Recent work from our lab suggests that the paraventricular nucleus of the thalamus (PVT) may represent a central node that integrates

subcortical and cortical input differentially in STs and GTs. Together, these data led us to hypothesize that in GTs, input to the PVT from the prelimbic cortex (PrL) may serve to suppress subcortical processes critical for the expression of sign-tracking behavior. In support, preliminary data indicates that the activation of this PrL-PVT circuit using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) decreases sign-tracking behavior while the inhibition of the same pathway has the opposite effect. Here, we investigated the effects of selective manipulation of the PrL-PVT pathway on extracellular levels of DA in the NAc of STs and GTs. To this end, we used a dual viral vector approach to selectively express stimulatory Gq- or inhibitory Gi/o- DREADDs in PrL to PVT projecting neurons. Clozapine-N-oxide (CNO) was administered to activate DREADDs during PCA and levels of DA and other neurotransmitters in the nucleus accumbens were subsequently assessed using in vivo microdialysis. We found that, in STs, turning on" the PrL-PVT pathway appears to enhance DA in the NAc while, in GTs, "turning off" the PrL-PVT pathway appears to attenuate acetylcholine levels, without affecting DA. These studies may help to better understand the dynamics of the interaction between bottom-up and top-down processes involved in the neural circuitry that regulates cue-motivated behaviors.

Title: Glutamatergic neurons are intermixed with midbrain dopaminergic neurons in nonhuman primates and humans

Authors: *D. H. ROOT[1], H.-L. WANG[1], B. LIU[1], D. BARKER[1], L. MÓD[2], P. SZOCSICS[2], A. C. SILVA[3], Z. MAGLÓCZKY[2], M. MORALES[1];
[1]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD; [2]Inst. of Exptl. Med. of the

Hungarian Acad. of Sci., Budapest, Hungary; [3]Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Midbrain dopamine neurons have been documented in the nonhuman primate and human ventral tegmental area (VTA) and substantia nigra pars compacta (SNC) for nearly fifty years. Nonhuman primate studies have shown that midbrain dopamine neurons within these regions play key roles in reward, aversion, and learning. Clinical findings have led to the hypothesis that midbrain dopamine neurons are fundamental to addiction, schizophrenia, depression, and movement disorders. We have recently shown that glutamatergic neurons that express vesicular glutamate transporter 2 (VGluT2) are within subdivisions of the rodent VTA and SNC. Subsets of rodent VGluT2-expressing midbrain neurons co-express markers of dopamine or GABA synthesis, and are capable of co-transmitting glutamate with dopamine or GABA. Furthermore, our optogenetic studies in mice have shown that midbrain glutamatergic neurons participate in reward or aversion. However, the cellular compositions of the nonhuman primate and human VTA and SNC are unclear, contributing to a translational gap in our understanding of midbrain function. To determine whether glutamatergic neurons are present within the VTA or SNC of nonhuman primates and humans, we combined immunodetection of tyrosine hydroxylase (TH), and radioactive *in situ* hybridization to identify neuronal expression of transcripts encoding VGluT2 mRNA. In the marmoset VTA, half of rostral linear nucleus (RLi) neurons are VGluT2-only neurons and the other half are TH-only (dopaminergic). VGluT2-TH neurons are largely restricted to the parabrachial pigmented subdivision (PBP). The marmoset SNC pars lateralis subdivision contains VGluT2-only neurons but the SNC is otherwise dominated by TH-only neurons. Similar to the marmoset RLi, the human RLi contains equal percentages of VGluT2-only and TH-only neurons. However, a larger percentage of VGluT2-TH neurons are located in the human RLi (10%). Similar to the marmoset PBP, the human PBP contains the highest percentage of VGluT2-TH neurons (16%). The human SNC pars lateralis subdivision contains VGluT2-only neurons (16%) but the SNC is otherwise dominated by TH-only neurons. We conclude that subtypes of glutamatergic neurons are conserved from rodents to nonhuman primates and humans. Subtypes of glutamatergic neurons show preferential localization to discrete subdivisions, which are likely to participate in different circuits and functions. The discovery that glutamatergic neuronal subtypes are differentially distributed within the midbrain dopamine system from rodents to humans provides novel translational insight into studies of midbrain-related illnesses.

Title: Characterizing optically evoked dopamine in the olfactory tubercle of the rat brain using *In vivo* fast-scan cyclic voltammetry

Authors: *K. T. WAKABAYASHI[1], R. V. BHIMANI[2], C. E. BASS[3], J. PARK[1];
[1]BCLS, [2]Neurosci. Program, [3]Pharmacol. and Toxicology, Univ. At Buffalo, Buffalo, NY

Abstract: The olfactory tubercle (OT), as a component of the ventral striatum, serves as an important multisensory integration center for reward-related processes in the brain. Recent studies show that dense dopaminergic innervation from the ventral tegmental area (VTA) into the OT may play an outsized role in disorders such as psychostimulant addiction and disorders of motivation. However, due to its anatomical inaccessibility, relative small size, and proximity to other dopamine-rich structures, neurochemical assessments using conventional methods cannot be readily used. Recently, we investigated dopamine (DA) regulation in the OT of urethane-anesthetized rats using *in vivo* fast-scan voltammetry (FSCV) coupled with carbon-fiber microelectrodes, following optical stimulation of the VTA expressing channelrhodopsin-2 (ChR2), a non-native light sensitive cation channel, whose expression was driven by a generalized non-restricted promotor. Using FSCV, we compared DA modulation in the OT to the nucleus accumbens (NAc), a structure located adjacent to the OT and which also receives dense DA innervation from the VTA. We found that optical stimulation of DA occurred in two distinct regions of the ventral striatum, the OT and NAc. As well, optically evoked DA in the OT only occurred when the VTA was optically stimulated. Finally, we showed that DA transporters play an important role in regulating DA in the OT. However, the VTA is a highly heterogeneous brain region containing many different types of neurons including DA. Therefore the use of a generalized non-restricted promotor results in ubiquitous expression of ChR2 in all neurons in the VTA. Using a recently developed viral system, we have been able to target ChR2 expression to DA neurons in the VTA and are comparing the regulation of this neurotransmitter in different OT subregions.

Title: Dopamine D2 receptors on indirect pathway medium spiny neurons regulate motivation, but not learning, in a water T-maze

Authors: *T. J. O'NEAL[1], D. M. FRIEND[1], A. V. KRAVITZ[1,2];
[1]NIDDK, Bethesda, MD; [2]NIDA, Baltimore, MD

Abstract: Cognitive flexibility is the ability to adapt one's decision making based on current and prior circumstances. Within the striatum indirect pathway medium spiny neurons (iMSNs) have been implicated in cognitively flexibility and behavioral regulation, yet their exact role in cognitive flexibility has not been established. Here, we generated mice specifically lacking D2Rs in iMSNs (iMSN-D2R-KO mice) and tested learning and cognitive flexibility using a water T-maze reversal learning paradigm: mice placed at the base of a water-filled maze were taught to swim to an escape platform at the end of a single arm and, once learning criteria was reached, the platform location was reversed. iMSN-D2R-KO mice learned the location of the platform similarly to WT mice, as evidenced by similar number of days to reach criteria, errors within trials, and latency to reach the platform once initiating a trial. In addition, iMSN-D2R-KO mice reversed normally, as assayed with the same measures. However, iMSN-D2R-KO mice had a significant, progressively increasing delay to leave the entry arm at the start of each trial ($p < 0.001$) due to significant immobility within the entry zone ($p < 0.001$), and this delay became even more pronounced during reversal learning ($p < 0.0001$). These findings demonstrate that while iMSN-D2Rs are not necessary for either acquisition of the T-maze task or learning the new location of the platform during reversal, they appear to be involved in the motivation to initiate trials. We next tested iMSN-D2R-KO mice in a learned helplessness paradigm involving repeated forced swim tests and found that they did not differ from WT mice in the development or expression of learned helplessness, as measured by immobility within the water. We conclude that WT mice adapt their behavior from helpless to goal-seeking in the presence of an escape, as in the water T-maze, while iMSN-D2R-KO mice do not. This suggests that D2Rs on iMSNs are particularly relevant for motivating negatively reinforced behavior.

Title: Dorsal raphe nucleus serotonergic and glutamatergic neurons: distinct roles in reward learning

Authors: *R. A. MCDEVITT, R. M. MARINO, A. BONCI;
NIDA, Baltimore, MD

Abstract: The dorsal raphe nucleus (DRN) is a brain region best known for containing the majority of the brain's ascending serotonergic neurons. A subset of these serotonergic neurons express the vesicular glutamate transporter-3 (vGlut3) gene, which allows them to co-release glutamate. Additionally, the DRN contains a group of pure glutamate neurons that express vGlut3 in the absence of serotonergic markers. Recent studies suggest that mice will work to obtain optogenetic stimulation of serotonergic or glutamatergic DRN populations, although the relative strengths of these cell types in driving reward seeking have not been clearly defined. To address this, we have systematically compared self-stimulation rates of mice stimulating these populations. We directed expression of channelrhodopsin-2 (ChR2) to serotonergic or glutamatergic populations by injecting a cre-dependent viral vector (DIO-ChR2-eYFP) into DRN tissue of knock-in mice expressing cre recombinase controlled by the serotonin transporter (SERT-cre) or vGlut3 (vGlut3-cre). We allowed mice to perform a nose-poke task to obtain brief trains of laser stimulation, with light directed at DRN tissue. After several days of training, vGlut3-cre mice performed significantly more nose pokes than SERT-cre mice in this task, suggesting that the population of neurons primarily responsible for the reinforcing effects of DRN stimulation are non-serotonergic glutamate neurons. In future experiments we plan to explore the role of these neurons in reward learning tasks using optogenetic inhibition.

Title: VTA projection neurons releasing glutamate and GABA in the dentate gyrus

Authors: *N. NTAMATI, C. LÜSCHER;
Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: Both dopamine and non-dopamine neurons from the VTA project to a variety of brain regions. Here we examine non-dopaminergic neurons in the mouse VTA that send long-range projections to the hippocampus. Using a combination of retrograde tracers, optogenetic tools, and electrophysiological recordings, we show that VTA GABAergic axons make synaptic contacts in the granule cell layer of the dentate gyrus, where we can elicit small postsynaptic currents (PSCs). Surprisingly, the currents displayed a partial sensitivity to both bicuculline and NBQX, suggesting that these meso-hippocampal neurons co-release both GABA and glutamate. Finally, we show that this projection is functional in vivo and its stimulation reduces granule cell-firing rates under anesthesia. Altogether, the present results describe a novel connection between GABA and glutamate co-releasing cells of the VTA and the dentate gyrus.

Title: Resolving accumbal projections to lateral hypothalamus

Authors: *E. C. O'CONNOR, S. THOENI, C. LÜSCHER;
Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: Nucleus accumbens sends inhibitory projections that express dopamine D1Rs or D2Rs to several downstream targets, including ventral pallidum, lateral hypothalamus (LH) and ventral midbrain. Our previous work has shown that the dominant accumbal projection to lateral hypothalamus comprises dopamine D1R-expressing medium sized spiny neurons (D1-MSNs), which inhibit LH GABA neurons to rapidly control food consumption. Here using neuronal tracing, combined with *in vitro* electrophysiology in transgenic mouse lines that permit identification and control of specific cell types, we report that D1R-MSNs also inhibit LH glutamate neurons. We further explore the identity and projection specificity of these LH glutamate neurons and probe their role in food intake control and arousal. Taken together, our data suggest heterogeneity in accumbal projections to lateral hypothalamus and expand upon our understanding of ventral striatal output in the control of motivation and emotional behaviour.

Title: Viral vector-mediated reversible blockage of the VTA-Nacc circuit and its role in motivational behavior in primates

Authors: *P. VANCRAEYENEST[1], J. ARSENAULT[1,2], K. ISA[3], K. KOBAYASHI[4], T. ISA[3,4,5], W. VANDUFFEL[1,2,6];
[1]Neuro and Psychophysiology, KU Leuven, Leuven, Belgium; [2]Massachusetts Gen. Hosp., Athinoula A. Martinos Ctr. for Biomed. Sch. of Med., Kyoto Univ., Kyoto, Japan; [6]Radiology, Harvard Med. Sch., Boston, MA

Abstract: Although the role of the ventral tegmental area (VTA) in reward-driven behaviors is supported by electrophysiology (Schultz et al., 1997) and electrical microstimulation (Arsenault et al., 2014), the specific role of the VTA-Nucleus accumbens (NAcc) pathway in such behaviors remains untested in primates. We examined the neural and behavioral role of this specific circuit in macaques using a pathway-selective double-infection technique (DIT, Kinoshita et al. 2012). Neuronal transmission was blocked by injecting a highly efficient retrograde gene-transfer (HiRet) LVV in NAcc, followed by an injection of an AAV carrying a reverse tetracycline transactivator in VTA. Reversible expression of a fluorescent protein (FP)-tagged enhanced tetanus neurotoxin (eTeNT) in the VTA-to-NAcc projection neurons could be controlled by oral administration of doxycycline (DOX). To assess the effects of this intervention on functional connectivity and behavior, we used resting state fMRI (rfMRI) and a reward-based reversal discrimination paradigm. Afterwards, immunohistochemistry (IHC) and in-situ hybridization (ISH) was performed to determine the distribution and type of effectively inactivated VTA-NAcc projection neurons.
During the behavioral experiments, monkeys had to select between two simultaneously presented visual cues using a reward reversal paradigm. Reward probability varied across cue identity (1/3 vs. 2/3 of cue A and cue B trials were rewarded, respectively) which was reversed after a random number of trials. A learning model (Dayan & Abbot, 2001) applied to the data, revealed an increase in explorative behavior and decrease in learning rate after reversible inactivation of the VTA-NAcc pathway, bilaterally (N =2). The opposite effect was seen during DOX administration in naïve control monkeys (N = 2), indicating that ongoing learning in these monkeys was unaffected. Due to possible compensation of the contralateral hemisphere, behavioral effects during unilateral blockage were less pronounced (N =1). The rfMRI data showed a surprising but robust increase in functional connectivity between VTA and connected sites in all double-infected hemisphere (N=5), which suggests a release of inhibition of the VTA, possibly via a feedback loop, after inactivation of the VTA-NAcc pathway. IHC and ISH confirmed the successful double-transduction of both HiRet and AAV and therefore blockage of the VTA-NAcc neuronal circuit. Most of the FP-positive VTA neurons were TH-expressing dopaminergic cells. These results causally demonstrate the role of primate VTA-NAcc signaling in the regulation of stimulus-specific reinforcement.

Title: Uncovering the molecular diversity of GABA neurons in the ventral tegmental area and substantia nigra.

Authors: *E. PAUL, K. TOSSELL, E. KALK, K. GREEN, J. LEIPER, M. UNGLESS; Neurophysiol., MRC Clin. Sci. Ctr., London, United Kingdom

Abstract: Midbrain dopamine neurons of the ventral tegmental area (VTA) and substantia nigra (SNC) are central to controlling voluntary movement, working memory, motivation and reward processing, as well as being implicated in multiple neuropsychiatric disorders. Dopamine neuron activity is strongly regulated by GABA neurons, including those found in the VTA and SNC, which make up around 30% of the neuronal population. Little is known about the functional roles of GABA neurons in this system and in particular whether there are functionally-distinct subgroups (e.g., dedicated interneurons, projection-specific output neurons and so on). Indeed, GABAergic neurons in other regions, including the hippocampus, cortex and spinal cord, exhibit considerable molecular, anatomical and functional diversity. We, therefore, hypothesized that GABA neurons in the VTA and SNC are also likely to exhibit similar levels of diversity. As a first step, we are seeking to uncover molecular markers that might identify distinct GABAergic subpopulations. To do this, we are taking two complimentary approaches. First, we are using a biased approach by investigating the expression of neuronal nitric oxide synthase (nNOS), parvalbumin and somatostatin, molecular markers known to identify GABAergic subgroups in other regions (e.g., hippocampus) using immunostaining. We find that nNOS is selectively expressed in a subset of GABA neurons in the parabrachial pigmented area of the VTA. In contrast, parvalbumin is expressed by a subset of dopamine neurons in the VTA; and somatostatin is absent in both the VTA and SNC. Second we are taking an unbiased approach, using tagged ribosomal affinity purification to isolate RNA specifically from GABA neurons in the ventral midbrain for RNA sequencing and the subsequent identification of novel molecular markers. Identification of these molecular markers, will allow for the future selective targeting and manipulation of subpopulations of GABA neurons in the VTA and SNC (by, for example, using cell-type-specific optogenetic stimulation) and a clearer understanding of the role of GABA neuron diversity within the midbrain dopamine system.

Title: Investigating the role of mesolimbic dopamine transmission in incentive motivation

Authors: *B. HALBOUT[1], K. M. WASSUM[2], S. B. OSTLUND[1];
[1]Anesthesiol., Univ. of California, Irvine, Irvine, CA; [2]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Cues that have been repeatedly paired with rewards can exert a strong influence over reward-seeking behaviors. In particular, such cues tend to acquire incentive motivational properties, which allow them to (1) trigger previously learned reward-seeking actions and (2) reinforce new actions. These sources of influence are separately studied using Pavlovian-to-instrumental transfer (PIT) and condition reinforcement tasks, respectively. While numerous studies suggest that mesolimbic dopamine transmission is critical for the acquisition and expression of incentive motivation, there is still debate regarding how dopamine contributes to this process, including whether phasic and tonic dopamine signals differentially contribute to this aspect of behavior.

Using in-vivo optogenetics, we investigated the effect of phasic activation of ventral tegmental area (VTA) dopaminergic neurons on the expression of cue-motivated reward seeking using a food-reinforced PIT task. Interestingly, our preliminary results indicate that such treatment has no impact on PIT performance, even though these stimulation parameters were effective in supporting intra VTA self-stimulation when delivered in a response-contingent manner. A separate experiment was conducted to examine whether an auditory cue paired with optogenetic VTA dopamine self-stimulation would develop the ability to conditioned reinforce. However, this study also found little evidence that phasic stimulation of mesolimbic dopamine release served as an incentive motivational signal. Together these results raise questions about the involvement of phasic dopamine transmission in incentive motivation.

Title: Functional characterization of inputs between parabrachial nucleus and ventral tegmental area

Authors: *J.-H. TSOU[1,2], H.-J. YAU[1,3], A. BONCI[1,4,5];
[1]Cell. Neurobio. Res. Br., NIDA/NIH, Baltimore, MD; [2]Grad. Inst. of Med. Sciences, Col. of Medicine, Taipei Med. Univ., Taipei, Taiwan; [3]Grad. Inst. of Brain and Mind Sciences, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [4]Solomon H. Snyder Dept. of Neuroscience, The Johns Hopkins Univ., Baltimore, MD; [5]Dept. of Psychiatry, The Johns Hopkins Univ., Baltimore, MD

Abstract: Taste helps establish food preference and the neural processing of taste aspect of food reward starts from the gustatory system. The gustatory information via cranial nerves reaches the brain first in the nucleus of the solitary tract (NST). The Parabrachial nucleus (PBN) receives the excitatory glutamatergic input from the NTS and has been shown to modulate feeding behaviors. In addition, PBN is also necessary to convey hedonic information of stimuli related to taste. Given that PBN sends substantial projections to midbrain dopamine neurons, it raises the possibility that taste stimuli may engage dopamine neurons in the ventral tegmental area (VTA) via PBN to modulate food intake. Thus, in the present study, we set out to study the functional connection between PBN and VTA in relationship to food consumption. We first carried out *in situ* hybridization to verify the neuronal types in PBN. In the past, locally electrical stimulation or pharmacological manipulation has the limitation to characterize defined connections. Thus, we would employ optogenetic approach by selectively express channelrhodopsin (ChR2) in specific Cre transgenic mouse line to target specific subtype of PBN neurons. We specifically tweaked PBN-to-VTA afferent input by delivering 473 nm blue light to the VTA via fiber optics while mice were performing behavioral task. The preliminary results showed that VTA receives functional inputs from the PBN and photostimulation of PBN-to-VTA input affects food consumption.

Title: Ventral tegmental area glutamate neurons co-release GABA in a target-dependent manner to drive positive reinforcement

Authors: *V. ZELL, J. H. YOO, N. GUTIERREZ-REED, J. WU, R. RESSLER, M. A. SHENASA, A. B. JOHNSON, K. H. FIFE, L. FAGET, T. S. HNASKO;
Neurosciences, UCSD, San Diego, CA

Abstract: The ventral tegmental area (VTA) is a heterogeneous midbrain structure implicated in goal-directed behaviors. The VTA contains well-characterized dopamine neurons, but also GABA and glutamate neurons, subsets of which can co-release more than one of these transmitters. In our study, we report that optogenetic stimulation of VTA glutamate soma or terminals serves as a positive reinforcer on operant behavioral assays. Further, mice display marked preference for brief over sustained VTA glutamate neuron stimulation resulting in behavioral responses that are notably distinct when compared to dopamine neuron stimulation in operant choice and real-time place assays. Whole-cell recordings reveal EPSCs following stimulation of VTA glutamate terminals in the nucleus accumbens or local VTA collaterals; but reveal both excitatory and monosynaptic inhibitory GABA postsynaptic currents in the ventral pallidum (VP) and lateral habenula (LHb). The net excitatory effect in the VP and inhibitory effect in the LHb are both consistent with the measured relative GABA-glutamate components, and the observed rewarding behavioral effects. These data indicate that VTA glutamate neurons co-release GABA in a projection-target dependent manner and that their transient activation drives positive reinforcement distinct from dopamine.

Title: Ventral pallidum roles in cue-elicited sucrose seeking versus alcohol seeking

Authors: *J. M. RICHARD[1], N. STOUT[1], A. M. ARMSTRONG[1], P. H. JANAK[1,2];
[1]Dept. of Psychological and Brain Sci., [2]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The mechanisms by which neutral cues elicit reward seeking are a critical area of inquiry in the neurobiology of addiction. Recently we have shown that activity of ventral pallidum (VP) neurons in response to a cue predicting reward availability encodes both the likelihood and latency of subsequent instrumental reward-seeking actions. Additionally, inactivation of VP neurons during the cue period reduces the likelihood and rapidity of reward-seeking behavior, suggesting that VP neurons encode and functionally contribute to the incentive motivational properties of cues. Here, we investigate whether VP neuron activity plays a similar role for conditioned responses to Pavlovian cues predicting reward delivery, and whether this differs for sugar versus alcohol rewards. Male and female Long Evans rats were trained to associate one auditory cue (the CS+) with delivery of 20% alcohol or 10% liquid sucrose reward and an alternative auditory cue (CS-) with no delivery of reward. Rats were trained until they entered the reward port on >70% of CS+ trials and <30% of CS- trials, and then were implanted with microwire arrays aimed at the VP. We find that ~25% of VP neurons (42/180) are excited by the CS+, and that these excitations are greater to the CS+ than the CS-, and greater on trials when rats make a port entry during the cue. VP neurons exhibit similar responses to cues predicting alcohol (10/21 neurons excited by the CS+). These results suggest that VP neural responses to Pavlovian cues may functionally contribute to cue-elicited reward seeking in the form of port entries. Consistent with this, in rats receiving sucrose, we find that pharmacological inactivation of VP with GABA agonists suppresses the number of entries and time spent in the reward port during the CS+, but not during the CS- or the pre-cue period. Further, in rats trained with alcohol, optogenetic inhibition via ArchT3.0 in VP neurons just during the cue period reduces the likelihood of a port entry and time spent in the port during the CS+, but not during the CS- (when port entry responses are already low). These results suggest that, in addition to

encoding and contributing to the ability of cues to invigorate instrumental reward-seeking actions, that VP neuronal activity during cue presentations is required for Pavlovian responses to reward cues for both natural and drug reward.

Title: Orexin and melanin-concentrating hormone (MCH) receptor activation in the nucleus incertus of adult rats alters locomotor activity and food intake

Authors: *A. SABETGHADAM[1], A. GRABOWIECKA[2], A. KANIA[2], A. BLASIAK[2], S. MA[1], A. L. GUNDLACH[1];
[1]The Florey Inst. Neurosci and Mental Hlth., Melbourne, Australia; [2]Dept Neurophysiol and Chronobiol, Jagiellonian Univ., Krakow, Poland

Abstract: The brainstem nucleus incertus (NI) contains a discrete population of GABA/peptide projection neurons that are highly responsive to psychological stressors via corticotrophin-releasing factor (CRF) and CRF1 receptor signaling [Ma S et al. J Physiol 591, 3981-4001, 2013]. Furthermore, the NI receives an orexinergic innervation from the lateral hypothalamus (LH) and expresses orexin receptors (OX1 and OX2), with strong activation observed via OX2 in vitro [Blasiak A et al. Neuropharmacology 99, 432-47, 2015]. Moreover, the NI relaxin-3 and LH orexin systems are implicated in the regulation of arousal and feeding [Ganella DE et al. Behav Pharmacol 23, 516-25, 2012]. As MCH and MCH1 receptor signaling is also involved in these processes and interacts with orexin signaling; with anatomical evidence of MCH1 expression within the NI; in the current study in adult rats, we examined the effect of acute bilateral injections into the NI of orexin-A and MCH and vehicle on locomotor activity and food

intake and the comparative effects of these peptides on NI neuron activity in vitro. Infusion of orexin-A (600 pmol) into the NI of conscious, satiated rats during the light phase produced an increase in total activity in a 240 min trial in a locomotor cell ($P<0.05$, n=5/group) and a modest increase in cumulative food intake ($P<0.01$, n=10/group) across a 4 h period, with increases seen from 30 min post-injection. Under the same conditions, intra-NI infusion of MCH (600 pmol) decreased the relatively low levels of locomotor activity ($P<0.05$, n=7-9/group) and the modest food intake observed in vehicle-treated rats ($P<0.05$, n=6/group). Interestingly, in 6 h light-phase, fasted rats, MCH (600 pmol) injected into NI during the early dark phase increased food intake for 1 h post-infusion ($P<0.01$, n=7/group), with no effect on the strong locomotor activity detected during the 240 min trial ($P>0.05$, n=6/group). Patch-clamp recordings revealed that ~1/3 of NI neurons tested were hyperpolarized by MCH (13/40 cells), with complex responses to MCH and orexin-A - 10 sensitive to orexin-A only, 6 MCH only, and 3 to both peptides. Other neurons tested (10) did not respond to either peptide. In conclusion, the impact of orexin/MCH inputs on NI neuron activity is largely consistent with those observed in other brain regions and related to modulation of integrated behavioral states such as sleep/wakefulness and appetite/metabolism. Further anatomical and functional studies are now required to determine how orexin/MCH projections to NI activate/inhibit different groups of neurons and circuits, and if this balance is altered during the light and dark phase, in relation to motivated activity and behaviors.

Title: A novel role for the periaqueductal gray in consummatory behavior

Authors: *V. L. TRYON, S. J. Y. MIZUMORI;
Psychology, Univ. of Washington, Seattle, WA

Abstract: The periaqueductal gray (PAG) has a well-established role in pain processing, autonomic function, and behavioral responses to fear. However, anatomical work alludes to the PAG having a functional role in food intake and reward processing. Indeed, the PAG sends excitatory and inhibitory projections to both GABAergic and dopaminergic VTA neurons (Omelchenko & Seasack, 2010). In fact, the PAG provides the third heaviest subcortical glutamatergic input to the VTA (Geisler et al., 2007). Additionally, the PAG has been shown to have extensive reciprocal connections with a core feeding circuit in the brain (Betley et al., 2013). Therefore, our question was whether or not the PAG has a functional role in appetitive or consummatory behaviors. To address this, the PAG was reversibly inactivated during two separate food intake tasks in food-restricted male Long Evans rats. PAG inactivation resulted in a significant decrease in the amount of food consumed, as well as an increased latency to consume a palatable reward. Our next study investigated PAG neural responses to reward encounters as a different group of rats performed on a spatial working memory radial maze task. Rats were trained to retrieve large and small rewards (four or one 45 mg sucrose pellets) that were consistently found in the same locations on a radial eight arm maze. Once rats reached asymptotic performance levels on the task, they were implanted unilaterally with a 6-12 tetrode array aimed at the PAG. Analysis of the neural data reveals that in a subset of PAG neurons, there was phasic excitation at the onset of reward encounters as well as phasic inhibition in a separate subset of PAG neurons. These reward responses scaled with the size of the reward, with sustained excitation or inhibition in response to large rewards compared to small for reward-excited and reward-inhibited neurons. These results, taken together with the inactivation studies and anatomical evidence, suggest that the PAG may in fact play a role in consummatory behavior and reward related processing.

Title: Adaptor protein, X11 and X11L have distinct roles in exploratory activity.

Authors: *T. SATO[1], R. MOTODATE[1], Y. SANO[2], S. KAMADA[3], S. UCHIDA[3], T. SUZUKI[1];
[1]Hokkaido Univ., Sapporo-Shi, Japan; [2]Tokyo university of science, Chiba, Japan; [3]Kyushu Univ., Fukuoka, Japan

Abstract: X11/Mint1 (Munc18-1 interacting protein) and X11-like (X11L/Mint2) proteins are strongly expressed in the brain and evolutionary-conserved [1]. It is well known that X11 and X11L interact with many molecules such as Munc18-1, N-type calcium channels, β-neurexin, and hyperpolarization-activated cyclic nucleotide-gated potassium channel 2, and regulate synaptic function [1-6]. Though X11 and X11L are composed of similar functional domains such as a PTB (phosphotyrosine binding) and two PDZ (PSD95/discs large/ZO-1) domains, their expression pattern in the brain is so different. These findings indicate that they have different roles in the brain. So far, the involvement of X11L in the motivated behavior and cognition have been well analyzed [7]. However, the role of X11 in the higher brain function is not well studied, and also especially it lacks comprehensive comparison about their roles in the brain. To address this issue, we analyzed exploratory activity in the open field using X11-, X11L- and X11/X11L - double knockout (KO) mice. Interestingly, X11-KO mice and X11L-KO mice were opposite in the number of rearing and jumping. And the traveled distance was time-dependency increased in X11/X11L double KO mice, although it was time-dependency decreased in Wild Type mice. Our results indicate X11 and X11L have distinct roles in exploratory activity. 1) Rogelj, B. et al., Brain Res. Rev. 52, 305-315 (2006) 2) Okamoto, M. et al., J. Biol. Title: A comparison of prefrontal cortex activity across emotional stroop and dot-probe tasks of attentional bias: a near-infrared spectroscopy study

Authors: ***K. J. KANGAS**, J. CARLSON;
Northern Michigan Univ., Marquette, MI

Abstract: Near-infrared spectroscopy (NIRS) research measuring prefrontal cortex (PFC) activity during emotional processing has been limited. Functional MRI research indicates that the amygdala and PFC are involved in orienting visuospatial attention to emotionally salient stimuli.

Two common tasks of attentional bias include the emotional Stroop and the dot-probe task. Both tasks appear to engage the PFC. However, research directly comparing attention-related PFC activation across these tasks is limited. Here, we examined PFC activity using NIRS while participants performed the dot-probe and emotional Stroop tasks in a counterbalanced order. In the dot-probe task participants had to locate a target dot, which was preceded by face pairs. There were three trial types: baseline (two neutral faces), congruent (dot appears behind the fearful face), and incongruent (dot appears behind the neutral face). The emotional Stroop task consisted of threating and neutral images surrounded by a boarder, which participants were asked to identify the color of. At a behavioral level, both tasks indicated that attention was captured by emotion. Reaction times were quicker for congruent (M = 361.07) compared to incongruent (M = 377.62) trials in the dot-probe task (t = -4.09, $p < 0.01$) and were slower for threatening (M = 615.13) compared to neutral (M = 603.30) images in the emotional Stroop task (t = 1.81, $p < 0.05$). At a neural level, both tasks elicited PFC activity. Thus by comparing these two tasks, NIRS data suggests the PFC is involved in emotional processing, along with orienting visuospatial attention to fearful stimuli.

Title: Difference with accordance and discordance of affective words with voice tone - A simultaneous EEG/MEG study

Authors: *M. KWON[1], H. CHO[1], S. AHN[1], K. KIM[2,3], S. JUN[1];
[1]Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of; [2]Korea Res. Inst. of Standards and Sci., Daejeon, Korea, Republic of; [3]Univ. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Emotion is evoked by various routes such as video clip, sound, smell, and touch. Among all, sound is a very important sense in that it may be delivered even when one's ears are almost closed and it may include significant information like emotion or intention from only one words. In this study, we investigated brain activation with collected EEG/MEG data when words are given with accordance or discordance of affective words with affective voice tone. Five positive and five negative affective words were spoken in Korean and each of words was vocalized with positive and negative voice tones. These stimuli consist of accordance and discordance set; accordance means positive (negative) words with positive (negative) tone, and discordance means positive (negative) words with negative (positive) tone. Twenty-three native Korean subjects (12 males, 11 females; age 23.82.9) listened the words and 21 EEG channels (Biosemi) and 152 MEG channels (KRISS, axial gradiometer system), vertical/horizontal EOG and EKG were measured simultaneously with 1024 Hz sampling rate. EEG and MEG data were filtered with 1 - 55 Hz, baseline corrected using 200 ms before stimulation, and EEG data were re-referenced with two earlobe channels. Power spectrum were calculated every 100 ms with time window of 100 ms. There was difference between accordance and discordance stimuli in the frontal area from EEG signal. When positive words vocalized with negative tone are given, the frontal area was more activated at 0 - 400 ms than those with positive tone. In addition, male subjects were more activated to accordance stimulus at 500 - 600 ms, where female subjects were not different. When negative words were given, accordance case was more activated, but male subjects lasted longer time (male: 100 - 700 ms, female: 200 - 300 ms). MEG showed the similar patterns to EEG, but notable different activation area between accordance and discordance was the temporal area, which yielded the shorter duration than EEG. From these results, it was believed that voice tone may be more influential on emotion than words, especially, negative tone may be critical. Furthermore, word processing is related with components at 400 - 600 ms, and brain activation of male subjects showed changes following meaning of words; thus it was inferred that the male may have more influenced with words than the female.

Title: Extracting insular activation using scalp EEG during expectation of emotional picture.

Authors: ***N. KANAYAMA**, K. MAKITA, T. SASAOKA, M. MACHIZAWA, S. YAMAWAKI;
Hiroshima Univ., Hiroshima-Shi, Japan

Abstract: The insular cortex is a very important brain area for understanding human emotion. The anterior insular cortex as a subdivision of the insula has an important role for inference of interoceptive signals that underlie our emotional response [1]. Moreover, there has been growing interest in the insula as a hub for cognition and emotion [2]. However, the position of the insular cortex is within the lateral sulcus, which separates the temporal lobe and the inferior parietal lobe. The insular cortex is folded deep within the brain; therefore, it is difficult to measure the activation using scalp electroencephalogram (EEG). Here, we tried to extract the EEG activation of the insular cortex using independent component analysis (ICA) implemented in EEGLAB [3] and a new source estimation method implemented in SPM [4].
We conducted EEG and functional magnetic resonance imaging (fMRI) experiments separately with the same task: the emotional expectation and evaluation task using auditory cue (High: 4000 Hz, Middle: 1500 Hz, Low: 500 Hz), which indicates the valance of an upcoming picture, positive or negative. After the expectation period (4 sec), participants viewed a picture with emotional valance (4 sec). During the picture presentation period, participants were requested to evaluate the valance of the presented picture (very positive/ positive/ negative/ very negative). The presented pictures were selected from the International Affective Picture System (IAPS). We recorded scalp EEG during the emotional expectation and evaluation task and applied ICA on the data to exclude the external and biological noise. Using the scalp EEG data cleaned by ICA, the source estimation method with multiple sparse prior (MSP), implemented in SPM12 was applied. The activation maps, which were acquired by the fMRI experiment with an identical task, were used as a prior for source estimation. The activation map was obtained by one sample t-test for each condition (FWE, $p < .05$). As a result, we could successfully extract the activation of the insular cortex, which was significantly different for positive and negative expectations ($p < .05$, using permutation test). This significant difference was not observed by the same source estimation without the fMRI prior or ICA. This highlights the effectiveness of the combined use of ICA and MSP source estimation using fMRI prior on scalp EEG.

Title: The utility of EEG frontal alpha power asymmetry in detecting emotional affect

Authors: *J. DREO, F. AGATIć, M. KAPITLER, Z. PIRTOŠEK;
Lab. For Cognitive Neurosci., Ljubljana, Slovenia

Abstract: It has previously been reported that asymmetries in frontal alpha-band power predict emotional affect in human subjects. While the limbic system is too deep to be reliably monitored using EEG, its widespread connections to the surface layers of the cortex offer an indirect way of inferring its activity. Basic electrophysiological investigations have confirmed a reliable inverse relationship between EEG alpha power and underlying cortical metabolic activity. Increases in alpha power thus correlate to decreased brain activity and vice versa. According to the frontal alpha power asymmetry hypothesis of affect detection, a relative increase of right vs. left frontal alpha power correlates to a subjective experience with positive emotional valence (approach) and a relative increase of left vs. right frontal alpha power with negative emotional valence (withdrawal). This method is increasingly being used in neuromarketing research to attempt to predict customer satisfaction with advertisements. We tested this hypothesis by conducting 128-channel EEG recordings on 22 subjects. The subjects were shown a series of 100 images from the Nencki affective picture system (NAPS). Half of the images were selected to have a strong negative emotional valence and half a strong positive one. The images were presented in a random sequence for 5 sec with an additional blank 5 sec “washout” period between them. EEG data was inspected and cleaned of artifacts (muscle, sweating, ocular) before being segmented into trials lasting from -1000 ms to +4000 ms relative to image onset. The average reference was calculated and spectral analyses (FFT and Wavelets) were performed on a channel by channel basis. Relative alpha power changes from baseline levels (before image onset) were calculated for each image. These were then averaged separately for positive and negative images. A statistical comparison was performed on several channel derivations and whole-scalp data. Additionally, the same analysis was run on data transformed with the spherical spline Laplacian operator. There were no statistically significant differences in left vs. right frontal alpha power asymmetry between negative and positive images. Our findings cast doubt on the reported robustness of a widely used method in neuromarketing research.

Title: The role of inferior parietal lobule and ventral premotor cortex in emotion body processing: a combined ctbs-fmri study

Authors: *T. ENGELEN[1], M. ZHAN[2], A. SACK[2], B. DE GELDER[2];
[1]Cognitive Neurosci., [2]Maastricht Univ., Maastricht, Netherlands

Abstract: The perception of emotion stimuli in the environment prepares our bodies for action, and especially when confronted with whole body expressions of an emotion like anger, action-related areas in the brain are triggered. Previously, parietal dorsal stream and premotor areas have been linked as crucial areas for processing of such stimuli, but questions about their contributions and specificity within the body processing network remain. We set out to disentangle the respective roles of dorsal stream areas crucial for action observation (Inferior Parietal Lobule (IPL)) and premotor areas involved in action preparation (ventral premotor cortex (PMv)) in the processing of emotional bodies by assessing local as well as remote effects of cTBS stimulation within the body processing network. Seventeen participants completed the experiment, which consisted of three fMRI sessions. Functional images were acquired using a 3T scanner with a 64-channel head-neck coil. During each session a passive viewing task was performed in which blocks of short videoclips of actors performing a neutral or angry action were presented. Two of the sessions were preceded by neuronavigated cTBS stimulation over either rIPL or rPMv based on individual anatomy. One session was used to assess baseline activity. During the baseline session two functional localizers were acquired to determine regions of interest (ROI). Functional ROIs include bilateral extrastriate body area (EBA), right temporoparietal junction (rTPJ), and right posterior superior temporal sulcus (rpSTS). Results indicate a general decreased response to both angry and neutral bodies in three of the functionally defined regions of interest (lEBA, rTPJ and rpSTS). Further analysis will focus on anatomically defined ROIs representing the areas stimulated (rIPL and rPMv), as well as whole brain group analysis comparing the three sessions and connectivity changes due to cTBS stimulation. Stimulation of IPL and PMv has previously shown effects on the behavioural level. The results of the current experiment extend these results by showing how also remote areas involved in body processing are affected by stimulation.

Abstract: Background. Obesity can have physical or psychological consequences, within these last, we have emotional distress, loss of self-esteem and high levels of anxiety and depression .However, it is not well established whether obesity participates in the detriment of self-esteem. **Objective**. Determine the level of self-esteem in obese adult patients attending the outpatient of General Hospital Area Family Medicine Unit N° 8 in the Federal District. **Materials and methods**. Cross-sectional descriptive study. Inclusion criteria: age greater than 18 years, Mexican Institute of Social Security patients, regardless of gender or occupation. Sample: 234 patients. CI: 90%. Instrument: Coopersmith Self-Esteem Inventory (for adults). Dependent variable: levels of self-esteem and independent variable: obesity. **Results**. A ratio of 79.9% was obtained women and 20.1% men. With respect to self-esteem, a frequency of 7.3% low self-esteem, 14.5% average low self-esteem, high average 59.8% and 18.4% self-esteem high esteem in obese patients was found. Furthermore, it was shown that levels of self-esteem may increase or decrease depending on some factors including gender, age, education, type of obesity or marital status. **Conclusions.** The results show the first evidence indicating positive levels of self-esteem in obese adults attending the outpatient HGZ / UMF No. 8. Also, a positive or negative relationship in the self-esteem of obese patients which are mainly related to biological, economic, cultural and educational characteristics of each individual.

Univ. of Singapore, Singapore, Singapore

Abstract: People often make decisions in the face of ambiguous information, but the neural substrates and response characteristics remain unclear. We used three types of ambiguous stimuli and combined EEG and fMRI to examine the neural representation of decisions about perceptual ambiguity. We identified a late positive potential, the LPP, which differentiated levels of ambiguity, and was specifically associated with behavioral judgments about choices that were ambiguous, rather than mere perception of ambiguous stimuli. Source modeling suggested that the LPP originated from multiple loci in cingulate cortex, a finding we further confirmed using fMRI and fMRI-guided ERP source prediction. Two further experiments revealed that the LPP encoded ambiguity in a domain-general fashion. Taken together, our findings argue for a role of an LPP originating from cingulate cortex in encoding decisions based on perceptual ambiguity, a process that may in turn influence others related to conflict and error correction.

Title: Investigating the timecourse of aesthetic experience

Authors: *A. M. BELFI[1], E. A. VESSEL[3], D. G. PELLI[1], G. G. STARR[2];
[1]Psychology, [2]English, New York Univ., New York, NY; [3]Neurosci., Max Planck Inst. for Empirical Aesthetics, Frankfurt, Germany

Abstract: Aesthetic experience is an essential aspect of everyday life. Humans tend to seek out these experiences, such as listening to music, viewing paintings, and reading literature, which are often highly pleasurable. Such aesthetic experiences have been shown to modulate activity in several brain regions, which can be characterized, roughly, into three networks: sensory/motor, emotion/reward, and the default mode network. This suggests that aesthetic experiences are not the property of one brain region but may reflect dynamic interactions between large-scale brain networks. Here, we sought to investigate the dynamic nature of aesthetic experience using fMRI. To capture this inherently dynamic behavior, participants (N = 30) continuously rated their pleasure while viewing images of artworks. To further probe the time-variant nature of aesthetic experience, images were presented for different durations: 1s, 5s, or 15s. Each stimulus was followed by a 14s 'decay' period during which the participant continued to rate their pleasure even though the stimulus was no longer present. After this decay period, participants gave an overall summary rating of the artwork on a sliding scale. Trials were characterized as 'high,' 'medium,' or 'low' based on this overall rating. Stimuli consisted of 90 visual artworks presented in a randomized order. Artworks were museum-quality paintings drawn from various cultures (American, Asian, European) and time periods (from the 15th century to the present) and were selected to be unfamiliar to the participants. To investigate the neural dynamics during aesthetic experience, we performed ROI analyses investigating the timecourse of activity in sensory, emotion, and default mode networks. Our results indicate that presentation duration (1s, 5s, 15s) did not alter the overall proportion of images rated as high, medium, or low overall. Interestingly, this suggests that longer presentation time did not bias participants towards rating the images as more pleasurable. In addition, the overall summary ratings were highly correlated with peak values in the continuous ratings. Neuroimaging results indicated that non-visual brain networks showed activation peaks later in time from visual networks, and unlike visual networks, were sustained during the 14s decay period. These results suggest that aesthetic

experience is represented differently in a range of brain networks and that the timecourse of activity in these networks varies during aesthetic experience.

Title: Representation of emotional contents in auditory stimuli by human insular cortex

Authors: Y. ZHANG[1], Y. DING[1], J. HUANG[2], W. ZHOU[1], Z. LIN[3], B. HONG[1], *X. WANG[4]; [1]Tsinghua Univ., Beijing, China; [2]Mind-Brain Inst., Johns Hopkins Univ., Baltimore, MD; [3]Dept. of Neurosurg., PLA Gen. Hosp., Beijing, China; [4]Dept Biomed Engin, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Accumulating evidence has suggested the role of the insula in emotion recognition. To examine whether the insula is involved in the perception of emotion from auditory stimuli, we recorded electrocorticographic (ECoG) signals from epilepsy patients when they were presented with emotional and non-emotional sounds. Neural signals recorded from different regions of insular cortex revealed different response properties. Posterior region of insular cortex, which is anatomically connected to sensory cortex, showed robust responses to all acoustic stimuli. Similar to the Heschl's gyrus, this region exhibited strong responses that are synchronized to the fundamental frequency of periodic stimuli. No differences were found in the posterior region of insular cortex between responses to emotional and non-emotional sounds. However, the anterior region of insular cortex on the right hemisphere showed robust high gamma responses to emotional sounds, but showed weak or no responses to non-emotional sounds, which indicated emotionally selective processing. In contrast, the anterior region of the left insular cortex did not show emotionally selective responses. Latency analyses showed much shorter response latency in the posterior region than the right anterior region of the insular cortex. Collectively, these observations suggest a role of the anterior insular cortex on the right hemisphere in transforming the basic sensory representations into inner affective representations.

Title: The relationship between emotion recognition performance and limbic gray matter volumes depends on sex and hormonal contraceptive use

Authors: *B. PLETZER[1], M. KRONBICHLER[1], J. CRONE[2], M. AICHHORN[1], H. KERSCHBAUM[1];
[1]Univ. of Salzburg, Salzburg, Austria; [2]Univ. of California, Los Angeles, CA

Abstract: Emotion recognition is central to social interaction and is impaired in a variety of disorders associated with poor social functioning, e.g autism or schizophrenia. Several studies indicate that women display a higher accuracy in recognizing facial emotions than men, particularly for the recognition of sadness and fear. Neuroimaging studies demonstrate that emotion recognition is associated with the activation of limbic and para-limbic regions including the Amygdala, Hippocampus, Parahippocampus, Fusiform gyrus, Insula and cingulate gyrus, with different emotions activating distinct circuits. However, no study has previously related emotion recognition performance to brain structure and resting state functional connectivity. In the present study, 20 men and 53 women (20 naturally cycling, 17 taking androgenic contraceptives, 16 taking anti-androgenic contraceptives) underwent high resolution structural MRI as well as resting state functional MRI. They completed an emotion recognition task three times outside the scanner with two-week intervals between test sessions. The results demonstrate that emotion recognition performance relates to gray matter volumes in limbic areas. However, in men and users of anti-androgenic contraceptives larger gray matter volumes are associated with better performance, whereas in naturally cycling women and users of androgenic contraceptives larger gray matter volumes were associated with poorer performance. The strongest relationships between performance and gray matter volumes were detected for the recognition of disgust and sadness, however recognition of anger also related to gray matter volumes in men, while recognition of fear also related to gray matter volumes in women. Furthermore, emotion-recognition performance related to resting state functional connectivity with the limbic network in the left Insula across all participants. In summary, this study demonstrates for the first time that emotion recognition performance relies not only on the activation of limbic brain areas, but also on limbic brain structure and resting state functional connectivity. Moreover it demonstrates that the former relationship is modulated by sex of participants and hormonal contraceptive use.

Title: Do we always approach positive and avoid negative stimuli

Authors: ***C. FINI**[1], T. EVEREART[2], L. BARDI[2], M. BRASS[2], A. MOORS[2];
[1]Dept. of Experimental-Clinical Psychology, Gent, Belgium; [2]Dept. of Experimental-Clinical Psychology, Ugent, Ghent, Belgium

Abstract: Research supports that positive stimuli lead to approach and negative stimuli to avoidance. To date, no studies have investigated this approach-avoidance effect using transcranial magnetic stimulation (TMS). Twenty students took part to this experiment. In the practice phase, they learned to press a button with the index finger to approach a stimulus and to press a button with the thumb to avoid the stimulus, depending on verbal instructions. When choosing "approach", a manikin moved toward a dot in the center of the screen; when choosing "avoid" the manikin moved away from the dot. In the experimental phase, the dot was replaced with images with a positive or a negative valence. In the compatible block, participants were instructed to approach positive and avoid negative stimuli. In the incompatible block, the instructions were to avoid positive stimuli and approach negative stimuli. Participants could respond only after hearing the instruction "choose". A TMS pulse was given 400 ms post stimulus onset, and MEPs from the first dorsal interosseous (FDI) and the opponent pollicis (OP) of the right hand were registered. The experiment was composed of two sessions: in the first session participants approached with the index finger and avoided with the thumb; in the second session the action-finger mapping was the opposite. The results showed that only the MEPS registered at the FDI were significantly modulated by the instruction, so the analyses were restricted to this finger. When approaching, the motor readiness was modulated by the instructions. Specifically, in the compatible blocks MEPs were significantly larger for positive than for negative stimuli; in the incompatible blocks, MEPs were significantly larger for negative than positive stimuli. When avoiding, instructions did not modulate MEPs amplitude. Indeed, MEPs were significantly larger with negative than positive stimuli irrespective of instructions. Thus approaching seems to be a more flexible action tendency than avoidance, since participants

can equally follow the instruction to approach positive and negative stimuli, whereas they can more easily follow the instruction to avoid negative compared to positive stimuli.

Title: Emotion processing in moebius syndrome patients

Authors: *S. LOKEY, S. JAPEE, C. BAKER, L. UNGERLEIDER;
Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Washington, DC

Abstract: Moebius Syndrome (MoS), a rare congenital neurological disorder, is characterized by abnormality of the VIth and VIIth cranial nerves, resulting in paralysis of the face and a lack of skeletal muscle feedback. The facial feedback hypothesis, a prominent concept in face perception, asserts that feedback from the skeletal muscle of the face alters the experience of emotion (Buck, 1980; Soussignan, 2001; Strack, Martin, & Stepper, 1988). Thus, it is possible that individuals with MoS have trouble identifying or processing emotion. Several studies have examined the ability of individuals with MoS to recognize familiar and unfamiliar faces (Calder et al., 2000; Bate et al., 2013), to experience and express emotion (Cole, 2010), and to recognize and label facial expressions (Giannini et al, 1984; Calder et al, 2000; Bogart & Matsumoto, 2010; Bate et. al, 2013). However, results from these studies have been mixed and it is thus unclear whether MoS leads to deficits in emotion processing. One reason for the conflicting results could be that most of the studies used only an emotion-labeling task, which may not have been sensitive to subtle deficits in emotion processing. Thus in our study, in addition to an emotion-labeling task, we used an emotion-detection task to assess emotion processing in individuals with MoS. Participants were shown morphs of neutral to fearful and neutral to happy faces, and were instructed to distinguish between fearful and neutral, and happy and neutral faces, with a button press. A one-up, three-down staircasing procedure was used to determine each participant's threshold for 79% accuracy. The same morph stimuli and staircasing procedure were used in a feature-detection control task, where participants were instructed to indicate with a button press whether the face depicted an open or closed mouth. For the emotion-

labeling task, participants were shown faces depicting each of 7 emotions (happy, sad, anger, disgust, fear, surprise, neutral) and instructed to press a button corresponding to each emotion. Analysis of threshold levels for the emotion-detection task revealed that individuals with MoS, as compared to controls, showed a deficit in detecting emotion, more so for fearful than happy faces. Performance on the emotion-labeling and control tasks did not differ between individuals with MoS and controls. These results indicate that the paralysis of, and lack of feedback from, the facial muscles in MoS may indeed impair emotion perception, but that this impairment is more in the ability to detect emotion rather than identify it.

Title: Emotional evaluation between young and middle adults with the International Affective Picture System

Authors: *X. CORTIJO-PALACIOS[1], E. ACOSTA-MARI[2], B. BERNAL-MORALES[3], C. GUTIERREZ-GARCIA[4], T. CIBRIAN-LLANDERAL[5];
[1]Inst. De Neuroetología, Xalapa, Mexico; [2]Facultad de Medicina, Univ. Veracruzana., Veracruz, Mexico; [3]Inst. de Neuroetologia, Univ. Veracruzana, Veracruz, Mexico; [4]Ctr. Estatal de Cancerologia Dr. Miguel Dorantes Mesa, Veracruz, Mexico; [5]CONACYT. Inst. de Neuroetologia, Univ. Veracruzana., Veracruz, Mexico

Abstract: Introduction: the International Affective Picture System (IAPS) uses a series of emotional, normative and internationally accessible pictorial stimuli and is considered to be the most reliable and valid system in the experimental study of emotions (Lang et al., 2008). Nevertheless, several studies have been conducted in a population group with very defined characteristics (college students and young adults) so the question arose whether emotional evaluation differ if the images are analyzed by a group of middle adults.
Objective: the purpose of this study was to examine if there are differences in the assesment of one block of sixty images from the IAPS database between young and middle adults.
Participants and Methods: in order to examine differences in the evaluation of IAPS images, we had two groups. The first group was composed for thirty-seven young adults (YA; 46% female and 54% male; mean age 20) and the second group was a sample of fifty middle age (MA; 66% female and 34% male; mean age 49), both groups participated voluntarily. Pictures task: the

pictures were selected from the fifteen block of IAPS database (Lang et al., 2008). The 60 images were set in a power-point presentation and presented individually during 5 sec followed by 5 sec of transition between images. Emotional response was recorded immediately after watching each image using the Self-Assessment Manikin (SAM) 9-point scale for registering the dimension of valence (pleasure) proposed by Bradley and Lang in 1994.
Preliminary results: we found significant differences between young and middle adults in 46% of the slide numbered pictures evaluated: 2153 (p = .0005); 2306 (p= .01902); 2332 (p= .0065); 2358 (p=.0130); 2594 (p=.0388); 2598 (p=.0050); 2704 (p=.0003); 2718 (.0022); 2799 (p=.0195); 2811 (p=.0451); 3017 (p=.0128); 3191 (p=.0026); 3225 (p=.0380); 4006 (p=.0049); 4225 (.0485); 4559 (p=.0347); 5961 (.0005); 6021 (p=.0485); 6825 (.0071); 7056 (p=.0498); 8205 (.0273); 9254 (p=.0010); 9425 (p=.0001), 9426 (.0052); 9427 (p=.0003); 9428 (p=.0177); 9900 (p=.0001), 9901 (p=.0002) t-test.
Conclusions: The findings demonstrate differential processing of emotional content between young ang middle aged adults and may suggest that the human response to affective pictures depends on the development stage and cognitive abilities. Currently we are evaluating the emotional discrimination between different population considering age, gender, education level and chronic diseases like cancer.

Title: The emotional valence of subliminal priming affects perception of facial expressions

Authors: *M. A. HUANG[1,2], K. D. RANA[2], L. M. VAINA[2,3];
[1]McGill Univ., Montreal, QC, Canada; [2]Biomed. Engin., Boston Univ., Boston, MA; [3]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Objectives: We conducted a psychophysical study to determine whether the emotional content of priming images presented subliminally (so briefly that they could not be consciously perceived) affected the subsequent perception of facial expressions.
Methods: The experiment consisted of a priming image shown for 16 ms, followed by a 100ms mask which was a scrambled version of the priming image, followed by a 500 ms presentation of an unfamiliar face (test-face) showing an angry or neutral expression. Observers indicated via

keypress their perception of the test-face expression.
Data was analyzed using a GLMM and an unpaired t-test to characterize the relationship between performance on the test-faces and the content of the primes: presence/absence of a face, centricity (egocentric, directed at the observer, or allocentric, directed away from the observer), and affective category of the prime (aggressive, pleasant, neutral). All prime images were selected from the IAPS [1] database and from image-data bases on the web, and were processed in Matlab to normalize for luminance and size.
Results: Emotional valence of priming images affected perception of test-face expressions. The effect was statistically significant only for aggressive and pleasant primes. Performance on neutral test-faces was significantly worse than on angry test-faces for the aggressive primes which contained a face. In trials displaying pleasant priming images, performance on angry test faces was significantly poorer than on neutral-test faces. Also, performance on angry test-faces was significantly poorer for egocentric primes (whether they contained a face or not).
Conclusion: Perception of target-face expressions was selectively affected by the emotional content of the affective primes. The valence of the priming images biased observers to categorize target-faces in an emotionally congruent way with the affective valence of the prime, although they could not consciously perceive them. All egocentric aggressive primes significantly biased perception of test-faces as angry, even when they showed a neutral expression. These results suggest that emotional valence, although not consciously perceived, can significantly influence conscious perception of emotional expressions.

Title: Lifestyle factors associated with performance in mobile affective training tasks

Authors: ***C. H. LIN**[1], K. YIP[2], M. BAXTER[2], C. RANKIN[1], P. NUSSBAUM[3];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Rosetta Stone Canada, Vancouver, BC, Canada; [3]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Lifestyle and demographic factors such as age, gender, education, health condition, physical activity, cognitive activity, social relationships, and nutrition may associate with performances in affective tasks. We compared the affective training performance of over 1 million users from the Fit Brains Trainer by Rosetta Stone with answers to 99 factors collected from the Brain Health Lifestyle® Assessment. We found that age and gender have an effect on performance and the strategy used to solve emotion stroop (ES) and facial expression recognition (FE) questions. Education had some protective effect on the age-dependent decline in performance, and had a different effect on gender-dependent differences in problem-solving strategy. Some factors were associated with performance in both ES and FE tasks, such as having regular social discussions, regular travel, marital status, and playing musical instruments. Other factors were better associated with performance in ES tasks (i.e. searching the Internet daily, artistic or creative activity), or in FE tasks (i.e. regular meditation and mindfulness practices, having depression or anxiety). This study provided insights on the relationship between lifestyle choices, psychosocial conditions, and the performance in emotion/affective tasks for a population that actively participated in mobile brain training.

Title: Measuring mother-child emotional connection via the welch emotional connection scale (wecs)

Authors: ***M. G. WELCH**[1], A. A. HANE[2], J. N. LACOURSIERE[3], R. J. O'DRISCOLL[3], R. J. LUDWIG[3], M. M. MYERS[4];
[1]Pathology & Cell Biol., Columbia Univ. Col. of Physicians & Surgeons, New York, NY; [2]Psychology, Williams Col., Williamstown, MA; [3]Pediatrics, [4]Psychiatry and Pediatrics, Columbia Univ. Med. Ctr., New York, NY

Abstract: We hypothesize that a child's biological regulatory mechanisms are dependent on reciprocal emotional connection and its accompanying physiological co-regulation. When the mother and child are positively co-regulated they approach each other more often; show mutual interest in each other; and exhibit eye contact, and responsiveness to each other's touch and affective state. The more this co-regulation occurs, the stronger the emotional connection becomes. Thus, physiological co-regulation and emotional connection, which we posit are the basis of healthy human development, are novel treatment targets. Most current interventions for emotional behavioral developmental disorders (EBDs) focus on helping children, even infants, to self-regulate. Due to this emphasis, current treatment outcome measures assess parameters of self-regulation of the child or potential of the mother to help the child self-regulate. Instead, we sought a scale that would measure co-regulation and emotional connection. The need for such a new measure emerged from Family Nurture Intervention (FNI), which is based on establishing mother-infant co-regulation and emotional connection. FNI is a novel approach to the treatment of children age 0-5 with EBDs. FNI is experiential, not didactic, guided by a Nurture Specialist who engages mother and child in repeated calming sessions to condition their visceral/autonomic nervous systems to respond to contact with each other by calming. A calm state is required for optimal learning and relating. As there is no instrument for assessing emotional connection, we have developed a new scale, the Welch Emotional Connection Scale (WECS). The WECS is designed to measure emotional connection through observable elements of mother-child interaction, scored either live or on video, for use in clinical and research settings. It has four constructs on which mother and infant are scored; attraction to each other, verbal communication, facial expressiveness, and mutual sensitivity/responsivity. In addition there is a binary (yes/no) determination to assess the mother and child's emotional connection. Preliminary results show high inter-rater reliability and construct validity. The WECS is being correlated with heart rate variability during mother-child interactions. The WECS is proposed as a tool to assess interventional need as well as treatment efficacy. The brevity of the scale is designed for quick and effective assessment in clinical settings. More importantly, the existence and implementation of this measure will shift the field toward targeting physiological co-regulation and emotional connection, no matter what the intervention.

Title: Neural correlates of facial emotion adaptation and autistic traits

Authors: ***H. XU**[1], C. LUO[1], X. LIN[2], E. BURNS[1], X. WANG[3], Z. YUAN[2];
[1]Nanyang Technological Univ., Singapore, Singapore; [2]Fac. of Hlth. Sci., Univ. of Macau, Macau, Macao; [3]Southwest Univ., Chongqing, China

Abstract: Autistic subjects have impaired recognition of facial emotions and face identity. However, the neural mechanism of the impaired facial emotion recognition is not fully understood. In the current study, we investigated subjects' performance in facial expression adaptation on partially occluded faces, by manipulating the flickering patterns of occluding bars. Three sets of adapting faces were generated by manipulating the synchronization of flickering facial parts (e.g., eyes and mouth), e.g., coherent, partially or incoherent flickering. Test faces are full faces ranging from sad to happy. After adapting to the flickering faces, subjects' task is to judge whether the test face is a happy or sad face. Baseline condition without adaptation is also included. Subjects showed significant facial expression aftereffect when the adapting face was perceived as flickering coherently, but relatively weaker in the disrupted conditions (partial and incoherent flickering). The flickering patterns in the adaptors also modulate the amplitude of both the early component (N170) and late components (~400ms) of ERPs for the test faces. Moreover, we observed significant positive correlation between the amplitude change in these components with the AQ scores of the subjects. As the early component is suggested to indicate the response to the onset of the face stimuli, and late component indicates the processing of meaning, our results indicate that both local and holistic processes are critical for facial emotion perception, and the integration between local and holistic processes is related to the autistic traits of the subjects.

Title: Social influence shapes neural and behavioral responses to emotional scenes.

Authors: *R. E. MARTIN, J. WEBER, K. N. OCHSNER;
Psychology, Columbia Univ., New York, NY

Abstract: Emotions, though generated individually, are strongly influenced by other people. The goal of this study was to examine how other people shape our emotions. We scanned participants while they viewed and rated how pictures of negative and neutral social scenes made them feel. Following each rating participants were shown what they believed to be a group rating from a sample of approximately 100 peers. After a rest period, participants then rerated the same scenes a second time, this time without seeing peer ratings. We found a strong main effect of social influence such that participants changed their second ratings of the scenes to conform to those of their peers. At the neural level, our findings replicated previous studies (e.g., Klucharev et al., 2009; Izuma & Adolphs, 2013) demonstrating activation of the dorsomedial prefrontal cortex during peer conflict (when peers rated items higher or lower than participants). Building off these prior studies, we found that magnitude of activation within subjects predicted greater conformity to peer influence. We also found activity in lateral prefrontal regions commonly associated with emotion regulation during peer conflict. Additionally, we found that amygdala activation increased during the second rating period when peers rated those scenes as more negative. Taken together these findings suggest that social influence modulates neural circuitry associated with emotional responding.

Title: Human social brain in media reception: the effect of emotional valence of video stimuli

Authors: *S. TUKAIEV[1], I. ZYMA[1], A. VASILCHENKO[1], D. KASHPUR[3], Y. HAVRYLETS[4], V. RIZUN[4], M. MAKARCHUK[2];

Taras Shevchenko Univ. of Kyiv, Fac. of Psychology, Kyiv, Ukraine; [4]Dept. of Social Communication, Natl. Taras Shevchenko Univ. of Kyiv, Inst. of Journalism, Kyiv, Ukraine

Abstract: Modern society increasingly depends on mass media, which may be accompanied by negative changes in mental health. TV is considered to be the most effective mass media channel due to the large audience and its influence on the psychophysiological and emotional condition of the viewers. The aim of this study was to determine the structure of audience ratings and the interrelation of negative TV news plots and ads perception. 86 healthy volunteers (women and men) aged 17 to 26 years participated in this study. We recreated the conditions similar to the "natural" TV news program and offered 4 TV-news plots (each 1-1,5 minutes long, containing violent episodes), interrupted by a pause for three 30 seconds-long ads (food and drink). EEG was registered over a period of 3 minutes during the rest state, 10 minutes during watching 5 TV plots, and 6 minutes of aftereffect. We estimated the spectral power density of all frequencies from 0.2 to 45 Hz. The Wilcoxon test was carried out to compare dependent samples data. After watching the news and the ads, the participants were asked to recall and evaluate them. The plots and the ads were evaluated as follows: on the scale "unpleasant - pleasant", the news stories were perceived as rather unpleasant, the ads – as rather pleasant; on the scale "relaxing - activating", the negative plots were perceived as rather activating, the ads – as rather relaxing. Neurodynamics showed that viewing both TV news stories and TV commercials caused activation changes in the information-analytical cognitive processes of neural networks. They increased actualization of attention (depression alpha2 rhythm), short-term memory with an emotional component (increase in theta1,2 in the central-posterior and right frontal areas only for negative TV news), as well as semantic-cognitive and emotional processes (depression alpha3 and exaltation of beta1,2 bands). Increasing the number of viewed TV news plots with ads interruption in spite of their negative emotional content led to the development of intellectual processes of adaptation (no changes in the reactivity of the theta-rhythm and activity reduction of cognitive beta1,2 and alpha3 neural networks). Depression of alpha1,2-bands (external attentional system) demonstrates the activity of the descending control systems. We revealed the absence of such changes in the functional activity of brain under prolonged viewing of TV ads. We demonstrated inhibitory effect of ads viewing on the activation of cognitive neural networks in response to watching TV news despite their negative emotional orientation. This suggests that viewing TV advertising and TV news are active cognitive processes.

Title: Neural correlates of acceptance and rejection during online interaction in teenagers.

Authors: *I. PERINI, P. GUSTAFSSON, P. HAMILTON, R. KÄMPE, M. ZETTERQVIST, M. ZETTERQVIST, M. HEILIG;
Dept. of Clin. and Exptl. Medicine, IKE, Linköping, Sweden

Abstract: Negative online social interactions incl. cyberbullying are a growing problem among teens. Here, we investigated the neural correlates of social interaction in a simulated online context. Healthy teenagers (age 15 to 18) engaged in a social online game in which they chose whether they liked or disliked pictures of other young adults. Similarly, their own pictures were judged by others. A picture of a young adult was shown on the screen for 3 seconds, and the subject was instructed to choose whether he or she liked that person or not by pressing a button. Following this choice, a “thumbs up” or a “thumbs down” appeared on the left side of the picture as feedback. The word “calculating” was then displayed over the picture for 2-4 sec, and signaled that other people were also rating the person (anticipation phase). Finally, the collective outcome was superimposed over the picture and shown for 3 seconds (outcome phase). Similarly, participants saw their own picture being rated by others. There were 16 “self” and 16 “other” trials occurring in two consecutive runs in the MR scanner. A within subject t-test for the anticipation and outcome phases and a 2x2 factorial ANOVA with factors Perspective (self and other) and Outcome (like and dislike) for the outcome phase were performed. During anticipation, right anterior insula (rAI) was significantly more active for self versus other conditions. During the outcome phase, rAI and the head of the right caudate were significantly more activated when the participant saw themselves as opposed to other people being liked. Significant activations were also found for the main effect (ME) of Perspective and the ME of Outcome. For the ME of Outcome left insula, posterior cingulate cortex (PCC) and dorso-medial prefrontal cortex (dmPFC) were activated. Beta values were higher in insula for the level “like” whereas dmPFC and PCC showed higher values for the level “dislike”. For the ME of Perspective, rAI and mid cingulate cortex (MCC) were significantly more active for the condition “self” versus “other.” These findings show that areas implicated in salience and goal directed behavior are more engaged when the subject is being judged. This paradigm offers insights about neural substrates of online communication during adolescence and can be used to investigate social interaction in individuals with more vulnerable psychological profiles.

Title: The impact of mathematics anxiety on mathematics performance at pre- and university level

Authors: *E. T. MULUH[1,2];
[1]9 Cumnor Court, 292 Main Road Kenilworth, Cape Town, South Africa; [2]Cape Peninsula Univ. of Technol., Cape Town, South Africa

Abstract: Aim: Mathematics anxiety (MA), a state of discomfort associated with performing mathematical tasks is thought to have a negative impact on pre-university students. The impact of MA on mathematics performance by university students is not fully understood. The aim of the current study was to establish the impact of MA on mental and advanced mathematics problem solving by pre- and university students while controlling for test anxiety (TA), a construct related to MA but which is typically not controlled for in most MA studies. **Methods**: Two-hundred and fifty students who have just obtained their matriculation (matric) and have been granted admission to study at the university participated in the study. They (1) completed a questionnaire containing the AMARS (Abreviated Mathematics Anxiety Rating Scale) and Sarason's Test Anxiety Scale, (2) performed simple addition and multiplication mentally and (3) participated in first year university mathematics evaluations. Their matric mathematics performance together with data from 1 - 3 was analyzed. **Results**: Mathematics performance differences as a function of mathematics anxiety was revealed in both mental and advanced mathematics at pre- and university levels. No gender differences emerged for mathematics performance but levels of MA and TA were higher for female than for men. A positive correlation between MA and TA with a negative correlation between MA and mathematics performance was obtained. TA was also negatively correlated with mathematics performance. **Conclusions**: Our study shows that performance in university mathematics is negatively affected by MA experience from secondary/high school. Preoccupation with math fears and anxieties might have function like a resource-demanding secondary task during mathematics solving by high math anxious students. Girls showed higher levels of MA than boys and high levels of MA

were related to poorer levels of mathematics performance. Therefore MA warrants attention in the mathematics classroom both at secondary and university level. In fact the cognitive literature now shows how critically math performance depends on working memory, for any form of arithmetic and math that involves processes beyond simple memory retrieval. **Key words**: Mathematics anxiety and test anxiety

Title: Overprotection with the familial environment and fMRI responses to emotional context: Exploratory evidence.

Authors: *P. PANDHER[1], V. DIWADKAR[2], K. RAMASESHAN[2], M. RE[3], P. BRAMBILLA[4], M. NOBILE[5];
[1]Sch. of Med., Wayne State Univ., Macomb, MI; [2]Wayne State Univ., Detroit, MI; [3]Univ. of Udine, Udine, Italy; [4]Univ. of Milan, Milan, Italy; [5]IRCCS Eugenio Medea, Bosisio Parini, Lecco, Italy

Abstract: Overprotection is defined as the degree of parental control within a familial environment, and parental overprotection mediates development of emotional responses (Parker et al. 1979; Ingram et al. 2001), though the neuronal correlates of these effects have remained unexplored. Here we explored the effect of parental overprotection estimated using the parental bonding instrument (PBI; Parker, 1989) on brain responses when subjects committed attention to negative, positive or neutral valenced faces (a proxy for assessing emotional responses).
Method:
Thirty-one typically developing subjects (N=31, =15.4) participated in an affective attention task where rapidly presented faces of varying valence were presented in blocks (30 s). To contextualize responses based on affective context (signaled before each block) faces had an “X” or “A” marked on the bridge of the nose. An “X” was a target only if the face was consistent with the block’s affective context. fMRI data (3T Philips Achieva) were processed in SPM8 with typical methods. First level contrasts were employed to identify fMRI correlates of activation to negatively, relative to positively valenced context. These maps were submitted to second level regression models wherein maternal and paternal overprotection scores from the PBI were modeled as covariates of interest. Significant clusters were thresholded ($p<.05$, cluster).

Results:
An *increase* in both maternal and paternal overprotection predicted *decreases* in fMRI responses to negative affective context. These effects were observed in specific regions of *both* maternal and paternal scores including the Cerebellum, Middle Frontal Gyrus, Fusiform Gyrus, Lingual Gyrus, and Middle Temporal Gyrus. Specific effects for each parent were also observed in the Superior Frontal Gyrus, Middle Occipital Gyrus, Middle Temporal Gyrus, and Lateral Occipitotemporal Gyrus (maternal), and in the Medial Frontal Gyrus, Anterior Cingulate, Inferior Parietal Lobule, and Insula (paternal).
Discussion:
Social and emotional development in an overprotective familial environment can adversely affect future interpersonal relationships and present vulnerability for psychiatric conditions (Ingram, et al. 2001). Our exploratory analyses suggest that parental overprotection statistically exerts inhibitory effects on fMRI responses to negatively emotional context. Though the specific mechanisms are unclear, it is plausible that these decreases particularly in cognitive and emotional control regions such as the cingulate and prefrontal cortices reflect signatures of controlling parental style on emotional regulatory responses.

Title: Neurophysiological indices of human - robot interactions.

Authors: *S. J. SMITH[1], B. T. STONE[1], T. RANATUNGA[2], A. MANNA[3], T. Z. RAMSOY[4], C. BERKA, 92008[5];
[1]RESEARCH, ADVANCED BRAIN MONITORING, Carlsbad, CA; [2]Fello Robots, San Jose, CA; [3]Lowe's Innovation Lab., Charlotte, NC; [4]Neurons Inc., Holbaek, Denmark; [5]Advanced Brain Monitoring, CARLSBAD, CA

Abstract: Human Robot Interaction (HRI) has long been a subject of interest, attracting scientists and engineers to explore possibilities of future relationship between human and machine. It is important to consider human perception of robot physical appearances,

movements, and social interactions when examining these relationships because perception can vary dramatically across cultures, generations, and genders. The goal of seamlessly integrating robots to live in harmony with humans is under exploration with robots designed to reflect human appearance, mannerisms, and motions. The resulting technological challenges include improving our understanding of human-human social interactions as well as human-machine interactions. The objective of this study was to examine neurological responses to a robot "assistant", in relation to movement, communication, and usability in a real world setting. Advanced Brian Monitoring (ABM), in collaboration with Lowe's Innovation Lab (LIL) and Neurons Inc., tested a total of N=28 subjects within San Jose, California comprising of 46.4% Female with an age range of 26-72. Participants were recruited by LIL, through a partnered external firm database whereby regular OSH shoppers, upon meeting pre-screening criteria, were asked to participate in a study. ABM's B-Alert X10 EEG headset was applied and subjects completed the ABM benchmark neurocognitive tasks: 3-Choice Vigilance Task (3CVT), Auditory Psycho-Vigilance Task (APVT), Verbal Psycho-Vigilance Task (VPVT), to individualize the model to support classification and quantification of engagement and workload. Focal attention was assessed using mobile eye-tracker during several tasks: 1) free will (find object with/without assistance-- human or robot); 2) incorporate robot's assistance; and 3)allow the subject to follow the robot with a smooth, or clunky mobile movement. Data was analyzed by events to explore neural responses for each instance of human-robot interactions. Z-scored data from the VPVT task and multiple bandwidths during the "first impression" phase revealed differences between genders; females showed higher levels of EEG-mental workload; one-way ANOVA results: $F(1, 15) = 2.69$, $p < 0.05$; Overall Slow EEG Theta: $F(1, 16) = .27$, $p < 0.05$; and Overall Slow EEG Alpha: $F(1, 16) = 1.7$, $p < 0.0$; while Males were higher in Overall EEG Delta: $F(1, 15) = 6.79$, $p < .05$; and Overall EEG Beta: $F(1, 16) = .37$. These neurophysiological and behavioral indices associated with human-robot interactions and gender can uncover aspects of social experiences to help shape the design of future robots.

Abstract: Previously, many studies have shown that bipolar disorder exhibited motor hyperactivity in the human and animal models. However, whether it can simultaneously exhibit the comorbidity anxiety behavior remains nuclear? The present study used various concentrations (0, 10^{-5}M, 10^{-4}M, 10^{-3}M) of ouabain, which is a Na^{+}- and K^{+}-activated adenosine triphosphatase inhibitor, to produce bipolar disorder-like symptoms in motor hyperactivity. Ouabain is often used to mimic motor dysfunction for bipolar disorder in the animal model. Also, the anxiety behavior was assessed in the present study. For the experimental procedure, all of rats were administered 5μl of artificial cerebrospinal fluid (aCSF) or 5μl of an appropriate concentration (10^{-5}M, 10^{-4}M, 10^{-3}M) ouabain solution into the left ventricle to assess motor activity and anxiety behavior. All rats received 15 min for testing motor and anxiety behaviors, simultaneously. All of rats were given 15 min for testing their motor activity and anxiety behavior in the open field task. The present results indicated that (a). mean distance travelled of the ouabain group (10^{-3}M) was longer compared with the control group (i.e., aCSF group). (b). Mean speed and maximum speed of the 10^{-3} M ouabain group was significantly increased than the other groups (including the control group). (c). Mean spent time in inside square of the 10^{-3}M and 10^{-4}M ouabain groups was significantly decreased than that of the control and 10^{-5}M ouabain groups. (d). mean inside-outside numbers of the 10^{-3}M and 10^{-4}M ouabain groups was significantly decreased than that of the control and 10^{-5}M ouabain groups. The present data indicated that the animal model of bipolar-like disorder can simultaneously show the motor function and the anxiety comorbidity symptom of bipolar disorder. The present findings are important for bipolar disorder in clinical. Keywords: ouabain, bipolar disorder, motor function, anxiety behavior NSC 102-2410-H-431-005-MY3

Title: The change in expression of hippocampal cholinergic neurostimulating peptide precursor affects psychiatric behavior

Authors: *M. MIZUNO[1], T. SATO[2], D. KATO[2], T. TOYODA[2], N. MATSUKAWA[2]; [1]Nagoya City Univ., Nagoya-Shi, Japan; [2]Neurol. and Neurosci., Nagoya City Univ., Nagoya-shi, Japan

Abstract: Hippocampal cholinergic neurostimulating peptide (HCNP) induces the synthesis of acetylcholine in the medial septal nucleus in vitro and in vivo. HCNP has precursor protein, HCNPpp, which was also reported as a multifunctional protein, participating in signal pathways and influencing in the function of G-protein-coupled receptors. We recently demonstrated that HCNPpp transgenic mouse had a psycho-behavior character of a depressive-like state in tail suspension test (TST). In this study, to further examine whether HCNPpp may be involved in neuropsychiatric behavior or not, we investigated tail suspension test (TST) in HCNPpp conditional knockout (KO) mice by using Cre recombinase transgenic mice driven by Calmodulin kinase II (CaMKII) promoter. Further insight of the period influence of HCNPpp reduction, we also examined TST in mice with HCNPpp knockdown in the hippocampus at 12-14 week-old by adeno-associated virus (AAV). Here, we demonstrated that decrease of HCNPpp in the hippocampus at 12-14 week-old may be involved in the disease development of mania-like behavior. We confirmed the decrease of gamma-aminobutyric acid (GABA) A receptor alpha 3 subunit in this model mice. These findings suggested that HCNPpp in the hippocampus may be involved in bipolar disorder, depressive-like and/or mania-like behavior.

Title: Altered excitatory synaptic activity of nucleus accumbens neurons in a genetic mouse model of mania

Authors: *P. K. PAREKH, D. BECKER-KRAIL, Y. HUANG, C. MCCLUNG;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: It is well established that the circadian molecular clock regulates monoaminergic systems controlling mood, anxiety and motivated behaviors. Disruptions in the circadian gene, *Clock*, are associated with increased risk for bipolar disorder (BD) in humans and manic-like behaviors as well as hyperdopaminergia have been characterized in *Clock*α19 mutant mice. While gross neural circuit function within mesocorticolimbic regions, particularly the nucleus accumbens (NAc), appears to be disrupted in this model, the underlying molecular and synaptic mechanisms have not been studied. Here we show that *Clock*α19 mice display reduced AMPA-receptor mediated excitatory synaptic responses (mEPSCs and EPSCs) at NAc medium spiny neurons (MSNs) across the light/dark cycle compared with wildtype (WT) littermates. We find that these alterations are likely postsynaptic as presynaptic release of glutamate onto MSNs is not disrupted in *Clock* mice. Additionally, we demonstrate that NAc surface levels of the AMPA receptor subunit, GluA1, are decreased in mutant mice compared with WT at both light and dark phases, consistent with reduced functional synaptic response. We also explored diurnal differences in the intrinsic membrane excitability of NAc MSNs in mutant and WT mice and found no change in firing rate, however we observed a significantly hyperpolarized resting membrane potential of *Clock*α19 MSNs suggesting lowered excitability. Lastly, we investigated whether overexpression of synaptic proteins, GluA1 and PSD-95, in the NAc of mutants could normalize manic-like behavior. These findings demonstrate that a deficient *Clock* gene results in alterations in NAc glutamatergic transmission and synaptic strength potentially as a consequence of increased dopaminergic tone.

Title: Neurodevelopmental differences underlie discordant psychosis in a pair of monozygotic twins

Authors: *T. SAWADA[1], T. E. CHATER[2], Y. GODA[2], T. KATO[1];
[1]Lab. for Mol. Dynamics of Mental Disorders, [2]Lab. for Synaptic Plasticity and Connectivity, RIKEN Brain Sci. Inst., Wako, Saitama, Japan

Abstract: Schizophrenia (SZ) and bipolar disorder (BP) are neuropsychiatric diseases characterized by psychotic and/or mood symptoms. Despite extensive studies, the cellular basis of these disorders is still not elucidated, partly because of the difficulty in analyzing patients' neurons at the cellular level. Though induced pluripotent stem cell (iPSC) technology is expected to provide a clue for understanding the neurobiological basis of psychoses, determination of subtle disease-associated cellular phenotypes is complicated by the large variability between individuals. Here, we generated iPSC-derived neural cells from a pair of monozygotic twins discordant for bipolar-type schizoaffective disorder that shares the clinical features with both SZ and BP, to understand the cellular basis of psychosis. Multiple iPSC clones were differentiated into neural cells by using the SFEBq (serum-free floating culture of embryoid body-like aggregates, quick) method in combination with dual-SMAD inhibition. iPSCs of both twins differentiated into neural stem/progenitor cells (NSPCs) expressing specific cell surface markers such as SSEA-1 and PSA-NCAM. However, the affected twin's aggregates were slightly but significantly smaller than the unaffected twin. Moreover, Nestin-positive NSPCs of the affected twin migrated more than the unaffected twin's cells. RNA sequencing-based transcriptomic analysis of neural cells revealed the increased expression of genes involved in cortical development such as *TBR1*, *DCX* and *RELN* in the affected twin-derived cells. Additionally, expression of genes critical during early developmental stages for neural patterning and specification were also different between the twins. Consistent with the previous studies, several genes involved in ventralization of the telencephalon were upregulated in the affected twin-derived neural cells that were also accompanied by increased expression of GABAergic neuron markers, such as *GAD1/2*.
These findings suggest that early neurodevelopmental differences underlie discordant psychosis between the twins. We are presently determining the effect of these changes on the function and morphology of neurons after culturing for an extended period (up to 120 days) and searching for fundamental causes of the discordance, including epigenetic differences.

Title: Cholinergic innervation of the hippocampus regulates behaviors related to depression and resilience to social stress.

Authors: *Y. S. MINEUR, T. MOSE, D. THOMPSON, C. PINEDA, M. BENTHAM, M. R. PICCIOTTO;
Psychiatry, Yale Univ. Sch. Med., New Haven, CT

Abstract: Cholinergic signaling is critical for regulation of normal mood and associated psychiatric disorders. Clinical imaging studies suggest that nicotinic acetylcholine receptor (nAChR) occupancy by acetylcholine (ACh) is increased in the brains of human subjects with depression or bipolar disorder during a depressive episode. Conversely, blockade of either nicotinic or muscarinic ACh receptors can have antidepressant effects in human subjects and in preclinical models. Stress can increase ACh levels in specific brain areas and alter acetylcholinesterase (AChE) activity. Further, increasing ACh signaling systemically or locally in the hippocampus can induce behaviors related to anxiety and depression. These studies suggest that cholinergic innervation of the hippocampus is involved in behaviors related to anxiety and depression, but the role of specific cholinergic inputs to the hippocampus in mediating depression-like behaviors remains unknown.
With the idea that environmental stimuli that can induce depression might increase ACh signaling in hippocampus by decreasing its breakdown, we first measured AChE activity in prefrontal cortex and hippocampus in C57BL/6J mice following restraint stress. Stress had significant region- and sex-dependent effects on AChE activity, with the greatest regulation occurring in ventral hippocampus. We next silenced or activated the cholinergic neurons innervating the hippocampus by infusing AAV-floxed-Gi-DREADD or AAV-floxed-Gq-DREADDs locally into the medial septum or hippocampus of Chat-CRE mice followed by peripheral administration of CNO to modulate the activity of cholinergic inputs or intrinsic hippocampal cholinergic interneurons, respectively. We then evaluated the effects on depression-like behaviors and response to social stress. While there was little effect of stimulating or inhibiting the medial septum, which provides about 70% of the cholinergic input to the hippocampus, stimulating the sparse population of ChAT-Cre-positive cells in the hippocampusin mice with AAV-floxed-Gq-DREADD using CNO increased anxiety-like behaviors, immobility in tests of antidepressant efficacy and interaction in the social defeat paradigm.
These results demonstrate that stress can alter expression of biochemical pathways that influence cholinergic signaling in the hippocampus. Further, the current study suggests that activating the ChAT-positive neurons in the hippocampus, but not the inputs from the medial septum/diagonal bands of Broca, can induce behaviors related to anxiety and depression in the mouse.

Title: Quercetin reduces manic-like behavior and brain oxidative stress in animal models of mania

Authors: *R. ANDREATINI[1], K. K. S. KANAZAWA[2], D. D. VECCHIA[2], E. M. WENDLER[2], P. A. S. HOCAYEN[2], F. A. R. LÍVERO[2], M. C. STIPP[2], I. M. R. BARCARO[2], A. ACCO[2]; [2]Pharmacol., [1]Univ. Federal Do Paraná, Curitiba, Brazil

Abstract: Despite the availability of many pharmacological agents for treating mania in bipolar disorder (BD), their management remains a challenge for various reasons (e.g. refractoriness side effects or relapse). Therefore, it is important to search new drugs with antimanic properties. Increase in protein kinase C and oxidative stress have been related to mania, so drugs with antioxidant or PKC inhibitory activity may have antimanic effect. The flavonoid quercetin has antioxidant and PKC-inhibiting activities, which resemble lithium, the first-line treatment for mania in BD. Thus, we hypothesized that quercetin may has antimanic-like effects.
In the present study, manic-like behavior (hyperlocomotion) and oxidative stress were induced in male Swiss mice by 24 h paradoxical sleep deprivation (PSD) or methylphenidate (5 mg/kg, i.p.) administration. Brain oxidative stress was measured by reduced glutathione (GSH) and lipid peroxidation (LPO) levels in the prefrontal cortex, hippocampus and striatum.
Lithium (100 mg/kg i.p.) and quercetin (10 and 40 mg/kg) prevented PSD-induced hyperlocomotion. Quercetin also reversed: PSD-induced decrease in GSH levels in the prefrontal cortex and striatum; PSD-induced increase in LPO in the prefrontal cortex, hippocampus, and striatum. In PSD mice Pearson's correlation analysis revealed a negative correlation between locomotor activity and GSH in the prefrontal cortex and a positive correlation between locomotor activity and LPO in the prefrontal cortex and striatum. Acute and chronic treatment with lithium reduced methylphenidate-induced hypercomomotion. Chronic, but not acute, treatment with quercetin (10 and 40 mg/kg) blocked methylphenidate-induced hyperlocomotion. In addition, chronic treatment with lithium or quercetin blocked methylphenidate-induced increase in LPO levels in the striatum. There was a positive correlation between

hyperlocomotion and LPO levels in the prefrontal cortex. Also, there was a negative correlation between hyperlocomotion and GSH levels in the striatum. All behavioral effects of lithium and quercetin were seen at dose that did not change spontaneous locomotor activity.
These results suggest an antimanic-like effect of quercetin and the antioxidant action of quercetin might contribute to its antimanic-like effects. It is interesting to note that quercetin has already studied in clinical trials (e.g. for sarcoidosis) and that the dose use in the present study is below the dose range tested in these clinical trials.

Title: Cortical abnormalities in patients with bipolar disorder more localized than in those with schizophrenia

Authors: *J. FASKOWITZ[1], F. PIZZAGALLI[2], B. MWANGI[3], P. KOCHUNOV[4], P. M. THOMPSON[2], J. C. SOARES[3], N. JAHANSHAD[2];

Ctr. at Houston, Houston, TX; [4]Dept. of Psychiatry, Maryland Psychiatric Res. Center, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Background: Bipolar disorder (BPD) and schizophrenia (SCZ) share partially overlapping neuropsychiatric symptom profiles, and the disorders also have overlapping genetic and environmental risk factors. Gray matter abnormalities are implicated in both disorders, but the nature and extent of overlap is still poorly understood. Here, we create a framework to map detailed patterns of cortical differences in multi-site MRI studies of each patient group compared to matched controls. We map out cortical thickness differences on a voxelwise level, and

examine detailed morphometric properties of the sulcal patterns, specifically the degree of fold opening. Methods: We analyzed cortical thickness and sulcal morphometry from T1-weighted brain MRI scans of patients diagnosed with BPD-I compared to healthy controls (HC), across 4 scanners (N: 183; cases: 108; mean age: 35.8 +/- 11.4; 60.1% F); we performed the same analysis comparing SCZ patients to HC, with data collected across 3 scanners (N: 386; cases: 386; mean age: 40.5 +/- 12.8; 41.7% F). Cortical thickness was computed using an ANTs pipeline with site-specific templates; sulcal morphometry was conducted with ENIGMA protocols built from FreeSurfer and BrainVISA tools. When comparing patients to controls, we adjusted for age, sex, and scanner. 10,000 permutations were run on the sulcal comparisons to obtain non-parametric estimates of significance for fold opening in 68 sulci; we corrected for multiple comparisons with FDR ($q<0.05$). Results: We observed a significantly greater fold opening of the right superior frontal sulcus and thinner cortex in the right intermediate pre-central gyrus in patients with BPD compared to HC (Figure 1, left). In SCZ patients however, greater fold opening was observed for 33 sulci and thinner gray matter was observed globally, with the greatest effects in the insula (Figure 1, right). Conclusion: Further work on the differences in neuro-circuitry between these groups of patients and controls may shed light on the overlapping symptoms and neurocognitive outcomes for patients with these disorders.

Title: How does sexual dimorphism in the brain's connectivity and structure relate to mood disorder symptoms in children?

Authors: *O. R. PHILLIPS[1], A. ONOPA, K[2], V. HSU[3], J. HALLMAYER[4], I. GOTLIB[5], L. MACKEY[6], M. K. SINGH[7];
[1]Neurology, neuroscience, [3]Mathematical and Computat. Sci., [4]Dept. of Psychiatry, Div. of Child and Adolescent Psychiatry, [5]Dept. of Psychology, [6]Statistics, [7]Dept. of Psychiatry, Div. of Child and Adolescent Psychiatry, Stanford Univ. Sch. of, [2]Stanford Univ., Stanford, CA

Abstract: Introduction:
Sex differences in psychiatric disorders are common and can emerge in childhood. Girls typically experience internalizing disorders (e.g. depression, anxiety), whereas boys experience externalizing disorders (e.g., ADHD, ODD). However, the human brain is not strictly male or female. In order to gain a more nuanced understanding of the role of sex in psychopathology, we investigated features that best discriminated male and female brains and their relationship to internalizing and externalizing psychopathology.
Methods:
Using data from the Philadelphia Neurodevelopmental Cohort (8719, 13.76±3.68, 4498F/4221M), we performed a factor analysis on the 256 psychopathological variables using regression. Two of the factors that emerged corresponded to internalizing and externalizing symptoms. Structural MRI MPRAGE data (977, age 14.03±3.50, 512F/465M) was run through Brainsuite and registered to the Colin-brain atlas. Cortical thickness values for sixty-four regions of interest were then extracted for each subject. We estimated the sexual dimorphism scores of each subject's cortical thickness regions of interest using the likelihood ratio of the male and female volume distributions. All sixty-four regions were then ranked according to their level of sexual dimorphism. Finally, we then performed a partial correlation analysis with age as a covariate between the factor scores and the top five most sexually dimorphic regions.
Results:
Correlations between the likelihood ratio of sexual dimorphism for the top five most dimorphic

regions and internalizing and externalizing factor scores are shown in Table 1:
Table 1: Correlations Between Internalizing and Externalizing and sexual dimorphism scores

Region:	Internalizing Score		Externalizing Score	
	r	p	r	p
Right Angular gyrus	0.123	**0.001**	-0.123	**0.001**
Right Supramarginal gyrus	0.110	**0.002**	-0.114	**0.001**
Right Lingual gyrus	0.069	0.054	-0.071	**0.048**
Right Fusiforme gyrus	0.102	**0.004**	-0.102	**0.004**
Right Pre-cuneus	0.38	0.283	-0.40	0.268

Discussion:
The following findings emerged from this study: (1) increased "femaleness" of the cortical gray matter thickness in the most dimorphic regions was correlated with increased "internalizing" symptoms (e.g. depression, anxiety), (2) increased "maleness" of the cortical gray matter thickness in the most dimorphic regions was correlated with "externalizing" symptoms (e.g., ADHD, ODD). Thus, a non-dimorphic quantification of the brain's sex can yield insights into internalizing and externalizing symptoms.

Mgmt., Partners Healthcare, Boston, MA

Abstract: Introduction: Emerging evidence suggests that individuals with bipolar disorder (BD) have an increased risk of developing Alzheimer's disease (AD) and non-specific dementia compared to the normal population. However, it is not yet known whether these clinical observations underlie increased severity of neuropathological changes typical of AD. Notably, chronic lithium exposure may decrease this risk, potentially exerting a neuroprotective effect in both BD and AD patients. The present postmortem studies test the hypothesis that BD subjects may present with earlier onset and/or increased severity of AD pathology with respect to control subjects. lithium exposure in BD subjects is expected to be inversely correlated to the severity of neuropathology. **Methods:** BD subjects (n=78), AD subjects (n=72) and healthy controls (n=81) were matched by age and gender. Neuropathological data such as Braak and Braak stage, presence of infarcts, small vessel disease, amyloid angiopathy, and athero/arteriosclerosis were collected from neuropathology reports. Exposure to lithium, lifetime and within 6 months prior to death, was collected for BD subjects (n=55). Potential confounds such as age, gender, brain weight, and cause of death were tested using stepwise regression analysis. **Results:** As expected, Braak and Braak stages were significantly higher in subjects with AD as compared to those with BD or controls (p=<.0001). Comparisons between healthy control and BD subjects did not show significant differences with regard to Braak and Braak stages. This result did not change when including lifetime lithium exposure as a covariate. Frequency of amyloid angiopathy was significantly higher in AD subjects (p=<.0001) with respect to the other two groups. There is no significant difference between AD, BD, and control subjects in prevalence of athero/arteriosclerosis, infarct, and small vessel disease. A positive correlation observed between lifetime lithium exposure and Braak and Braak severity (p=0.0318). Further testing shows that such positive correlation is an effect of age which is positively correlated with both Braak and Braak scores as well as lifetime lithium exposure. Presence of amyloid angiopathy, athero/arteriosclerosis, infarct, and small vessel disease in relation to lifetime exposure to lithium was not significant. **Conclusions:** It was found that there was no difference between BD subjects and controls in any of the dementia-related pathologies investigated. These results suggest that chronic exposure to lithium in subjects with BD may not significantly protect from these neuropathological changes commonly observed in subjects with dementia.

Title: Evaluation of BDNF and GSK3beta gene polymorphism frequencies in bipolar and control groups.

Authors: *D. MEROLA, R. S. KIDD, A. ZIVANOVIC, M. LIZER, N. HENGEN;
Sch. of Pharm., Shenandoah Univ., Winchester, VA

Abstract: Background: Linking genetic variations and psychiatric illnesses is a crucial first step towards elucidating the pathogenesis and varied treatment response of mental disorders. Emerging evidence has revealed that neurotrophic signaling pathways may be implicated in the pathophysiology of bipolar disorder. Two important components of this signal transduction cascade, Brain-derived neurotrophic factor (BDNF) and Glycogen synthase kinase-3beta (GSK-3β), are linked through crosstalk. In this study, we evaluate the relationship of BDNF and GSK-3β polymorphisms in bipolar disorder and control subjects.
Objective: The purpose of this study was to evaluate and compare the genotype frequencies, allele frequencies, and association of five single nucleotide polymorphisms (SNPs) of the GSK-3β gene and one SNP of the BDNF gene in bipolar disorder and control populations.
Methods: The genotype and allele frequencies for SNPs rs6265, rs6438552, rs334558, rs12630592, rs3755557, and rs2199503 were evaluated in bipolar disorder (n=101) and control (n=103) subjects using real-time PCR. Pearson's Chi-square test was used to compare genotype and allele frequencies in each population. Logistic regression was performed to assess the association of all of these SNPs with bipolar disorder.
Results: A statistically significant difference in allele frequency was observed for GSK-3β SNP rs2199503T>C between bipolar and control groups. The frequency of the C allele was 0.257 in the bipolar group compared to 0.364 in the control group (p=0.02). Significant differences were also observed in allele frequencies for BDNF SNP rs6265C>T. The frequency of the T allele was 0.149 in the bipolar group compared to 0.228 in the control group (p=0.04). The strongest associations in the logistic regression were also identified with rs2199503 (p=0.033) and rs6265 (p=0.042). These two SNPs were found to be significantly associated with bipolar disorder; rs2199503 yielded in an OR = 1.543 (95% CI of 1.036-2.298) and rs6265 had an OR = 1.697 (95% CI of 1.018-2.827).
Conclusions: Rs2199503 is a GSK-3β gene intron 1 region variant that has been associated with schizophrenia and major depressive disorder in one prior study. Rs6265 is a BDNF non-

synonymous SNP that results in a Val>Met substitution. The Met allele has been associated with decreased BDNF activity. Association of these SNPs with our bipolar disorder group warrants further investigation to determine the neurobiological effects of these SNPs and elucidate potential clinical implications.

Title: GSK-3β signaling pathway is altered in olfactory neuro-epithelial cells of bipolar patients

Authors: *R. RAY, T. MCCLOSKEY, M. BARRETT, N. MIRZA, M. THASE, K. BORGMANN –WINTER, C.-G. HAHN;
CNB, Dept. of Psychiatry, TRL-2302, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Glycogen synthase kinase -3(GSK-3), encoded by two separate genes GSK-3α and GSK3β, is a constitutively active, serine /threonine kinase, which is highly abundant in brain. GSK-3 activity is modulated by phosphorylation of the S^9 and Y^{216} residues; the former decreases and the latter increases the enzyme activity. GSK-3 modulates a variety of neuronal functions including neurotransmission, neurite outgrowth and synaptic plasticity. Multiple lines of evidence suggest altered GSK-3 function as a pathophysiologic mechanism of bipolar disorder. Nevertheless, molecular underpinnings for such dysregulation and their functional consequences in neural cells of patients are presently unknown. Previous studies have focused on phosphorylation of the S^9 residue and showed a decrease in BD cases, which predicted increased GSK-3β activity. The goal of this study was to further delineate GSK-3 dysregulation in BD by examining phosphorylation of both residues as well as GSK-3 activity in an isoform specific manner, in neural cells of patients. We examined olfactory neuro-epithelial cells (NE), the only neural cells derived from patients without genomic reprogramming for the current study. In olfactory NE cells , derived from 13 age- and sex- matched pairs, we found a significant increase of pY^{216}GSK3β ($p=0.04$, $t=2.2$, $df=12$) in NE cells of BD cases, while p-S^9GSK-3β level was

comparable. Consistent with this result, GSK-3β activity was significantly increased (p=0.02, t=2.66, df=11) in NE cells from BD patients. We then examined the effects of chronic lithium treatment (3mM for 5 days) in olfactory NE cells. As shown in previous studies, lithium treatment increased the level of p-S^{9}GSK-3b in both healthy and BD subjects (p=0.03, t=2.4, df=12 and p=0.01, t=2.26, df=12 respectively). We observed differential responses to the agent between the BD and healthy subjects; the level of p-Y^{216}GSK3β and the activity of GSK-3β were increased significantly(p=0.03,t=2.39, df=12 and p=0.0027, t=3.84,df=11 respectively) by lithium treatment only in healthy subjects but not in BD patients. Together, these results offer direct evidence for increased GSK-3β activity in NE cells of patients accompanied by parallel increases in pY^{216}GSK3β prior to lithium treatment and differential regulation of p-Y^{216}GSK3β in response to lithium. To assess functional consequences of these dysregulations, the phosphorylation status of the substrates for GSK-3b is presently investigated.

Title: Molecular indicators of stress-induced inflammation in patients with post-traumatic stress disorder and in rodent models

Authors: *S. MUHIE[1], A. GAUTAM[2], N. CHAKRABORTY[1], R. HAMMAMIEH[2], J. MEYERHOFF[1], M. JETT[2];

Abstract: Gene expression, DNA methylation and microRNA (miR) datasets from patients with post-traumatic stress disorder (PTSD) and from rodent (mouse and rat) models of PTSD were collected from the Gene Expression Omnibus. After quality assessment and normalization, we used two datasets of DNA methylation, three gene expression datasets and one miR dataset from human patients, and four datasets from brain regions of rat and mouse models for downstream analysis. Differentially expressed transcripts and methylated promoter regions across the different datasets were found to be commonly associated with activated inflammatory responses.

Other pathways associated with differentially changed molecules include mTOR signaling, oxidative stress, WNT signaling, insulin signaling, type II diabetes, transcription, chromatin modification, neurogenesis and synaptic plasticity. Our aggregate and meta-analyses of these datasets suggest that stress-induced inflammation may be negatively affecting brain regions responsible for cognition and traumatic fear memory extinction, leading to responses which modulate behavioral and systemic disorders (such as metabolic disorders, immune dysfunction and cardiovascular problems). Though it is difficult to infer the causal order of PTSD-associated pathologies, at the transcriptome and epigenome levels, inflammation seems to trigger cascades of PTSD-related disorders. A feedback loop is also highly probable between the different disorders and inflammatory responses whereby comorbid conditions can aggravate anxiety disorders.

Title: Posttraumatic stress disorder-related brain network organization: a novel combined approach using graph theory and scaled subprofile modeling

Authors: *J. KO[1], T. A. GIRARD[3], C. MONSON[3], R. PATEL[2];
[1]Dept. of Human Anat. and Cell Sci., [2]Clin. Psychology, Univ. of Manitoba, Winnipeg, MB, Canada; [3]Ryerson Univ., Toronto, ON, Canada

Abstract: INTRODUCTION
Posttraumatic stress disorder (PTSD) is prevalent mental illness (~9% life-time) that is caused by exposure to trauma involving death or the threat of death, serious injury, or sexual violence. As it is associated with vastly heterogeneous origins, accurate diagnosis and optimal treatment strategies are sometimes very difficult to achieve. As in many other mental disorders, no known biomarker exists, which makes it difficult to assess treatment response and to determine when to return to work. Recent brain imaging studies elucidated the underlying neural underpinnings of PTSD, mainly involving hyper-active limbic brain regions and mal-functioning top-down cognitive control of prefrontal cortices (Patel et al., Neurosci Biobehav Rev, 36:2130-2142, 2012). Functional connectivity analysis using graph theory has shed lights on how alterations of brain network organization affect brain function and ultimately translated to symptom expressions in brain disorders (Rubinov and Sporns, Neuroimage, 52:1059-1069, 2010).
METHOD
Here we proposed a novel approach combining graph theory' eigenvector centrality and scaled subprofile modeling (Spetsieris et al., J Vis Exp, 2013) to identify a disease-related covarying pattern of information flow in the context of brain network organization. Twenty two patients (11 PTSD and 11 controls) were analyzed using the proposed analysis pipeline.
RESULT
We have identified a spatial pattern of eigenvector centrality which was significantly increased in PTSD vs. control ($p=0.043$). The pattern was characterised by increased eigenvector centrality in the orbitofrontal regions, amygdala, anterior cingulate, middle frontal and angular cortices, and decreased eigenvector centrality in the paracentral lobule, inferior occipital, pre- and post-central, Rolandic operculum, fusiform gyrus and cerebellar lobule 4/5. Interestingly, this pattern expression was correlated with better memory performance on negative valence items vs. positive valence items only in PTSD ($p=0.034$) but not in controls ($p=0.664$).
DISCUSSION
While further studies are warranted, the proposed analytic method may produce an objective neuroimaging-based biomarker, which may benefit clinicians, patients and caregivers by significantly advancing our ability to establish a connection between brain-related changes and an improvement in clinical symptoms.

Title: Cognitive function in veterans with posttraumatic stress disorder (PTSD)

Authors: *R. JOHNSON[1], L. M. JAMES[2], B. ENGDAHL[2];
[1]Cognitive Sci., Univ. of Minnesota, Minneapolis VA, Minneapolis, MN; [2]Cognitive Sci., Univ. of Minnesota, Minneapolis, MN

Abstract: The Montreal Cognitive Assessment (MoCA) is a brief screening instrument that is widely used in clinical and research settings to evaluate for mild cognitive dysfunction. Diverse conditions including Parkinson's disease, Alzheimer's disease, traumatic brain injury, depression, schizophrenia, and substance use disorders have been associated with impaired performance on the MoCA. To date, no published studies have evaluated MoCA performance in individuals with posttraumatic stress disorder (PTSD). In the present study, 175 veterans with PTSD and 231 healthy control veterans completed the MoCA as part of a larger study on brain functioning and PTSD. Results indicated that both groups performed in the "normal" range; nevertheless, the MoCA total score, after controlling for group differences in age, was significantly lower in veterans with PTSD relative to healthy control veterans (p = .027). Multivariate analyses demonstrated that impairments on the abstraction (p = .017) and delayed recall (p= .034) domains accounted for the lower total score in veterans with PTSD. Notably, group differences were not accounted for by depression. Although veterans with PTSD may not exhibit broad cognitive dysfunction, relative deficits may impart specific functional impairment.

Title: Regionally specific cortical alpha-band asymmetry in mild traumatic brain injury with significant posttraumatic stress disorder symptoms: a magnetoencephalographic study

Authors: *J. D. HUGHES[1,2], M. POPESCU[2], A.-E. POPESCU[2], T. J. DEGRABA[2];
[1]Neurotrauma, Naval Med. Res. Ctr., Silver Spring, MD; [2]Res., Natl. Intrepid Ctr. of Excellence, Bethesda, MD

Abstract: Hemispheric asymmetries of EEG recorded alpha-band power in prefrontal cortices are indicative of trait differences in emotional response biases, based on differences in

hemispheric specialization in the processing of emotional valence and motivational direction. Studies have consistently demonstrated relatively greater alpha-band power recorded over left versus right frontal scalp electrodes in the setting of depression and anxiety. Despite the overlap in symptoms of these disorders with posttraumatic stress disorder (PTSD), no consistent hemispheric alpha asymmetry has been demonstrated in PTSD. However, in the case of EEG recordings: 1) prefrontal region specific asymmetries in opposite directions could result in cancellation of effects due to spatial averaging and 2) an asymmetry limited to orbitofrontal or ventromedial prefrontal cortices would likely be undetected due to the significant distance from scalp electrodes. Magnetoencephalography with source reconstruction methods would be better suited to detect asymmetries in these circumstances. Therefore, we sought to localize region specific differences in alpha-band power asymmetry between groups of mTBI patients with or without significant PTSD symptoms utilizing MEG, with particular interest in orbitofrontal and ventromedial prefrontal cortices. All 30 participants had a history of mTBI. PCLM-scores were used to assign patients to two groups based on the severity of their PTSD symptoms (high versus low). Resting-state MEG recordings (5 min duration, eyes closed) were filtered in alpha band (8 to 13 Hz). The power of the estimated current sources was integrated over 68 cortical regions. Region wise inter-hemispheric asymmetry coefficients were compared between groups using non-parametric Wilcoxon rank-sum tests. Patients with high PTSD symptom severity demonstrated a relative increase in mean alpha power of left versus right hemisphere over medial brain areas including the posterior cingulate, paracentral and superior frontal regions, similar to previously reported findings using EEG recordings in patients with depression and anxiety. Additionally, we found a relative decrease in mean alpha power of left versus right hemisphere in orbitofrontal cortex and inferior frontal gyrus, regions directly involved in the modulation of emotional responses to stimuli, in patients with severe PTSD symptoms. To our knowledge, this is the first study to demonstrate an alpha-band asymmetry specific to orbitofrontal cortex in any patient population. The findings in this study may provide novel insights into the pathophysiology of PTSD in patients with a history of mTBI.

Title: Brain structural alterations associated to peritraumatic tonic immobility in victims of urban violence with posttraumatic stress disorder.

Authors: V. ROCHA-REGO, C. M. FRANKLIN, I. FIGUEIRA, *E. VOLCHAN;
Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil

Abstract: Tonic immobility, the last-ditch defense under mortal threat, is characterized by profound motor inhibition and is known to increase the chances of surviving an attack. Tonic immobility may be elicited by intense and inescapable life threats. Psychometric measures in patients with posttraumatic stress disorder revealed the occurrence of peritraumatic tonic immobility associated with the severity of symptoms and refractoriness to pharmacological treatment. Postural and cardiac recordings from patients in response to autobiographical trauma audio-play revealed reduction of body sway and intense tachycardia associated with reports of tonic immobility, meaning that tonic immobility reaction can be induced in a laboratory setting, an otherwise safer environment. Here we conducted a voxel based-morphometry study (VBM/DARTEL) to investigate brain structural alterations associated with peritraumatic tonic immobility scores in a sample of victims of urban violence (mostly armed robbery) with posttraumatic stress disorder (N=16). By regressing gray mater volume against overall peritraumatic tonic immobility scores, we found a significant negative correlation in left extrastriate body area, right paracentral/precuneus, right frontal superior and right inferior temporal gyrus. These areas have been implicated in the processing of social cues and could be relevant to the interpretation of interpersonal threats. The present results suggest that PTSD patients with higher reports of peritraumatic tonic immobility present less gray matter volume in those areas. Brain abnormalities in those areas could lead to errors in the distinction of an actual interpersonal violence from a non risky trauma-related cue, leading to recurrent episodes of tonic immobility.

Title: Examining the relationship between PTSD and cognition among military veterans: Does gender make a difference?

Authors: *K. MONTRY[1], C. STARR[2], E. LARSON[3];
[1]Psychology, Rosalind Franklin Univ. of Med. & Sci., Chicago, IL; [2]Univ. of California Santa Cruz, Santa Cruz, CA; [3]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Posttraumatic stress disorder (PTSD) is associated with neurocognitive dysfunction across multiple cognitive domains, including memory, processing speed, attention, and various executive functions. Most studies of neurocognitive outcomes in PTSD have focused on mostly male samples and it remains unclear whether sex differences exist within these outcomes. The present study examined PTSD diagnosis, sex, and performance across five neuropsychological domains of the Repeatable Battery for Assessment of Neuropsychological Status (the RBANS) in a sample of 228 veterans. Bivariate analysis showed both sex and PTSD diagnosis each had significant relationships with performance on RBANS Visuospatial/Visuoconstructional Index. To further examine the relative contribution of sex and PTSD diagnosis to visuospatial abilities, we conducted two hierarchical regression analyses. The first analysis showed that after controlling for individual subject characteristics (i.e., premorbid intellectual ability, educational attainment, effort, age) and for PTSD diagnosis, sex continued to significantly contribute unique variance in visuospatial/visuoconstructional abilities, with females performing lower in this cognitive domain than males. Similarly, a second analysis of the same sample showed that after controlling for individual subject characteristics and sex, PTSD diagnosis significant contributed unique variance in visuospatial / visuoconstructional abilities. A comparison of the two predictive models shows that sex was a stronger predictor of visuospatial abilities than PTSD diagnosis. The present findings suggest that the neurocognitive profile of individuals with PTSD may differ between men and women. Further research regarding these potential sex differences in neurocognitive outcomes of PTSD as well as treatment development in addressing these cognitive differences between sexes are needed to address these findings.

Title: Meta-analysis reveals trauma-specific gray matter alterations in PTSD

Authors: L. MENG[1], J. JIANG[1], C. JIN[3], J. LIU[1], Y. ZHAO[1], W. WANG[1], *K. LI[2], Q. GONG[1];

Abstract: PURPOSE: Posttraumatic stress disorder (PTSD) is the only major mental disorder with a known cause, i.e., an event that threatens one's physical integrity or that of others. Examples of traumatic events are natural disasters, accidents, combats, childhood abuse, sexual abuse and indirect exposure by learning that a close relative or a friend was exposed to trauma. Previous studies have demonstrated that patients with posttraumatic stress disorder (PTSD) caused by different traumas may show divergence in epidemiology, clinical manifestation and treatment outcome. However, it is still unclear whether this divergence has neuroanatomical correlates in PTSD brains.
METHODS**:** To elucidate the general and trauma-specific cortical morphometric alterations, we performed a quantitative voxel-wise meta-analysis of grey matter (GM) changes in PTSD with different traumas and trauma-exposed controls (TEC) using anisotropic effect-size signed differential mapping (AES-SDM) and its subgroup analysis. Meta-regression was used to explore the effects of demographics and clinical characteristics.
RESULTS: Sixteen studies, consisting of 246 PTSD patients and 347 TECs, met our inclusion criteria. The pooled meta-analysis and subgroup meta-analyses revealed general GM reduction (GMR) foci in the prefrontal-limbic-striatal system of PTSD brains compared with those of TECs. Notably, the GMR patterns are trauma-specific. For PTSD by accidents, GMR foci were found in bilateral anterior cingulate cortex (ACC) and medial prefrontal cortex (mPFC); for PTSD by natural disasters in bilateral mPFC and ACC, the left amygdala and the left hippocampus; while for PTSD by combats, GMR foci were found in the left striatum, the left insula and the left middle temporal gyrus (MTG). Moreover, Clinician-Administered PTSD Scale scores were found significantly associated with GMRs in bilateral ACC and mPFC.
CONCLUSIONS: In summary, this meta-analysis performed a quantitative voxel-wise meta-analysis of GM changes in PTSD with different traumas using AES-SDM. We found that GMR regions were generally located in the prefrontal-limbic-striatal structures. In particular, subgroup

analyses revealed that the GMR patterns were associated with specific trauma categories. It provides further evidences for different brain mechanisms underlying PTSD by different traumas, and suggests that stratified diagnosis and treatment for PTSD patients are necessary in clinics.

Title: Modulation of signs and symptoms of post traumatic stress disorder and traumatic brain injury by peripheral nerve stimulation

Authors: *D. G. LAMB[1,2], E. S. C. PORGES[2], J. B. WILLIAMSON[1,2];
[1]Malcom Randall VAMC, Gainesville, FL; [2]Univ. of Florida, Gainesville, FL

Abstract: Post traumatic stress disorder (PTSD) and other forms of emotional dysregulation frequently occur after mild traumatic brain injury (mTBI). mTBI may result in diffuse axonal injury, disrupting limbic and executive networks. While PTSD is often transient, many do not achieve remission, even with the best available treatments. Unfortunately, chronic symptoms and signs of emotional dysregulation decrease quality of life and contribute to major cumulative health risk factors. Current treatment approaches, including psychotherapy and psychiatric medication, only achieve full remission in less than half of treated individuals. Thus, alternate approaches should be considered as primary treatment and rehabilitation approaches or as adjuvants to current best practices. We evaluated the impact of a non-invasive nerve stimulation approach on measures of PTSD symptoms including emotionally modulated autonomic nervous system function in combat veterans with medical record confirmed diagnoses of PTSD with current active symptoms of PTSD and closed-head mTBI, and healthy combat veteran controls. Participants were randomized into stimulation or sham stimulation groups and given an emotionally-modulated startle-blink paradigm and a postural modulated baroreceptor sensitivity and heart-rate variability assessment. We found that the stimulation was well tolerated and resulted in improvements to electrophysiological measures of autonomic nervous system state

and emotionally-modulated startle response, suggesting that this method affects systems underlying emotional dysregulation in this population.

Title: Deficient fear extinction memory in posttraumatic stress disorder

Authors: ***H. FLOR**[1,2], M. WICKING[1], F. STEIGER[1], M. RUTTORF[2], O. GRIMM[1], L. R. SCHAD[2], F. NEES[1];
[1]Central Inst. Mental Hlth. Heidelberg Univ. Mannheim, Mannheim, Germany; [2]Computer-Assisted Clin. Medicine, Med. Fac. Mannheim, Heidelberg Univ., Mannheim, Germany

Abstract: Posttraumatic stress disorder (PTSD) might be maintained by deficient extinction memory. We used a cued fear conditioning design with extinction and a post-extinction phase to provoke the return of fear and examined the role of the interplay of amygdala, hippocampus and prefrontal regions**.** We compared 18 PTSD patients with two healthy control groups: 18 trauma-exposed subjects without PTSD (nonPTSD) and 18 healthy controls (HC) without trauma experience. They underwent a three-day ABC-conditioning procedure in a functional magnetic resonance imaging scanner. Two geometric shapes that served as conditioned stimuli (CS) were presented in the context of virtual reality scenes. Electric painful stimuli were delivered after one of the two shapes (CS+) during acquisition (in context A), while the other (CS-) was never paired with pain. Extinction was performed in context B and extinction memory was tested in a novel context C. The PTSD patients showed significantly higher differential skin conductance responses than the non-PTSD and HC and higher differential amygdala activity than the HC in context C. In addition, elevated arousal to the CS+ during extinction and to the CS- throughout the experiment was present in the PTSD patients but self-reported differential valence or contingency were not different. During extinction recall, differential amygdala activity correlated positively with the intensity of numbing and ventromedial prefrontal cortex activity correlated positively with behavioral avoidance. PTSD patients show heightened return of fear in neural and peripheral measures. In addition, self-reported arousal was high to both danger (CS+) and safety (CS-) cues. These results suggest that a deficient maintenance of extinction and a failure to

identify safety signals might contribute to PTSD symptoms, whereas non-PTSD subjects seem show normal responses.

Title: Differential expression of long non coding rna gas5 in post traumatic stress disorder

Authors: *G. GUFFANTI[1], A. WINGO[2], T. JOVANOVIC[2], C. NEMEROFF[3], A. MYERS[3], K. J. RESSLER[1];
[1]Harvard Med. Sch., Belmont, MA; [2]Emory Univ., Atlanta, GA; [3]Univ. of Miami, Miami, FL

Abstract: BACKGROUND: Evidence is accumulating that non-coding RNAs might play arole in GR-mediated regulation of glucocorticoid signaling. lncRNA GAS5 has recently been characterized as a suppressor of transcriptional activity of glucocorticoid responsive genes in mice. Human genetic studies examining stress pathways have mostly focused on the glucocorticoid receptor (GR) and its target genes. Transcriptional and post-transcriptional regulatory function of lncRNAs might explain the missing "link" between the genetic make-up predisposing to PTSD and stress- and trauma-related disorders and GR-related neurobiology in a tissue specific way. We set up to test the hypothesis that lncRNA GAS5 regulation might be perturbed in PTSD. **METHODS:** The sample derives from the larger cohort of the Emergency Department (ED) collaboration for the analysis of the transcriptome of peripheral blood of PTSD patients. PTSD was diagnosed immediately after the trauma and confirmed up to three months later, yielding 23 cases and 23 trauma-exposed controls. Raw paired-end RNA-sequencing was aligned to the hg19 genome build using the Tuxedo pipeline. Further processing to delineate the transcriptional profiles of lncRNA was performed using the ad hoc lncRNA pipeline called PLAR. We tested for statistical significance of observed changes in gene expression between PTSD patients and trauma-exposed controls using the statistical negative binomial model implemented in R-Bioconductor EdgeR.**RESULTS:** We have characterized GAS5 expression profiles in a subset of 46 subjects among cases and controls from the GTP peripheral RNA-seq cohort. Out of the 29 non-redundant isoforms of GAS5, we were able to detect the expression of 12 isoforms. At least two GAS5 isoforms revealed significant down-regulation in PTSD patients compared to trauma-exposed controls ($p < 10\text{-}4$). Based on the information reported in the gene

expression database GTEx, these isoforms seem to be expressed in peripheral blood tissue but do not seem to be expressed in AM nor HC in favor of other isoforms.**CONCLUSIONS:** The results highlight the importance of tissue specificity in the assessment of lncRNA expression profiles, and support the original hypothesis that lncRNA GAS5 plays a role in PTSD, and suggest that lncRNA GAS5 may be differentially expressed in stress-related syndromes compared to traumatized controls. The mechanism by which GAS5 performs its regulatory function remains to be elucidated.

Title: Brain structure associated with military deployment and its relation to PTSD symptomatology in a non-clinical population

Authors: *O. BUTLER[1], G. WILLMUND[2], P. ZIMMERMANN[2], U. LINDENBERGER[1], J. GALLINAT[3], S. KÜHN[1];
[1]Lifespan Psychology, Max Planck Inst. For Human Develop., Berlin, Germany; [2]Psychotrauma Ctr. of the German Military, Military Hosp. Berlin, Berlin, Germany; [3]Univ. Clin. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Research investigating the effects of trauma exposure on brain structure and function in adults has mainly focused on posttraumatic stress disorder (PTSD). The effects of repeated or long-term stress exposure on brain structure, in the absence of psychopathology, have largely remained unexplored.
By assessing 27 healthy combat trauma-exposed individuals by means of whole-brain voxel-based morphometry on 3 T MRI scans, we identified a negative association between duration of military deployment and gray matter volumes in ventromedial prefrontal cortex (vmPFC) and dorsal anterior cingulate cortex (ACC). We also found a negative relationship between deployment-related gray matter volumes and psychological symptoms, but not between military deployment and psychological symptoms.
This is the first whole-brain analysis showing that longer military deployment is associated with smaller regional brain volumes in combat-exposed individuals without PTSD. Notably, the observed grey matter associations resemble those previously observed in PTSD populations, and

concern regions involved in emotional regulation and fear extinction. The current data cannot unambiguously identify the temporal dynamics of these associations but are consistent with the hypothesis that stress exposure leads to alterations in brain structure, resulting in reductions in fear regulation and greater subsequent psychological symptomatology, even in individuals without a clinical diagnosis. These findings have implications on the current dichotomy between clinical and subclinical populations in PTSD neuroimaging research and emphasize the need to incorporate measures of stress exposure when investigating differences between PTSD patients and trauma-exposed controls.

Title: Calbrain is reduced in PTSD orbitofrontal cortex in parallel with reductions in dendritic spine density

Authors: *K. A. YOUNG[1], L. D. SELEMON[2], D. A. CRUZ[3], D. E. WILLIAMSON[3]; [1]Psychiatry & Behavioral Sci., Texas A&M HSC / Central Texas VA, Temple, TX; [2]Yale Univ. Sch. of Med., New Haven, CT; [3]Duke Univ. Sch. of Med., Durham, NC

Abstract: The orbitofrontal cortex (OFC, BA11) plays an important role in the management of emotional learning and helps link cognitive processing with visceromotor responding. As outlined by Ongur and Price (2000), the OFC integrates information from the cortex, amygdala and mediodorsal thalamus and provides output to the striatum and brainstem/hypothalamus, modulating the autonomic nervous system and the HPA axis. One of its functions may be to act as a buffer between fear signaling from amygdala-related circuits and regulation of autonomic nervous system (ANS). We previously examined the relationship between dendritic OFC spine densities and FKBP5 gene expression in PTSD and normal controls (n=8/8). ANCOVA revealed that PTSD cases had a significantly elevated density of stubby spines and a trend for a reduction in mushroom spine density, with an inverse correlation between FKBP5 gene expression and

mushroom/overall spine density (Young et al., 2015 PMID 26844242) In the present study, we investigated gene expression of calbrain (CABP1), a calcium channel protein associated with synaptic function. Specifically, calbrain is a calmodulin "antagonist" at the C-terminal domain of L-type calcium channels like CACNA1C. Reductions in calbrain occurred in parallel with reductions in mushroom spine density in PTSD (20-30% reductions in both spine density and calbrain expression). Calbrain may be one of a class of transcripts that are expressed at lower levels because there are fewer mushroom spines in PTSD. Alternatively, it could be expressed at normal levels within existing neurons, but neuron numbers could be reduced in PTSD. Either of these anatomical changes could stem from premature senescence related to ANS and/or HPA axis regulation in PTSD.

Title: Rumination is associated with PTSD severity, symptom clusters, and self related brain structures

Authors: T. A. FLOYD, *C. L. PHILIPPI, S. E. BRUCE;
Univ. of Missouri, St. Louis, Saint Louis, MO

Abstract: Previous research has associated the occurrence of rumination with PTSD. Additionally, neuroimaging studies have consistently implicated the rostral anterior cingulate (rACC) and posterior cingulate cortex (PCC) in self-related thought, including rumination. Previous functional imaging studies have found abnormal brain activity in these self-related brain regions, rACC and PCC, in PTSD. However, no research to date has examined rumination and structural neuroimaging measures in relation to PTSD severity and symptom clusters. In the current study, we measured rumination and collected structural MRI scans in trauma-exposed (n = 16) and PTSD (n = 73) participants. Compared to trauma-exposed subjects, PTSD participants reported higher levels of rumination ($p < 0.05$). Within the PTSD group, we found a correlation

between rumination and PTSD symptom severity ($r = 0.460$, $p = 0.000$) as well as rumination and all PTSD symptom clusters: re-experiencing, avoidance, and hyperarousal (each $p < 0.01$). We also found a significant correlation between PTSD and right PCC volume as well as a trend-level correlation for right rACC volume and thickness. Together, these results are consistent with previous clinical and neuroimaging studies associating PTSD with rumination, negative self-related thought, and altered activity in self-related brain regions. Future research will be necessary to investigate the relationships among negative self-thought, structure and function of self-related brain regions, and PTSD symptoms and severity after successful treatment.

Title: Whole-genome epigenetic changes in postmortem human posttraumatic stress disorder brains

Authors: *D. A. CRUZ[1], K. A. YOUNG[2], D. E. WILLIAMSON[3];
[1]Psychiatry & Behavioral Sci., Duke Univ. Hlth. Syst., Durham, NC; [2]Psychiatry & Behavioral Sciences, Tx A&M Hlth. Sci. Ctr., Central TX Veterans Hlth. Care Syst., Temple, TX; [3]Durham VAMC, Duke University, Dept Psychiatry & Behavioral Sci., Durham, NC

Abstract: Recent evidence from genome-wide association studies coupled with targeted genetic studies has begun to point toward the importance of genetic contributions to posttraumatic stress disorder (PTSD). However few studies to date have examined epigenetic mechanisms, specifically DNA methylation targeting brain regions previously implicated in this debilitating condition. Here we report on a study examining 19 PTSD brains and 38 controls. DNA was isolated from the medial orbital frontal cortex (mOFC) (BA11) and motor cortex (MC) (BA4). DNA methylation of CpG sites across the genome was assessed using the Illumina 450K Methylation BeadChip. Gene set enrichment analysis (GSEA) in mOFC revealed decreased methylation in PTSD for genes enriched in several genetic pathways. These pathways include glutamate receptor activity (e.g. GRIA1 & 2 and GRM1,3-5), glutamate signaling (e.g. GRIA3 & 4), and neuronal differentiation (e.g. YWHAH, APOE and BAI1). Similarly, GSEA in MC revealed PTSD brains to be hypomethylated for genes involved in axonogenesis (e.g. S100B,

AMIGO1, and APOE) and glutamate signaling (e.g. GRIA3 & 4). These results suggest that the hypomethylation of these gene pathways are likely to result in alterations in the expression of these genes and may play a central role in the onset and persistence of PTSD. Moreover, these results add to a growing body of literature implicating changes in the glutamate signaling pathway in PTSD and associated morphological changes in neuronal development.

Title: Quantitative sleep EEG in a mouse model and in human subjects with post-traumatic stress disorder

Authors: *R. A. OPEL[1], M. MODARRES[2], D. J. AKINS[1], N. N. KUZMA[1], M. R. GIEGER[1], M. M. LIM[1,3];
[1]Portland VA Res. Fndn., Portland, OR; [2]North Florida/South Georgia Veterans Hlth. Syst., Gainesville, FL; [3]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Post-traumatic stress disorder (PTSD) often results in significant sleep disturbances, daytime sleepiness, depressed mood and hypervigilance. Little is known about the interactions between sleep and the other relevant neural circuits involved in chronic stress. We analyzed sleep staging, EEG coherence, and behavior in a mouse model of PTSD (Single Prolonged Stress (SPS), a well-validated protocol which comprises a series of stressors including restraint stress, a group forced swim, exposure to ether, and social isolation for 1 week (n=7-9 per group)). Following SPS, mice underwent fear extinction testing and EEG/EMG signals were recorded and scored as Wake, NREM, and REM sleep. EEG coherence (a normalized value that reflects the degree of coupling between EEG waveforms from 2 skull sites for a given frequency bin) was computed using MATLAB. As expected, SPS mice showed significantly more freezing behavior

during the fear extinction task ($p < 0.05$). In the novel environment task, SPS mice showed significantly more sleep-wake transitions ($p < 0.01$) and a shorter latency to fall asleep ($p < 0.01$) compared to controls. SPS mice showed significantly decreased delta EEG coherence between hemispheres during NREM sleep ($p < 0.05$). Next, human subjects with sleep disturbances were consented during in-lab polysomnography and administered validated questionnaires to assess self-reported sleep and PTSD symptoms. As expected, Veterans with severe PTSD symptoms reported more insomnia and worse functional outcomes from sleep disturbances compared to those with mild or no PTSD symptoms ($p < 0.05$). Similar to mice after SPS, human subjects with PTSD showed significantly decreased delta EEG coherence between right and left hemispheres during NREM sleep ($p < 0.05$). Furthermore, the severity of PTSD symptoms as reported on the PCL-5 scale was significantly negatively associated with NREM delta EEG coherence ($R^2 = 0.78$, $p < 0.001$). In summary, our data suggest that quantitative EEG markers during sleep may represent a useful marker to further query brain circuit dysfunction and individual differences in PTSD symptomatology in both mice and human subjects. Ongoing studies will examine patterns of neural activation across sleep and stress circuits, and relationships between EEG and behavior.

Title: Alpha 7 nicotinic receptor agonist attenuates pain-evoked brain function in an experimental pain fMRI paradigm

Authors: *R. RAJAGOVINDAN, R. CARR, B. HOOKER, C. ZHU, M. SCHRIMPF, L. LEE, J. BEAVER;
AbbVie, North Chicago, IL

Abstract: Pain is a complex percept involving supraspinal processing that is not adequately characterized by simple reflexive preclinical measures of pain and subjective patient reports resulting in poor preclinical-clinical translation. In contrast, functional MRI (fMRI) has emerged as a promising tool to probe pain-related brain function associated with disease and therapeutic intervention in both preclinical and clinical setting. In this study we investigate the effects of an alpha 7 (α_7) nicotinic receptor agonist (ABT-107) on pain-related brain function, previously

shown to be effective in various preclinical models of pain. α_7 receptors are expressed on GABAergic neurons of brain and spinal cord and are implicated in pain processing. Knockout models exhibit hyperalgesia and agonist ligands demonstrate analgesic action. We hypothesized that ABT-107 will attenuate pain-evoked blood oxygen level-dependent (BOLD) fMRI response in brain regions that mediate pain processing underlying its analgesic action. We employed noxious electrical stimulus (NES) evoked pain fMRI paradigm to test this hypothesis. Following a single acute dose of ABT-107 (2 μmol/kg, n=9) or vehicle (n=9), NES was administered to the plantar surface of the paw following a block design in anesthetized animals. T2* weighted fMRI images were acquired using a single-shot GE EPI sequence on a 4.7T scanner (TR=2000ms, TE=12ms, 0.5x0.5x1.25mm, 14 slices). The functional images were motion corrected, brain extracted, high-pass filtered and subject to first-level general linear modeling followed by group-level mixed-effects analysis to estimate the group means and drug-vehicle contrast using FSL software. Correlation between the magnitude of pain-induced response under the drug condition and the plasma drug level was also assessed. ABT-107 attenuated pain-evoked fMRI response in regions such as the anterior cingulate relative to vehicle group. Statistically significant negative correlation between the fMRI response to NES and plasma drug levels were observed in the anterior cingulate, thalamus and somatosensory cortex; key regions involved in pain processing. Thus inhibition of increased neural activity in pain-related brain circuitry may underlie the analgesic effect of α_7 agonists. Furthermore, these findings demonstrate that fMRI provides a sensitive measure of pain-induced changes in brain function, as well as its modulation following therapeutic intervention highlighting its effectiveness as an experimental medicine tool for pain drug development.

Title: Antisense Oligonucleotides can target the key cell populations in the pain system

Authors: *A. MOHAN, B. FITZSIMMONS, H. ZHAO, H. KORDASIEWICZ, E. SWAYZE; Neurodrug discovery, Ionis Pharmaceuticals, Carlsbad, CA

Abstract: Chronic pain remains an unmet clinical need. Antisense oligonucleotides (ASOs) are an RNA therapeutic capable of selectively downregulating target RNAs, and can be used to suppress traditionally "undrugable" targets. ASOs are stable single strands of DNA that bind to their complementary target RNA and direct its catalytic degradation through the action of RNase H, an endogenous enzyme present in most cells. ASOs do not cross the blood brain barrier, but are soluble in cerebrospinal fluid (CSF) and distribute throughout the CNS when delivered to the CSF via intrathecal (IT) or intracerebroventricular (ICV) injection. ASOs delivered IT or ICV suppress target RNA in the pain system including the brain, spinal cord, DRG and trigeminal ganglia. We set out to characterize the cell populations within these tissues that are targetable with ASOs. To that end, we have treated rodents with ASOs to multiple targets and have used both immunofluorescence with a high-throughput fluorescent laser scanning system and cell sorting techniques to quantify the targetability of the various cell populations in the pain system. The populations assessed include, but are not limited to, NeuN, Iba1, GFAP, CGRP, SP, TRPV1, P2X3, IB4, NF200 positive cells. These data provide a deeper understanding of the pattern of ASO-mediated target suppression at a cellular level in the pain system, which allows us to better implement the ASO technology for the treatment of chronic pain.

Title: Activators of the two-pore-domain potassium channel TRESK - potential small molecule therapeutics for migraine and neuropathic pain.

Authors: *P. D. WRIGHT[1], C. KETTLEBOROUGH[1], D. TICKLE[1], Z. CADER[2], J. JERMAN[1];
[1]MRC Technol., Stevenage, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: TRESK, also known TWIK-related spinal cord potassium channel or $K_{2P}18.1$, is a two-pore-domain potassium channel. TRESK primarily functions to restore membrane potential, allowing the outward flow of potassium ions as the membrane depolarizes. Mutations in the TRESK gene (*KCNK18*) have been linked to familial migraine with aura and TRESK knockdown mice show behavioral evidence of increased pain and sensitivity to stimuli. Relatively restricted protein expression in sensory ganglia suggests a small molecule TRESK activator could act to reduce neuronal excitability and responsiveness, providing targeted therapeutic benefit in both migraine and neuropathic pain. Using baculovirus to deliver the human TRESK gene into mammalian cells a cell-based assay was developed to measure TRESK activity and identify novel activators. This system enabled controlled expression of TRESK in a variety of cellular backgrounds and demonstrated that titratable protein expression of the channel leads to differential channel activity. Using human TRESK expressing U2OS cells we configured a high throughput 384-well plate-based fluorescence screen to identify selective activators of TRESK. The FluxOR Potassium Ion Channel system (Life Technologies, USA), which utilizes thallium as a surrogate of potassium movement, was used to screen approximately 20000 compounds, including a subset of known ion channel pharmacaphores. A number of novel small molecule activators were identified and activity confirmed in concentration-response curve experiments, with sub-µM activity observed for some examples. Preliminary structure-activity relationship (SAR) studies further reinforced focus on a number of chemical sub-series. Selectivity was assessed versus alternative two-pore-domain potassium channels and non-transduced cells and compounds were confirmed as active at both rat and mouse TRESK. Further investigation into the activity and molecular mechanism of activity for these compounds is on-going. Initial screening identified Cloxyquin (5-Chloro-8-ol) as an activator of TRESK (EC_{50} 3.8µM). Cloxyquin was shown to be selective versus the alternative potassium channels TREK, ROMK and hERG. Importantly, Cloxyquin was also shown to activate TRESK in conventional whole-cell electrophysiology experiments, validating the use of a thallium assay in the screening cascade. It is hoped that compounds with appropriate TRESK activity and acceptable physical

chemical properties can be used to further elucidate the role of TRESK in behavioral models of migraine, neuropathic pain and ultimately lead to novel therapeutics.

Title: Characterization of G-protein biased CB1 agonists reveals potential for development of functionally selective cannabinoids with improved therapeutics

Authors: *B. M. FORD, S. TAI, L. N. FRANKS, W. E. FANTEGROSSI, P. L. PRATHER; Pharmacol. and Interdisciplinary Toxicology, Univ. of Arkansas For Med. Sci., Little Rock, AR

Abstract: The cannabinoid subtype 1 receptor (CB1R) is ubiquitously expressed in the CNS and serves as a target for modulating nociception in acute and neuropathic pain by endogenous ligands as well as synthetic cannabinoids. Unfortunately, acute use of cannabinoids acting at CB1 receptors also produces unwanted psychotropic effects, and chronic administration results in development of tolerance and dependence. Studies in β- arrestin knockout mice suggest that interaction of certain GPCRs, including μ-, δ-, κ- opioid and CB1-receptors, with β-arrestins might be responsible for several adverse effects produced by agonists acting at these receptors. Indeed, agonists that bias opioid receptor activation toward G-protein, relative to β-arrestin signaling, produce less severe adverse effects. These observations indicate that therapeutic utility of analgesics acting at CB1 receptors might be improved by development of G-protein biased CB1 agonists. Our laboratory recently reported a novel class of indole quinuclidine (IQD) compounds that bind cannabinoid receptors with relatively high affinity and act with varying intrinsic activity. The purpose of this study was to determine whether agonists in this novel cannabinoid class exhibit ligand bias at CB1 receptors. Our studies found that a novel IQD-derived CB1 receptor agonist PNR-4-20 elicits robust G-protein signaling (as measured by G-protein activation and inhibition of cAMP accumulation), with transduction ratios similar to CP-55,940. In marked contrast, PNR-4-20 produces little to no β-arrestin recruitment. Quantitative calculation of bias factors indicate that PNR-4-20 exhibits from 55- to 210-fold bias for G-

protein, compared to β-arrestin signaling (when compared to G-protein activation or inhibition of cAMP accumulation, respectively). Importantly, as expected due to reduced β-arrestin recruitment, chronic exposure of cells to PNR-4-20 results in significantly less desensitization and down-regulation of CB1 receptors compared to similar treatment with CP-55,940. Finally, PNR-4-20 (i.p.) is active in the cannabinoid tetrad in mice and studies of a structurally similar analog PNR- 4-02 is also a highly G-protein biased CB1 agonist. It is predicted that, similar to recently reported data for biased opioid agonists, cannabinoid agonists that bias CB1 receptor activation toward G-protein, relative to β-arrestin signaling, will produce fewer and less severe adverse effects both acutely and chronically.

Title: Application of calibrated forceps for evaluating antinociceptive effect induced by short-acting analgesic in mice

Authors: E. INOUE[1], T. KUWAKI[1], *H. KASHIWADANI[2];
[1]Dept. of Physiol., Kagoshima Univ. Grad. Sch. of Med. and Dent. Sci., Kagoshima, Japan;
[2]Kagoshima Univ., Kagoshima, Japan

Abstract: In nociceptive information processing, subpopulations of peripheral nociceptors and central nociceptive neurons are involved depending on nociceptive modalities. Therefore, the pain-relieving effects of analgesics could vary among those modalities. Though various sources of stimulation can evoke nociception, the thermal, the chemical, and the mechanical modalities are frequently used to evaluate the analgesics. In the past, several standardized nociceptive tests have been developed with respect to the modality: the von Frey test, the Randall-Selitto test, and the calibrated forceps test for mechanical; the hot/cold plate test, the radiant heat test, and the tail flick test for thermal; and the formalin test for chemical nociception. Of those tests, the von Frey test has been most frequently applied to examine mechanical nociception in mice because the Randall-Selitto and calibrated forceps tests were developed for rats. The von Frey test, however, takes a long time to determine the nociceptive threshold so it is inadequate to evaluate the rapid

change of the threshold induced by short-acting analgesics. In this study, we evaluated the capability of the calibrated forceps test to measure the mechanical nociceptive threshold in the tail of mice. Daily measurements of the threshold revealed that the device obtained stable and reliable results. Furthermore, repeated measurements with 5 minute intervals detected the rapid change of the threshold induced by subcutaneous injection of remifentanil, a short-acting μ-receptor agonist. In the meeting, we will also discuss time course data pertaining to odor-induced analgesia in mice.

Title: Limbic brain asymmetry predicts placebo response propensity in chronic back pain

Authors: ***T. B. ABDULLAH**, S. BERGER, E. VACHON-PRESSEAU, A. APKARIAN, T. SCHNITZER;
Northwestern Univ., Chicago, IL

Abstract: The limbic system is involved in emotional regulation, cognition, memory formation, and reward processing. It is comprised of cortical and subcortical regions including specifically the prefrontal cortex, amygdala, hippocampus, and nucleus accumbens. Here we investigate of the relationship between subcortical volume differences and placebo response propensity in chronic back pain patients (CBP). We collected high-resolution anatomical images from 67 CBP patients who were randomized into one of three treatment arms: placebo (n=43), no treatment (n=20), and positive control (n=4). Participants were enrolled for a total of eight weeks and completed 2 two-week treatment periods each followed by a one-week washout. Additionally, participants were asked to continuously monitor their pain and mood twice a day using a smartphone application. Here, we analyzed data from the first brain scans collected before any treatment was administered, to unravel anatomical biomarkers that a priori predispose subjects for placebo response. We extracted subcortical structural volume measurements using FSL-First and Freesurfer. We examined the ratio of right to left subcortical volume measurements. This measurement was created by summing the amygdala, hippocampus, and nucleus accumbens volumes for each hemisphere, and taking the ratio of right/left subcortical volume for each

person. Participants were classified as responders based on a permutation test between pain ratings acquired during baseline and during each of the treatment periods. The null hypothesis was generated by randomly resampling the distribution of pain ratings 10,000 times and was rejected at $p < 0.05$. Based on this criterion, we obtained 24 responders and 19 non-responders to placebo. On average, placebo responders showed a nearly proportional symmetry, while non-responders had a smaller right limbic volume; those individuals allocated to no-treatment had ratios in between these two groups ($F(2,60) = 4.12$, $p = 0.028$; Responders = 1.01, Non-Responders = 0.96, No treatment = 0.99). Volumetric outputs by FSL-FIRST showed significant results, while Freesurfer did not significantly differ between the groups, but showed a similar trend. These results indicate significant anatomical differences that are present prior to treatment, implying that limbic structural neuroanatomy may contribute to a predisposition to respond to placebo in individuals with CBP. Title: rTMS induced supraspinal functional changes in patients with MTBI related headache

Authors: *A. KHALAF[1], M. LIM[1], E. YANG[1], V. METZGER-SMITH[2], J. CORDERO[1], Y. HE[1], L. LIN[2], D. D. SONG[1], R. R. LEE[1], G. R. POLSTON[1], A. TSAI[2], A. LEUNG[1]; [1]UCSD, La Jolla, CA; [2]VA San Diego Healthcare Syst., La Jolla, CA

Abstract: Introduction:
Repetitive transcranial magnetic stimulation (rTMS) exists as a feasible non-invasive and low

cost therapeutic tool for those suffering from mild traumatic brain injury related headaches (MTBI-HA)[1; 2]. This study aims to assess the effect of rTMS in improving supraspinal pain processing and modulatory functions in patients with MTBI-HA.

Materials and Methods: Veterans with MTBI-HA were randomized to receive four treatments (>24 and <72 hours apart) of either Real or Sham rTMS at the left dorsolateral prefrontal cortex (LDLPFC) with neuronavigation guidance. Pre- and One-Week Post-treatment functional magnetic resonance imaging (fMRI) assessments were performed in a GE 3.0T 750 MRI scanner with T2*- weighted EPI-sequence (TE=30 ms, TR=2.0s, α=90°, TH=4mm, 32 slices, FOV=220x220 mm^2, MA=64x64) while intermittent 6 seconds of subject specific heat pain was delivered via fMRI-compatible Peltier probe at the medial aspect of the left mid-calf with various intervals (20-40 seconds) of a baseline temperature of 32°C. Heat pain stimulation was repeated 20 times to complete the session [3].

Results: Pre-treatment between-group (Real minus Sham) random effect analyses showed no significant difference. In the Real Post-minus-Pre treatment between group analysis, a significant ($P<0.01$, cluster threshold>150) deactivation in the rostral anterior cingulate cortex (rACC) was noted. In Sham Post-minus-Pre treatment between group analysis, deactivation ($P<0.01$, cluster threshold>150) was noted in the secondary somatosensory cortex (SSC2), premotor, and temporal cortices. In Real-minus-Sham Post-treatment between group analysis, significant ($P<0.01$, cluster threshold>150) deactivation was noted in the basal ganglia, rACC, ventral cingulate cortex, and SSC2.

Conclusion: In patients with MTBI-HA, rTMS at the LDLPFC appears to diminish activity in supraspinal regions involved in encoding acute and chronic pain. The rTMS treatment most notably appeared to decrease activation in the rACC, which is thought to underlie the affective component of pain experience, and the SSC2, which is involved in somatosensory response to pain. Correlation with treatment related headache relief benefit is to be established.

Title: Fibromyalgia and microglial TNF-α: Translational research using human blood induced microglia-like cells.

Authors: *M. OHGIDANI[1], T. A. KATO[1], M. HOSOI[1], M. TSUDA[1], K. HAYAKAWA[1], C. HAYAKI[1], R. IWAKI[1], R. HASHIMOTO[2], K. INOUE[1], N. SUDO[1], S. KANBA[1];

Abstract: Background: Fibromyalgia is a refractory disease characterized by chronic pain, the cause of which has not yet been elucidated due to its complex pathology. Recently, activation of immune cells in the brain called microglia has attracted attention as a potential underlying pathological mechanism in chronic pain. Until recently, however, technological and ethical considerations have limited the ability to conduct research using human microglia.
Methods: We have developed a technique to create human-induced microglia-like (iMG) cells from human peripheral blood monocytes. This study investigated activation of iMG cells in patients with fibromyalgia at the cellular level. iMG cells were created from 14 patients with fibromyalgia and 10 healthy individuals, and analyzed.
Results: No significant difference in phagocytic capacity or cytokine response associated with phagocytosis was observed between iMG cells derived from healthy participants and patients with fibromyalgia. Interestingly, however, the expression of the cytokine tumor necrosis factor-α (TNF-α) at mRNA and protein levels significantly increased in ATP-stimulated iMG cells from patients with fibromyalgia compared to cells from healthy individuals. Furthermore, there was significant correlations between ATP-induced upregulation of TNF-α expression and clinical parameters of subjective pain and other mental manifestations of fibromyalgia.
Conclusions: These findings suggest that the microglia in patients with fibromyalgia are hypersensitive to ATP. TNF-α from microglia may be a key factor underlying the complex pathology of fibromyalgia.

Title: Discovery of biomarkers associated with acamprosate treatment response by untargeted metabolomics

Authors: *M. HO[1], D. TUMPA[2], D. J. HINTON[1], S. CHOI[1], V. M. KARPYAK[3], M. A. FRYE[3], J. M. BIERNACKA[4], D.-S. CHOI[1];
[1]Mol. Pharmacol. and Exptl. Therapeut., [2]Metabolomics Resource Core, [3]Psychiatry and Psychology, [4]Hlth. Sci. Res., Mayo Clin., Rochester, MN

Abstract: Metabolomic biomarkers will increase treatment response and provide novel insights for new drug development for alcohol use disorder (AUD). Using acamprosate as a probe medication, we aims to discover metabolomic biomarkers to predict acamprosate treatment outcome and to uncover metabolic pathways associated with positive treatment outcome of acamprosate. We collected serum samples from 84 alcohol-dependent subjects before and after a 3-month acamprosate treatment and identified the biomarkers using ultra high performance liquid chromatography (UPLC) and time-of-flight mass spectrometry (ToF/MS). Subjects were classified as responders if they had maintained complete abstinence during the 3-month treatment, or else as non-responders. Comparing relative levels of metabolites between response groups, 48 metabolites were significantly different at baseline (unpaired t test $q<0.001$). These metabolites might contain metabolomic biomarkers for predicting acamprosate treatment outcome. Comparing relative levels of metabolites at 3-month to baseline, responders showed significant changes in 100 metabolites whereas non-responders only had changes in 16 metabolites (paired t test: $q<0.05$). Interestingly, pathway analysis on the 95 metabolites revealed that caffeine metabolism was significantly enriched ($q<0.05$) in the responders. Thus, we examined the effects of caffeine in combination of acamprosate on ethanol drinking in ethanol-dependent mice. Co-administration (i.p) of caffeine (30mg/kg) and acamprosate (400mg/kg) reduced ethanol preference and increased water consumption in limited access two-bottle choice

drinking (one-way ANOVA followed by Tukey posthoc $p<0.05$), but did not significantly affect locomotor activity as in sole caffeine administration. In conclusion, we have identified a panel of serum metabolites that might predict acamprosate treatment response. We also discovered that an enhanced caffeine metabolism might contribute to positive acamprosate treatment response, ,suggesting that caffeine could potentially be an adjunct to enhance antidipsotropic property of acamprosate.

Title: Cue reactivity selectively differentiates stimulant-dependent patients and controls

Authors: ***K. HENNIGAN**[1], E. L. S. JENSEN[1], L. NGUYEN[3], K. HUMPHREYS[2], B. KNUTSON[1];
[1]Psychology, [2]Psychiatry, Stanford Univ., Stanford, CA; [3]VA Palo Alto Hlth. Care Syst., Palo Alto, CA

Abstract: Patients with dependency on stimulant drugs such as cocaine and methamphetamine, which exert their reinforcing effects by acting on mesolimbic dopamine circuitry, are particularly susceptible to relapse, yet little is known about which factors confer risk for relapse. We compared neural and behavioral responses to stimulant and other appetitive cues in stimulant-dependent patients (n=8) and healthy volunteers (controls; n=26) as they underwent functional magnetic resonance imaging (FMRI). During a novel cue reactivity task, subjects viewed distinct shapes which preceded images of stimulants (drug cues), alcohol (alcohol control), food (appetitive control), and office supplies (neutral control). As predicted, stimulant-dependent patients exhibited increased activity in response to drug versus neutral control cues in motivational circuitry (i.e., ventral tegmental area, ventral striatum), but controls did not. Both groups, however, showed responses in motivational circuitry to appetitive control cues. Together, these findings suggest that the impact of stimulant dependence on mesolimbic responses is specific to drug cues, rather than all appetitive cues, or other more general processing demands. The selectivity of this group difference suggests that brain activity in

response to drug cues may provide a useful candidate marker for forecasting relapse in the context of stimulant dependence.

Title: Deep brain stimulation of the rat's subthalamic nucleus reduces cocaine-induced addiction-related behaviors

Authors: ***M. DEGOULET**[1], A. TIRAN-CAPPELLO[1], C. BAUNEZ[1], Y. PELLOUX[2]; [1]Inst. de Neurosci. de La Timone, CNRS, Marseille, France; [2]Natl. institute on Drug Abuse IRP, Baltimore, MD

Abstract: Resurgence of surgical techniques such as deep brain stimulation (DBS) for the treatment of psychiatric diseases has recently opened new therapeutic perspectives for the treatment of addiction, since no medication is currently truly effective at treating addicts. Indeed, high frequency stimulation (HFS, ~130Hz) of the subthalamic nucleus (STN), a part of the basal ganglia, reduces the motivation to take cocaine in rats, suggesting a critical contribution of the STN in addiction processes. To further characterize its involvement in cocaine addiction, we tested the effect of STN DBS, applied either at high or low frequency (LFS, ~30Hz), on the loss of control over drug intake and compulsive drug seeking, two key features of drug addiction. After being trained to self-administer cocaine under a fixed, or a seeking/taking, schedule of reinforcement, rats were given the opportunity to escalate their intake across multiple sessions of daily long access (6h per day) to cocaine. During escalation, we recorded STN local field potentials in order to monitor STN oscillations during cocaine intake. Then, some animals were returned to the seeking/taking task in which seeking responses were associated to intermittent punishment (electric foot shock) while others observed a 6-weeks forced withdrawal period before being re-exposed to the daily long access sessions. Although acute (6h) STN HFS prevented the escalation of cocaine intake, both acute and chronic (24h) STN HFS were ineffective on cocaine intake when applied after escalation. However, STN HFS reduced drug intake after extended withdrawal, while non-stimulated animals quickly recovered their pre-

withdrawal cocaine consumption. Interestingly, a progressive increase in the STN low (~6-12Hz), but not high, frequency oscillations was observed during cocaine escalation, but only in compulsive animals exhibiting resistance to punishment afterwards. Finally, LFS, but not HFS, of the STN tends to reduce persistent cocaine seeking observed in compulsive rats. Thus, our results evidence the STN as a critical locus for the development and expression of addiction-related behaviors and further highlight that manipulating STN activity with DBS might normalize important features of cocaine addiction. Overall, these data strengthen the emerging view that STN DBS represent a promising alternative in the treatment of drug addiction.

Title: Deep brain stimulation of the subthalamic nucleus reduces motivation for cocaine while increasing that for apple sauce in the monkey

Authors: *S. RAVEL[1], J. NACEF[1], J.-L. ANTON[1], I. BALANSARD[1], P.-Y. BORIUS[2], C. W. BRADBERRY[3], R. DESBRIÈRE[4], A. EUSEBIO[1], B. NAZARIAN[1], L. RENAUD[1], J.-M. RÉGIS[2], C. BAUNEZ[1];

Abstract: There is currently no pharmacological treatment for cocaine addiction, therefore it's important to look for alternative treatment strategies. One possibility could be a surgical approach. Indeed, it has been shown in the rat that the inactivation of the subthalamic nucleus (STN), by either lesions or high frequency Deep Brain Stimulation (DBS), reduces motivation for cocaine while increasing motivation for food. It has thus been suggested that STN high frequency DBS could be a good strategy to treat cocaine addiction. Before testing in human addicts, the aim of the present study was to validate this hypothesis in non-human primates. We

have trained two monkeys to work under various schedules of reinforcement (Fixed Ratio 15 (FR15) and Progressive Ratio (PR)) for either apple sauce or cocaine (intraveinous 0.1 mg/kg/injection). After stabilisation of performances, electrodes have been implanted bilaterally in the STN, and chronic stimulation has been further applied (130 Hz, 2V). All conditions (apple sauce-stimulation ON, apple sauce-stimulation OFF, cocaine-stimulation ON, cocaine-stimulation OFF) have been tested in alternance. Results have first shown that the level of motivation was higher for cocaine than for apple sauce before stimulation. Then, after STN DBS, the motivation for apple sauce was significantly increased while that for cocaine was significantly decreased. These results confirm the opposite effect of STN DBS on motivation that has been previously demonstrated in rats. Since decreasing the motivation for the drug, without diminishing other forms of motivation is the goal for a possible treatment of cocaine addiction, STN DBS may thus be the appropriate strategy.

Title: Lesions of the Subthalamic nucleus potentiate the beneficial effect of stranger observer on cocaine self-administration

Authors: ***C. BAUNEZ**[1], E. GIORLA[1], C. MONTANARI[1], K. DAVRANCHE[2], C. MANRIQUE[3], P. HUGUET[2], Y. PELLOUX[1];
[1]INT CNRS & Aix-Marseille Univ., Marseille, France; [2]Lab. Psychologie Cognitive, CNRS&AMU UMR7290, Marseille, France; [3]Fédération 3C FR3C- FR3512, CNRS & AMU, Marseille, France

Abstract: Among the global social context in drug addiction, proximal social factors (PSF, i.e those surrounding the drug exposure, such as the presence of a peer) have been shown to affect

drug self-administration, but neurobiological basis of such processes still remain unclear. Here, we focused our interest on the Subthalamic Nucleus (STN), a brain structure which lesion reduces affective responses and motivation for cocaine. Here, we first aimed at determining the involvement of the STN in rewarding properties of social interactions in adult rats (not socially isolated). We then tested whether or not PSF's influence could be modulated by STN lesions on cocaine self-administration. To address the issue regarding the rewarding properties of social interactions in adults, we used a conditioned place preference procedure in which one compartment was associated with the presence of the cagemate, while the other compartment was associated with loneliness. In the self-administration procedure, we have used cages in which rats (sham controls or STN lesioned) could self-administer cocaine, while a peer (familiar or stranger) observed them through a grid allowing communication. The ultrasonic vocalizations (USVs) emitted by both rats were thus recorded. We first found that, in STN lesioned rats, whatever the status, the presence of the peer is rewarding. In contrast, for sham rats, the presence of the cagemate is only rewarding for the dominant individuals. In the second experiment, when the rats are alone in the self-administration chamber, sham and STN rats emit equivalent level of USV. The presence of the familiar observer has no effect on cocaine intake but increases the number of USV emitted in sham rats, while a stranger peer induces a decreased of both consumption and USV. For STN lesioned rats, interestingly, the familiar peer induces a reduced level of both cocaine intake and USV. The stranger observer induces a further decreased intake, but increased number of USV emitted. These results show that STN is involved in the neurobiological basis of the PSF' influence on drug consumption. STN lesions shift the effect of a stranger peer to the familiar one, suggesting that the beneficial influence of a stranger observer can be obtained even in presence of a familiar peer, resulting in a dramatic decrease in drug intake. This makes the STN even more promising as a therapeutic target for drug addiction.

Title: Repeated electrical stimulation of medial prefrontal cortex reduces intravenous methamphetamine self-administration in wistar rats.

Authors: V. BATRA, G. GUERIN, N. GOEDERS, *J. WILDEN;
LSU Shreveport, Shreveport, LA

Abstract: INTRODUCTION: Methamphetamine abuse is a global health problem with no proven treatment. Chronic drug use causes neuroadaptations in reward circuitry, including the nucleus accumbens (Acb), ventral tegmental area (VTA), and medial prefrontal cortex (mPFC). We previously demonstrated that daily, intermittent Acb electrical stimulation reduces intravenous methamphetamine self-administration. The main objective of this study was to determine the effect of repeated electrical stimulation of mPFC on intravenous methamphetamine self-administration. METHODS: Rats implanted with IV catheters and bilateral mPFC electrodes (N=14) underwent daily 2-hour sessions in two-lever (active/IV methamphetamine; inactive/no reward) operant chambers to establish methamphetamine self-administration. After stable responding developed, 45 minutes of treatment with electrical stimulation (100 Hz, 50 pulse train every 2s, 200 micro amp) was administered in a separate environment immediately prior to the daily operant sessions for 4 consecutive days. Following each stimulation session, subjects were disconnected from the stimulation apparatus and moved into the operant chambers. RESULTS: There was a significant decrease in total 2-hour methamphetamine intake on days 2, 3, and 4 with an average reduction of 52% ($P<0.05$). Despite similar histology/electrode function, rats demonstrated a clear *bimodal response* to stimulation. Treatment "non-responders" (N=5; 35%) overall maintained methamphetamine intake while "responders" reduced intake by 83% (N=9; 65%) and demonstrated a prolonged effect by failing to return to baseline levels post-treatment. CONCLUSIONS: Repeated electrical stimulation of mPFC decreased intravenous methamphetamine self-administration on 3 of 4 treatment days. The mPFC is a key neuroanatomical substrate for methamphetamine reinforcement. This region may be a promising target for neuromodulatory intervention in intractable cases of stimulant addiction. Identification of biomarkers underlying stimulation responsiveness could help identify the optimal population for these therapies.

Title: Role of training dose in the discriminable stimulus effects of 4-methylmethcathinone (4-MMC) in male Sprague-Dawley rats

Authors: M. D. BERQUIST, II, N. A. THOMPSON, *L. E. BAKER;
Psychol Dept, Western Michigan Univ., Kalamazoo, MI

Abstract: Recreational abuse of synthetic cathinones (aka "bath salts") has recently become a popular alternative to other commonly abused psychostimulant drugs. Preclinical psychopharmacology investigations have characterized the neurochemical and behavioral profile of 4-methylmethcathinone (4-MMC), one of the common constituents of psychoactive "bath salts". Neurochemical and electrophysiological studies indicate 4-MMC is a substrate at monoamine transporters that increases extracellular dopamine and serotonin, similar to the amphetamines and MDMA. Consistent with its neurochemical profile, 4-MMC has a high abuse liability as indicated by evidence of self-administration by nonhumans and self-reports by humans. Only a few published studies have implemented drug discrimination procedures to characterize the interoceptive stimulus effects of 4-MMC. Whereas the drug discrimination paradigm is predictive of the pharmacological actions contributing to these effects, it is considered a highly informative *in vivo* drug-detection assay. The current study implemented drug discrimination methods to train 16 male Sprague-Dawley rats to discriminate either 1 mg/kg (n=8) or 3 mg/kg (n=8) 4-MMC from saline. Once adequate discrimination was observed in each training group, substitution tests were conducted with substances that function as dopamine (DA) releasers (*d*-amphetamine, (+)-methamphetamine), DA transport inhibitors (MDPV, cocaine), or a serotonin (5-HT) releaser (MDMA). Stimulus control was established in fewer sessions and more reliably maintained in the subjects trained with 3 mg/kg compared to those trained with 1 mg/kg 4-MMC. Furthermore, all of the aforementioned test compounds produced full substitution in 1 mg/kg 4-MMC-trained rats. However, only MDMA produced full substitution in rats trained to discriminate 3 mg/kg 4-MMC, while all other compounds produced only partial substitution at doses that significantly reduced response rate. These preliminary findings indicate the relative contribution of DA and 5-HT to the interoceptive stimulus effects of 4-MMC are dose-dependent. Further experiments with DA and 5-HT selective antagonists are in progress. This study expands on current knowledge regarding the psychopharmacology of 4-MMC and may further assist in characterizing its subjective effects in habitual users.

Title: PPARgamma agonism to treat white matter damage in cocaine use disorder

Authors: *A. DIMET[1], L. DENNER[1], W. R. MILLER[1], K. CUNNINGHAM[1], M. J. HUENTELMAN[2], S. LANE[3], K. DINELEY[1];
[1]Univ. of Texas Med. Br. at Galveston, Galveston, TX; [2]Translational Genomics Res. Inst., Phoenix, AZ; [3]Univ. of Texas Hlth. Med. Sch., Houston, TX

Abstract: Cocaine use disorder elicits both behavioral and structural changes in the brain. Behaviorally, it is characterized by increased impulsivity, impaired decision-making, and increased reactivity to cocaine-paired cues ("cue reactivity"). Structurally, it is characterized by altered white matter (WM) integrity, implying lost fidelity in the tracts that interconnect the grey matter structures thought to underlie the behavioral changes typical of cocaine use disorder. Rat models of the disorder display both phenotypes. Cocaine craving and relapse behaviors can be modeled in rodents by performing a cue reactivity test following forced abstinence (FA) from chronic cocaine self-administration (SA). We discovered that the FDA-approved peroxisome proliferator-activated receptor γ (PPARγ) agonist pioglitazone (PIO, Actos™) attenuates cue reactivity in rats when PIO is given during FA from cocaine SA, *demonstrating the translational potential of PIO*. Importantly, this decreased cue reactivity is reversed by administration of the PPARγ *antagonist* GW9662 prior to the cue reactivity test. Thus, ***we hypothesize*** that PPARγ agonism counteracts the cocaine-mediated damage underlying cue reactivity through the induction of markers for functional and structural integrity in WM. With RNA-Seq we determined the gene expression profile of rats which received cocaine then FA, rats which received cocaine then PIO during FA, and rats which received cocaine then PIO during FA and GW9662 prior to the cue reactivity test. Using Ingenuity® Pathway Analysis we created functional networks of genes regulated by PPARγ agonism, and these networks have supported our hypothesis and implicated a role for several genes important to the functional and structural integrity of WM. Using Protein Simple Wes™ technology, we are now investigating the expression of proteins important to WM integrity which are affected by chronic cocaine use and regulated by PPARγ and/or phosphorylated extracellular signal-regulated kinase, a protein which

we have found to be in complex with PPARγ during memory consolidation and thus a potential co-regulator. Current results support that the expression of some proteins important to WM integrity is modulated by PPARγ agonism, while others' expression is modulated by cocaine but not by PPARγ agonism. In conclusion, our work reveals that the attenuation of cue reactivity through PPARγ agonism may be achieved, at least in part, through modulation of the expression of proteins important to WM integrity. Further studies are needed to determine if the expression of these proteins plays a direct role in the behavioral phenotypes of the cocaine use disorder model.

Title: The glutamate carboxypeptidase II (GCPII) inhibitor 2-PMPA reduces the rewarding properties of 3,4-methylenedioxypyrovalerone (MDPV) in rats: the role of N-acetylaspartylglutamate (NAAG)

Authors: *C. HICKS[1,2], R. A. GREGG[1,2], S. U. NAYAK[1,2], C. S. TALLARIDA[1,2], A. B. REITZ[3], G. R. SMITH[3], S. M. RAWLS[1,2];
[1]Pharmacol., Temple Univ. Sch. of Med., Philadelphia, PA; [2]Ctr. for Substance Abuse Research, Temple Univ. Sch. of Med., Philadelphia, PA; [3]Fox Chase Chem. Diversity Ctr., Doylestown, PA

Abstract: 3,4-methylenedioxypyrovalerone (MDPV) is a commonly abused constituent of the synthetic cathinone class of illicit psychoactive substances ("Bath salts"). We recently showed that MDPV withdrawal alters glutamate (GLU) homeostasis in corticolimbic regions via downregulation of the glutamate transporter subtype 1 (GLT-1), and that treatment with a GLT-1 activator attenuates the rewarding effects of MDPV. Another important regulator of GLU transmission involves presynaptic metabotropic glutamate 2 and 3 receptors (mGluR2 and mGluR3) that act to prevent excessive synaptic GLU release. The neuropeptide N-

acetylaspartylglutamate (NAAG) is an endogenous agonist at mGluR2/3s that is inactivated by the glutamate carboxypeptidase II (GCPII) enzyme. Interestingly, GCPII inhibitors, and NAAG itself, attenuate a number of cocaine addiction-related behaviors in rodent models, thereby implicating the NAAG-GCPII signaling pathway in psychostimulant addiction. We hypothesized that administration of a GCPII inhibitor (2-(phosphonomethyl)-pentanedioic acid; 2-PMPA), or NAAG itself, would reduce the rewarding properties of MDPV in rats. Results showed that withdrawal from repeated MDPV administration significantly reduced GCPII protein expression in the prefrontal cortex, but not in the nucleus accumbens or striatum. Systemic injection of 2-PMPA (100 mg/kg) did not affect the acute hyperactivity produced by MDPV (0.5 - 3 mg/kg). However, nasal administration of NAAG (10, 100 and 500 µg/10 µL) did reduce MDPV-induced hyperactivity, but only at the highest dose tested. Furthermore, both 2-PMPA (1, 10 and 30 mg/kg) and NAAG (10, 100 and 500 µg/10 µL) dose-dependently attenuated MDPV (2 mg/kg)-induced conditioned place preference. The current findings demonstrate that MDPV withdrawal produces dysregulation in the endogenous NAAG-GCPII signaling pathway in corticolimbic circuitry. Targeting this system through systemic administration of the GCPII inhibitor 2-PMPA, or NAAG itself, attenuates MDPV drug-seeking behavior.

Title: On Target effect of Mu opioid receptor activation identified by mouse rsfMRI and Spectroscopy

Authors: *E. DARCQ[1], M. NASSEEF[1], J. NEAR[1], B. L. KIEFFER[1,2];
[1]Douglas Res. Centre/McGill Univ., Montreal, QC, Canada; [2]Inst. de Génétique et de Biologie Moléculaire et Cellulaire, CNRS/INSERM/Université de Strasbourg, Illkirch, France

Abstract: In the area of psychiatric disorders, success in developing effective drugs from highly promising molecular targets has been limited. Although drug-induced molecular processes are

well understood at the cellular level, and behavioral effects have been characterized in animal models, the overall impact of target activation and inhibition on neural network structure, neurochemistry and connectivity at the whole-brain level remains largely unknown. Our goal is to develop a new platform to identify and screen novel drugs in the area of psychiatric disorders, using combined resting state functional Magnetic Resonance Imaging (rsfMRI) and Spectroscopy (MRS) in living mice. Here we present a proof-of-principle study based on Mu opioid Receptor (MOR) responses to opiate drugs. MORs are expressed in brain areas belonging to pain and addiction circuits and, using gene knockout (KO) in mice, our laboratory demonstrated that this particular opioid receptor mediates both the remarkably potent analgesic and addictive properties of opiates like morphine [1]. MOR is a prime target in the development of novel potent analgesics, possibly devoid of adverse effects, and also new treatments for substance use and mood disorders [2-3]. Our approach consists in measuring morphine-induced modifications of Blood oxygen level dependent (BOLD) signal in the brain of live wild-type (WT) and MOR KO animals. Images are acquired using 7 Tesla Scanner with morphine injection after five minutes of initial scan. Functional data are preprocessed using standard pipeline. Activation maps are then established, functional connectivity is characterized for key selected regions by subgrouping before and after morphine injection and finally, information flow is characterized within small networks using Granger causality [3] on both group and subject level [4]. Comparing WT and MOR KO data will allow subtracting non-specific effects, and establish the on-target signature of MOR-mediated activation of neural networks in living animals. We also characterize neurotransmitter modifications by 1H-MRS in a MOR-enriched region (habenula) to profile neurochemical modifications. Altogether, the combined characterization of activation, connectivity and neurochemical effects induced by the prototypic opiate drug provides a reference dataset to further test other mu opiates used in the clinic and under development. Title: Selective small-molecule agonists for the nociceptin opioid (NOP) receptor attenuate ethanol-induced conditioned place preference in mice

Authors: *N. T. ZAVERI[1], M. E. MEYER[1], V. B. JOURNIGAN[1], P. V. MARQUEZ[2], A. HAMID[2], K. LUTFY[2];
[1]Astraea Therapeutics, LLC, Mountain View, CA; [2]Col. of Pharm., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Alcohol-related disorders represent major public health issue and places tremendous burdens on society and economy. However, a very limited number of pharmacotherapies are available to treat alcoholism and related disorders. A growing body of evidence suggests that the nociceptin opioid receptor (NOP, previously known as opioid receptor-like (ORL1) receptor) may be a potential target to treat alcohol addiction. Indeed, nociceptin/orphanin FQ (N/OFQ), the endogenous peptide agonist for the NOP receptor, has been shown to reduce the rewarding action of alcohol in a mouse conditioned place preference (CPP) assay. Further, a small-molecule NOP agonist Ro 64-6198 also reduced the acquisition and reinstatement of alcohol CPP in mice. Here we examined the effect of a series of novel, selective and potent small-molecule NOP receptor agonists on the rewarding action of ethanol using the CPP paradigm as an animal model of ethanol reward. Mice were tested for preconditioning place preference on day 1; in which mice were placed in the central neutral chamber of the CPP apparatus and allowed to explore the chambers for 15 min. The amount of time that mice spent in each chamber was recorded. On days 2-4, mice were treated with vehicle or one of the NOP agonists (AT-312, AT-328, AT-202 and a known NOP agonist SCH221510), followed by saline/ethanol (2 g/kg) or ethanol/saline administration and conditioned to the CPP chambers for 15 min. Mice were then tested under a drug-free state for postconditioning place preference on day 5, as described for day 1. Our results revealed that AT-312 and AT-328 that exhibit high affinity toward the NOP receptor compared to AT-202, abolished ethanol CPP in wild-type mice. In contrast, these compounds failed to alter the CPP response in mice lacking NOP, suggesting that the NOP receptor mediates the inhibitory action of these compounds on alcohol reward. Together, these data suggest that the NOP receptor may be a potential pharmacotherapeutic target to develop medications to treat alcoholism and alcohol-related disorders. Title: Differential effects of ketamine on alcohol intake in male vs female alcohol-preferring (P) rats

Authors: *A. H. REZVANI[1], E. D. LEVIN[2], M. CAULEY[2], B. GETACHEW[3], Y. TIZABI[3]; [1]Dept. of Psychiatry, [2]Duke Univ., Durham, NC; [3]Howard Univ., Washington DC, DC

Abstract: The complex neurobiological substrates of drug addiction in general and alcoholism in particular may be responsible for lack of optimal interventions in these disorders. Treatment strategies for alcoholism include disulfiram, naltrexone and acomprosate, which target the metabolism of alcohol, opioid receptors or variety of other neurotransmitters, respectively. Recently, a major role for the glutamatergic system in alcohol addiction has been suggested. This study was conducted to test the effectiveness of ketamine, an NMDA receptor antagonist on alcohol consumption in P rats. Moreover, since gender differences in response to alcohol and other drugs have been demonstrated, both male and female rats were studied. Adult male and female P rats originally obtained from Indiana University, but bred locally at Duke University were given 24 h access daily to two bottle choice (10% alcohol or water) for a period of over 1 month. These animals were then injected with various doses of ketamine (0, 5, 7.5 and 10 mg/kg s.c.) and their alcohol consumption was recorded at 2, 4, 6 and 24 Hr. A dose-dependent effect of ketamine in both male and female rats was observed, although the total alcohol consumption was lower in vehicle-treated female compared to vehicle-treated male rats. Moreover, it appears that the female rats are much more sensitive to ketamine's effect. Thus, 10 mg/kg ketamine resulted in approximately 26% decrease in alcohol intake in male, but 48% decrease in female alcohol consumption over the 24h period. Ketamine, a potent dissociative anesthetic, has been shown to have rapid and lasting antidepressant effects at doses much below the anesthetic dose, equivalent to the doses used in this study. Ketamine itself may be a drug of abuse, thus its usefulness in treatment of alcoholism may not be a viable option. However, identification of specific NMDA or other glutamate receptor subtypes that may be responsible for reducing alcohol consumption could hold the key to novel intervention in alcoholism or alcohol use disorders. The effectiveness of the drug for inhibiting nicotine self-administration is also being tested. Supported by NIH/NIDA P50 grant DA027840 and NIH/NIAAA R03 grant AA022479.

Title: Fyn kinase in the dorsomedial striatum controls action-outcome association to drive goal-directed alcohol responding

Authors: ***N. MORISOT**[1], K. PHAMLUONG[1], A. CROSS[2], D. RON[1];
[1]Neurol., Univ. of California San Francisco, San Francisco, CA; [2]Innovative Medicines and Early Develop. Biotech Unit, AstraZeneca Neurosci., Cambridge, MA

Abstract: Fyn is a non-receptor tyrosine kinase, crucial for synaptic function (1). We previously found that excessive alcohol drinking in rodents promotes Fyn activation in the dorsomedial striatum (DMS), resulting in Fyn-mediated phosphorylation of GluN2B which enhances NMDARs activity (2, 3). Importantly, we found that Fyn signaling in the DMS contributes to alcohol-drinking behaviors (2-6). AZD0530 is an oral Fyn inhibitor developed for the treatment of Alzheimer's disease and cancer (7, 8). We therefore tested the potential use of AZD0530 in the treatment of alcohol use disorders (AUDs). First, we confirmed that systemic administration of AZD0530 prevents alcohol-induced Fyn activation in the DMS of mice. Importantly, we showed that systemic administration of AZD0530 in mice decreased alcohol intake and seeking in an operant self-administration paradigm. We further demonstrated that intra-DMS infusion of AZD0530 reduced alcohol self-administration and seeking in rats. Given that the DMS controls goal-directed behaviors, which is a key step in the development of AUD (9), we hypothesized that Fyn in the DMS drives goal-directed alcohol use. Goal-directed actions rely on the association between the action and the outcome and therefore are sensitive to changes in i) the outcome value and ii) action-outcome contingency. To test whether Fyn in the DMS contributes to processing changes in alcohol value to drive goal-directed alcohol seeking, we used a devaluation test. We found that systemic or intra-DMS administration of AZD0530 prior to alcohol devaluation did not affect the devaluation sensitivity in mice and rats, revealing that Fyn in the DMS does not signal alcohol value to promote goal-directed alcohol seeking. We then tested whether Fyn is important for the contingent association between lever pressing and alcohol delivery, using a contingency degradation test. We found that systemic administration of

AZD0530 blocks the sensitivity to contingency degradation in mice, revealing a role for Fyn in underlying the contingency between lever-pressing and alcohol delivery that drives goal-directed alcohol behaviors. Together, our results suggest that AZD0530 may be used for the treatment of AUDs. Our findings further reveal a critical role for Fyn in DMS-dependent mechanisms that drive goal-directed alcohol intake and seeking.

Title: Characterizing the structure-function relationships of atypical dopamine uptake inhibitors with fast scan cyclic voltammetry and microdialysis i mice

Authors: *J. KEIGHRON[1], A. H. NEWMAN[2], G. TANDA[2];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Mol. Targets and Medication Develop., Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Atypical dopamine uptake inhibitors (DUIs) such as Modafinil and compounds derived from it are potent potential treatments for psychostimulant abuse disorders, and the relationship between each of these compounds and the result effect on the dopamine transporter (DAT) are of vital interest for the development of treatments. In the past two decades several advances into understanding how the DAT is affected by both typical (cocaine, etc.) and atypical (Modafinil, JHW 007, etc.) DUIs have been published. Here, we demonstrate how the structural changes in DAT caused by DUI binding relate to the dopamine (DA) actions of DAT. By studying several known DUIs (cocaine, R-Modafinil, JHW 007, WIN 35 428) and structurally related derivative compounds (JJC8-016, JJC8-088, JJC8-091) with both microdialysis (MD) and Fast Scan Cyclic Voltammetry (FSCV) in male Swiss-Webster mice we have been able to draw direct correlations to binding studies with wild type and mutant (Y335A, Y156F) DAT in vitro. The data indicate that (1) blockade of DA clearance by DAT is strongly correlated with the DAT affinity for each compound. That (2) the duration of effect for each inhibitor tested correlates well with the DAT conformation as demonstrated by the Y335A/WT binding ratios with both techniques, which indicates that DUIs with a smaller ratio of Y335A/WT binding are more likely to be in an inward or occluded conformation. Finally that (3) the interactions of atypical

inhibitors with Tyr156 may play a role in the tonic (MD) and phasic (FSCV) concentrations of DA, as demonstrated by the correlation between Y156F/WT binding ratio and DA concentrations. Together, these results provide insight into the design of future treatments for psychostimulant abuse disorders by elucidating the relationships behind the DAT structure with DUIs bound and its function.

Title: Rs-fMRI directional connectivity is modified in conditional mice lacking the mu opioid receptor gene in striatal neurons

Authors: *M. T. NASSEEF[1], E. DARCQ[1], A. MECHLING[2], D. V. EVERFELDT[2], J. HENNIG[2], L.-A. HARSAN[2,3,4], B. L. KIEFFER[1,5];

Hosp. Strasbourg, Strasbourg, France; [5]Inst. de Génétique et de Biologie Moléculaire et Cellulaire, CNRS/INSERM/Université de Strasbourg, 1 rue Laurent Fries, 67404 Illkirch, France

Abstract: In humans, resting state magnetic resonance neuroimaging (rsfMRI) has opened the era of connectome/imaging genetics, in order to elucidate how genetic factors affect brain organization and functional connectivity in healthy individuals and disease. Yet the causal impact of a single gene on functional and directional information flow remains largely unknown, and animal research is best suited to this goal. Here, we tested whether functional MRI in living animals would reveal connectivity alterations upon total or conditional targeted inactivation of a single gene, the mu opioid receptor (MOR) gene. MOR is broadly distributed throughout the nervous system and mediates the remarkably potent analgesic and addictive properties of opiates like morphine. This receptor facilitates rewarding effects of both drugs of abuse [1] and social interactions [2] with potential implications for autism [3]. Here we explore the influence of striatal MORs on whole-brain connectivity in live animals by rs-fMRI. We created conditional

knockout(cKO) mice, using targeted inactivation of the MOR gene in GABAergic neurons of the forebrain (Charbogne et al, submitted) and obtained mutant mice with complete MOR deletion specifically in the striatum, a brain area essential for reward and motivation processing. Functional rsMRI images were acquired on a 7T Bruker scanner as previously described[4], and preprocessing performed using a homemade template and a standard pipeline. Voxelwise functional connectivity(FC) maps with group difference and Granger Causality (GC) [5], a measure of directed causation, were performed using standard seed analysis. Subject level analysis was implemented by generating Iterative Multivariate Amplitude Adjustment Fourier Transformation surrogates(IMAAFTs)[6]. Our data show pronounced modifications of voxelwise FC maps in cKO mutant animals, and group differences reveal significant changes in several regions of the brain, in particular striatum, habenula and VTA. Further, GC analysis of selected small networks shows distinct dominant directionality in cKO mutant mice versus controls, following both population and single subject IMAAFTs analysis. Our work demonstrates that MOR activity in the striatum regulates brain activity under resting state, which is detectable by rsfMRI in live animals, and is characterized by intrinsic functional and directional information flow signatures.

Title: Aberrant resting state functional connectivity of the insula in internet gaming disorder

Authors: *K. KIM[1,2], D. LEE[1,2], J. LEE[1,2], Y. JUNG[2];
[1]Severance Hosp., Seoul, Korea, Republic of; [2]YONSEI UNIVERSITY COLLEGE OF MEDICINE, Seoul, Korea, Republic of

Abstract: Objectives : Internet gaming disorder (IGD) is defined as the excessive and uncontrolled internet gaming behavior despite a variety of negative psychosocial consequences. Previous studies have reported that many aspects of IGD are similar to those of substance addiction. The insula serves as a key neural substrate in substance addiction, playing a crucial role in salience processing and interoceptive awareness. The insula is subdivided into distinct subregions that have different connections and functions. The anterior insula is embedded in the salience network, which facilitates access to attention by switching between large-scale networks when a salient event is detected. The posterior insula is functionally involved in interoception and sensorimotor information. The aim of this study is to evaluate the insula subregions based network in young adults with IGD, using the resting-state functional magnetic resonance imaging (fMRI). **Methods :** The participants were 14 young male adults with IGD (mean age=23.6±2.6) and 20 age-matched male healthy controls (HCs). Resting state functional magnetic resonance image data were obtained from subjects during a 6 minute passive-viewing block scan. We selected the right and left insula subregions (anterior, posterior) as seed regions in a connectivity analysis. **Results :** In comparison with the HC group, the IGD group demonstrated decreased functional connectivity between the right anterior insula and dorsal attention network related regions including frontal eye field (FEF) and superior parietal lobule (SPL). The IGD group also show significantly stronger functional connectivity between the right posterior insula and subgenual anterior cingulate cortex (sgACC). **Conclusion :** Our results suggest that young male adults with IGD exhibit aberrant insula-based network. Participants with IGD demonstrated weaker insula-centered resting state functional connectivity with brain regions implicated in attentional processes. They also showed abnormal connection between the insula and sgACC which has been related to craving in addiction. These resting-state functional connectivity findings might underpin a biological basis for IGD and are functionally related to disruption of salience processing and interoceptive awareness in young adults with IGD.

Title: Effect of Vasopressin and Oxytocin on Adrenocorticotropic hormone in cocaine dependent patients

Authors: M. S. HELLER[1,2], *W. N. RABY[1,2];
[1]Columbia Med. Ctr. Dept. of Psychiatry, New York City, NY; [2]Dept. of Psychiatry, Albert Einstein Col. of Med., Bronx, NY

Abstract: Aims: Chronic stress models describe Vasopressin (VP) control over ACTH secretion and reduced regulatory control by Oxytocin (OT) as consequences of stressor chronicity. If cocaine-dependence is a form of chronic stress, do these mechanisms apply? In cocaine-dependent patients (CDP) we measured serum ACTH levels under 3 conditions: 1) after administration of intranasal (IN) Desmopressin (DDAVP); 2) in response to IN DDAVP after a pretreatment with IN OT; 3) after 6-wks of IN OT vs. placebo (PBO). This study is conducted as part of a 6-wk clinical trial investigating if daily IN OT (24 IU) can reduce relapse risk in CDP.
Methods: Phase 1 tests effects of IN DDAVP vs. IN OT on serum ACTH in consented CDP (n=18) relative to healthy controls (CON;n=8) after abstinence is reached. Testing begins with a 2-hr habituation period. On Day 1, ACTH is collected at 30',20',10' prior to 80 IU DDAVP and 10',20',30'45',90' after. On Day 2, ACTH is collected at 30',20',10' before 20 IU IN OT, at 10',20',30' after; and 10',20',30',45',90' after 80 IU IN DDAVP. Phase 2 is a 6-wk, double-blind, randomized, PBO-controlled trial of daily IN OT vs. PBO for CDP. Phase 3 repeats Day 1 of Phase 1.
Results: Compared to baseline, ACTH levels increase in CDP (t=4.65;p=0.0002) and CON (t=3.62;p=0.0086) after IN DDAVP. However, ACTH levels are not elevated in both CDP (t=0.951;p=0.3547) and CON (t=0.909;p=0.3941) after IN OT. In CDP, compared to the effect of IN DDAVP alone, pretreatment with IN OT at study entry reduced ACTH secretion induced by IN DDAVP (t=4.65;p=0.0002). This effect was not seen in CON (t=0.295;p=0.7802). To date for 8 CDP who completed 6-wks of IN OT vs. PBO, the effect of IN DDAVP on ACTH did not differ from study entry (t=1.05;p=0.3329).
Conclusions: IN DDAVP elevates ACTH in CDP and CON, IN OT by itself does not. Pretreatment with IN OT appears to block the ACTH-stimulating effect of IN DDAVP in CDP, but not in CON. So far, 6 weeks of treatment with IN OT or PBO does not alter the ACTH response to IN DDAVP in CDP. Considering that stress mechanisms have repeatedly been observed to perpetuate cocaine addiction, the sensitivity of cocaine-dependent patients to exogenous OT opens a possible treatment approach, based on reinstating regulatory control over CNS-based stress mechanisms. The impact on relapse risk in cocaine-dependent patients is presently being investigated in the clinical trial phase of this study.

Title: Transdermal CBD attenuates cocaine intake in rats with addiction-linked cocaine history

Authors: F. WEISS[1], *A. LAQUE[2], G. WAGNER[1], G. DENESS[1], T. KERR[1], D. WATRY[1], N. SUTO[1];
[1]The Scripps Res. Inst., La Jolla, CA; [2]Mol. and Cell. Neurosci., The Scripps Res. Institue, LA Jolla, CA

Abstract: A major challenge for successful treatment of cocaine addiction is to effectively reduce both chronic cocaine intake and long-lasting susceptibility to relapse. Various medications to treat cocaine addiction are currently in use, but with largely unimpressive success rates. Previously our lab identified possibly substantial potential of cannabidiol (CBD) - a major non-psychoactive component of *cannabis sativa* - for cocaine relapse prevention. Where treatment with CBD via the transdermal (i.e., a clinically relevant) route reduced both cue- and stress-induced reinstatement of cocaine seeking in rats. Here, we sought to determine whether tCBD's therapeutic effects extend to cocaine self-administration. Wistar rats were divided into two separate cohorts based on their histories of cocaine self-administration: extended history (12wk; serving as a rat model of cocaine addiction) and short history (2wks). All rats were treated at 24h intervals with tCBD (0, 15, 30 mg/kg) for nine days. Cocaine self-administration tests were conducted on treatment days 3-9 under a FR1 schedule of reinforcement. In these experiments, both doses of tCBD reduced cocaine self-administration in rats with an extended cocaine history. Moreover, tCBD produced these actions without non-specific behavioral suppression or tolerance to the drug's "therapeutic" effects with repeated treatment. However, neither tCBD dose was effective at reducing cocaine intake in rats with a short cocaine history. These observations suggest that tCBD may reverse neuroadaptive changes underlying cocaine motivation linked to histories of long-term chronic cocaine use - rather than to 'recreational' or brief exposure. Thus, clinically relevant transdermal application of CBD may have unique potential for the treatment of cocaine addiction at the level of both drug intake and relapse.

Title: Non-invasive brain stimulation for addiction: can we boost a hypothetical frontal ephaptic signaling of theta/gamma waves?

Authors: *J. F. GOMEZ-MOLINA[1], U. M. RICOY[3], M. CORREDOR[4], L. F. BOTERO-POSADA[5], J. VELEZ[2];
[1]Intl. Group of Neurosci. (IGN), Medellin, Colombia; [2]USA-member, Intl. Group of Neurosci. (IGN), New York, NY; [3]Biology, Chem. and Envrn. Sci., Northern New Mexico Col., Española, NM; [4]Biol. (GEBIOMICS, GRC research groups), Univ. of Antioquia, Medellin, Colombia; [5]Med. Sch., CES Univ., Medellin, Colombia

Abstract: INTRODUCTION 1. TMS activation of some regions of the PreFrontal Cortex (PFC, like DLPFC and DMPFC) cause a therapeutic effect on addiction (Dunlop et al 2016) 2. Frontal theta is a signal of cognitive control (Cavanagh et al 2014) and it is modulated by alcohol intoxication (Marinkovic et al 2012) 3. Electric fields precede electrochemical communication and guides network activity (Frohlich and McCormick 2010) 4. Electric fields are fast enough and far reaching enough to functionally organize the brain. They generate an activity that appears as "self-controlled" (Llinas, 2001) 5. Important ephaptic effects can be caused by waves and traveling depolarizations (Gomez-Molina, Restrepo Velazquez, Botero-Posada 2015 http://repository.eia.edu.co/revistas/index.php/BME/article/view/732). HYPOTHESIS. Population bursts, traveling along aligned cell membranes in frontal lobes (pyramidal dendrites and axons), represent an ephaptic signal for cognitive control of addictive behaviors. Non-invasive brain stimulation (NIBS), when applied at Fp1 or F3 (EEG-coordinates), can amplify the wave-form of this bursting causing 2 therapeutic effects: 1. It can increase the strength of frontolimbic connections by Ca2+-dependent plasticity mechanisms (Gomez, Ricoy, Escobar, Velez, SfN-abstract 2013) 2. It can cause important ephaptic effects that can guide network activity. PROPOSED METHODS 1. Electrophysiological and Engineering analysis and design

2. EEG/MEG-inverse solutions to determine the intracranial electric fields 3. Cognitive methods/therapies or meditation techniques designed to enhance frontal cognitive control can be simultaneous to NIBS. DISCUSSION 1. The existence of this effects is suggested based only in theoretical considerations and indirect evidence 2. The development of sensitivity to weak fields gives important advantages and exotic properties to brain cells that conventional methods of communication (synaptic, diffusive, conventional spiking etc) does not have 3. Ideally, friendly NIBS should work by mimicking or amplifying neural correlates of frontal will action. CONCLUSIONS 1. NIBS (e.g. Theta burst stimulation) can boost possible ephaptic effects generated by will action. 2. Although generally considered too weak to have a major role in controlling brain activity, electric fields have the potential of produce non-local, global effects that can be rapidly amplified to change networks and functional connectivity in certain phases. 3. Gamma-theta activity can represent a hypothetical correlate of a "self-determined", free will mechanism susceptible of addiction therapy.

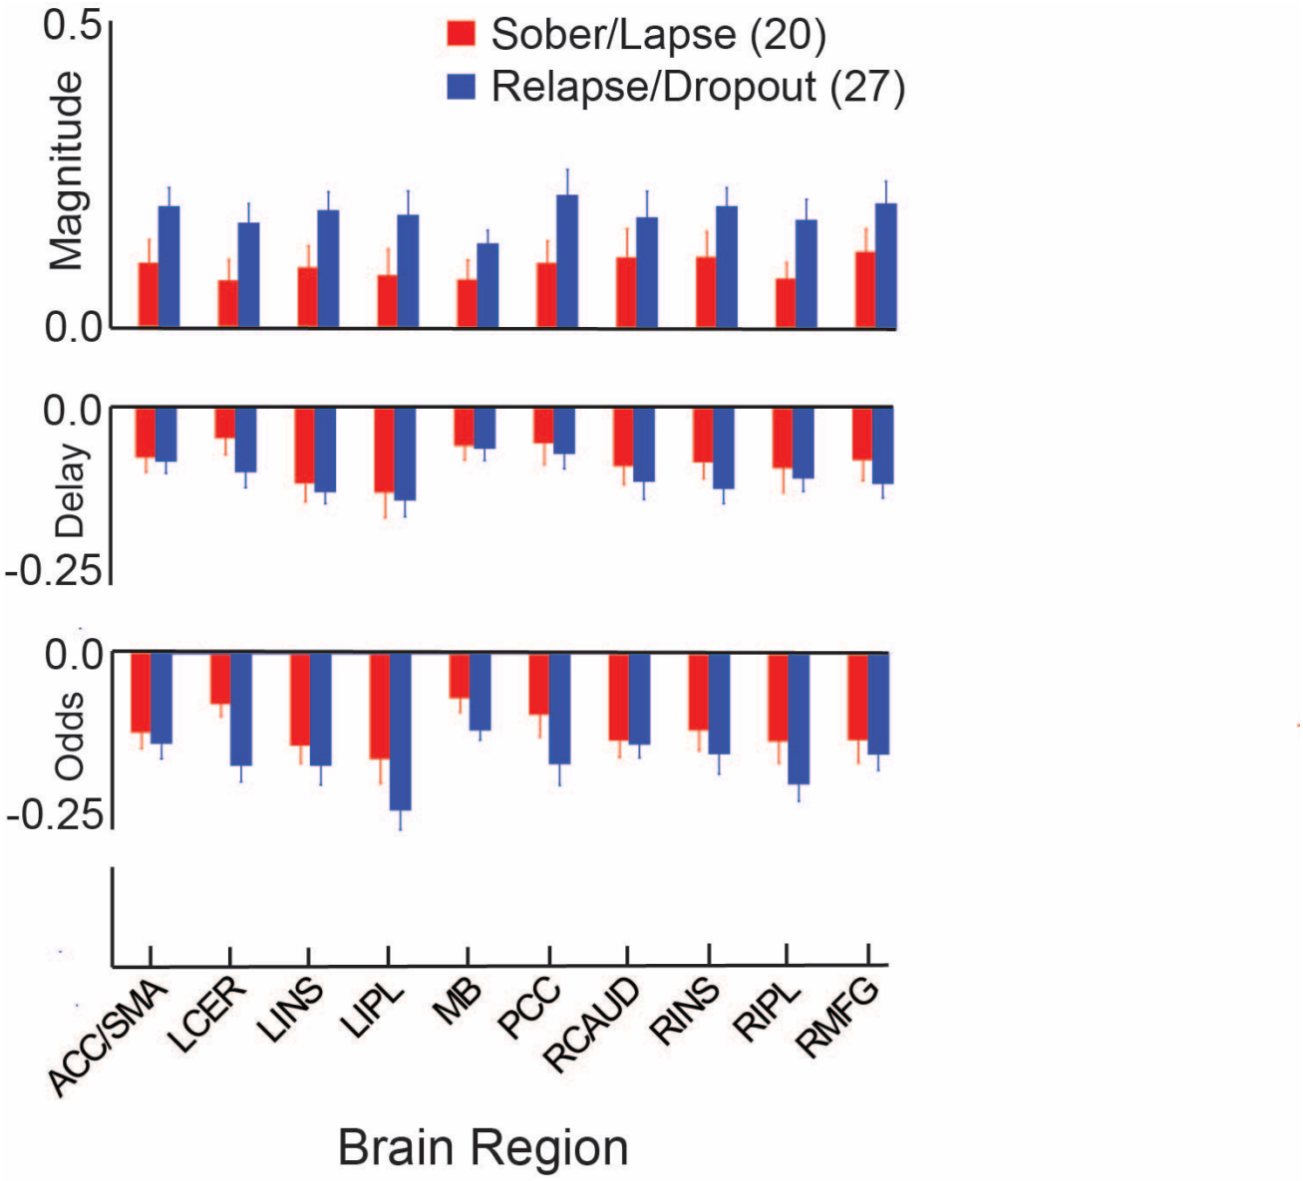
Title: Parametric BOLD activation by a discounting task predicts sobriety at three months in alcohol dependent subjects

Authors: *W. F. HOFFMAN[1,2], L. DENNIS[2], H. MCCREADY[2], D. SCHWARTZ[3], B. TREMBLAY[3], M. KOHNO[3];
[1]Mental Hlth. Div. P35C, Portland VA Med. Ctr., Portland, OR; [2]Psychiatry, [3]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Subjects: Forty-seven subjects who met DSM-IV TR criteria for alcohol dependence were enrolled in a prospective study to test the hypothesis that neural phenotypes associated with probability and delay discounting could predict sobriety at three months. Subjects averaged 19 ± 11 standard drinks per day, had, at minimum, problem drinking for 3 years and were 2-4 weeks abstinent at study entry.
Methods: Subjects were evaluated with an fMRI Probability Delay Discounting task. For each choice, the subject was asked to choose between a fixed, immediate, 100% certain reward of $20 and an alternative reward. The alternative varied by odds against ([1-p]/p) from 0 to 3 (100% to 25% likelihood of success), delay from 0 to 12 months and monetary reward amount from $20 to $140.
A drinking diary was reviewed at each of three monthly follow-up visits. Twenty subjects had minor lapses (non-heavy drinking on no more than 2 consecutive days) or remained sober, while 27 subjects relapsed (one or more days of heavy [more than 5 drinks/day] drinking) or were lost to follow up and presumed relapsed.
fMRI Analysis: fMRI scans were preprocessed in a standard manner with AFNI. We identified brain regions sensitive to parametric variation of reward magnitude, delay and odds against with amplitude modulated regression. We chose a set of brain regions where activation by the three cardinal characteristics overlapped and met the cluster size criterion of 200 voxels at a voxelwise p = .001. We created a mask from these regions and extracted average regional values of the parametric regressors for magnitude, delay and odds against. **3 Month Outcome:** We used a linear mixed effects model to test the hypothesis that the value of the parametric regressors at baseline predicted outcome at three months.
Results: Subjects who relapsed or dropped out were more sensitive to the magnitude of reward (p = .046), delay (p = .095) and odds against (p = .082) (**Figure).**
Conclusion: Neural response to characteristics of discounted rewards may be a useful predictor of treatment outcome in recovering alcohol dependent individuals.



Mean regional parametric regressor for Magnitude, Delay and Probability (Odds against) predicts outcome three months after initial sobriety. Linear mixed effects model of outcome: Magnitude, p = .046, Delay, p= .095, Odds Against, p = .082. ACC/SMA: anterior cigulate cortex/supplementary motor area; LCER: left cerebellum; LINS: Left insula; LIPL: left inferior parietal lobule; MB: midbrain; PCC: posterior cingulate cortex; RCAUD: right caudate; RINS: right insula; RIPL: right inferior parietal lobule; RMFG: right middle frontal gyrus. Title: Effects of Acamprosate, Naltrexone and $CaCl_2$ on cognitive flexibility and synaptic function in mice following chronic-intermittent ethanol (CIE) exposure or operant alcohol self-administration

Authors: *A. J. PHENSY[1], G. PRADHAN[2], R. KANDUNURI[2], M. RAZZAQUE[2], M. PARKER[2], A. CARRASCO[2], S. KROENER[2];
[1]Univ. of Texas At Dallas - BBS, Dallas, TX; [2]Univ. of Texas at Dallas, Richardson, TX

Abstract: Alcohol abuse leads to functional impairment of the prefrontal cortex (PFC), which weakens inhibitory control over excessive drinking, leading to increased alcohol consumption, forming a vicious cycle that contributes to alcohol addiction and dependence. Acamprosate is the leading medication approved for the maintenance of abstinence, shown to reduce craving in both animal models and human alcoholics. Acamprosate may reduce relapse by restoring balance of glutamatergic synaptic transmission in the PFC. We have recently shown that (passive) CIE exposure enhances N-methyl-D-aspartate receptor (NMDAR) function, causing aberrant synaptic plasticity in the PFC and disruption of normal PFC function. CIE exposure led to decreased performance in an attentional set shifting task as well as an increase in synaptic NMDA currents at PFC pyramidal neurons (Kroener et al., 2012). Treatment with acamprosate prior to testing recovered the behavioral deficit but did not significantly affect the synaptic dysfunction (Hu et al., 2015). In order to further investigate how acamprosate affects cognitive flexibility and alcohol intake, we compared the effects of 2 doses of acamprosate (100 and 200 mg/kg) to the effects of CaCl2 (the active moiety of acamprosate) and the opioid antagonist naltrexone in our attentional set-shifting task, as well as a novel object recognition and social recognition task following CIE. Animals treated with either acamprosate, naltrexone or CaCl2 for three days following 3 cycles of CIE showed a reversal of the alcohol-induced deficits in cognitive flexibility in the attentional set shifting task. Novel object recognition and social recognition were unaffected by CIE. In order to better distinguish alcohol-induced effects on learning and goal-directed behavior from the pharmacological effects of high-level alcohol exposures (as they occur in CIE), we also examined if mice that self-administer alcohol in brief (30 min) daily training sessions show similar deficits in behavior and synaptic plasticity, and if so, whether these changes can be recovered by acamprosate. Following operant conditioning, animals were tested for behavioral deficits and then sacrificed to investigate synaptic changes through whole

cell patch clamp recordings. Animals showed impairment in the attentional set shifting, as well as an upregulation of the NMDA:AMPA ratio at PFC pyramidal neurons. Acamprosate ameliorated the behavioral deficits and recovered NMDA:AMPA ratios similar to those of water-drinking controls. These experiments will further our understanding of the mechanisms responsible for the transition from controlled drug taking to alcohol addiction.

University, Col. of Med., Seoul, Korea, Republic of

Abstract: Internet gaming disorder (IGD) is defined as the repetitive use of Internet-based games leading to significant difficulties with social and psychological functioning. Previous studies have reported that patients with addiction problems showed dysfunctional cortical connectivity as well as altered brain functional connectivity. However, there were little evidences about brain connectivity using electroencephalographic (EEG) in patients with IGD. This study aimed to find a biological marker of IGD using resting-state EEG coherence. We analyzed data from a total of 92 male participants (intelligence quotient (IQ) $\geq$ 80), comparing the EEG coherences of 31 patients with IGD who aged 23.39 $\pm$ 5.03, with those of 29 patients with alcohol use disorder (AUD) who aged 30.07 $\pm$ 7.17 and 32 healthy controls who aged 24.97 $\pm$ 3.70 (HCs). The results showed that increased beta (12-25 Hz) coherences in the inter-hemisphere (FP2-T3 pair and F4-T3 pair), midline-left hemisphere (T3-Cz pair) and midline-

right hemisphere (C4-Cz pair and F4-Fz pair) were found in the IGD group compared with the HCs ($P < 0.05$), whereas increased beta coherence in midline-right hemisphere (F4-Cz pair) was found in the AUD group compared with the HCs ($P < 0.05$). It was also figured out that theta (4-8 Hz) and delta (1-4 Hz) coherences were increased in the AUD group compared with HCs in the right frontotemporal hemisphere (theta = FP2-T4 pair and F8-T4 pair; delta = F8-T4 pair; $P < 0.05$). We further analyzed to identify correlation with the severity of IGD and AUD in each patient group. Increased beta coherence was not correlated with the severity of IGD measured by Young's Internet Addiction Test (IAT) in the IGD group. In addition, increased beta, theta and delta coherences in the AUD group were not associated with Alcohol Use Disorder Identification Test (AUDIT) score that indicates the severity of AUD. In conclusion, the result implies that hyperphasic synchrony measured by EEG coherence during the resting state may be utilized for a bio-marker of IGD and AUD. Especially, the different aspects of EEG coherence suggest that it may serve as a neurophysiological marker to discriminate AUD and IGD features.

Title: Greater frequency of alcohol consumption is associated with a decrease in daily caffeine consumption among cigarette smokers but not non-smokers

Authors: *N. R. GUBNER, N. L. BENOWITZ;
Univ. of California San Francisco, San Francisco, CA

Abstract: Higher caffeine consumption has been reported among cigarette smokers, which is thought to be in part due to an increase in rate of caffeine metabolism (induction of CYP1A2 enzyme activity) by combustion products in tobacco smoke. In contrast, there is evidence that alcohol may inhibit CYP1A2 activity. Since there are known differences between African Americans and Non-Hispanic whites for alcohol consumption, cigarette smoking, and rate of nicotine metabolism, the current study examined the relationship between caffeine consumption and frequency of alcohol intake in cigarette smokers and non-smokers of both races using data from the National Health and Nutrition Examination Survey (NHANES). A total of 2425 current

smokers, and 7964 non-smokers were identified by combining three waves of the NHANES data from 2007-2012. Participants were divided into 5 groups based on frequency of alcohol consumption (never, <1 day/ week, 1-2 days/ week, 3-6 days/ week, and daily). Caffeine consumption was estimated based on reported dietary intake of caffeine containing beverages. Consistent with previous reports, daily caffeine consumption was higher in Non-Hispanic whites compared to African Americans. Overall, caffeine consumption was higher in smokers versus non-smokers. In African Americans and Non-Hispanic whites there was a significant interaction between alcohol drinking frequency and smoking status for daily caffeine intake (African Americans: $F=13.7$, $p<0.001$, Non-Hispanic whites: $F=19.8$, $p<0.001$). Within both races there was a significant decrease in caffeine consumption associated with greater frequency of alcohol consumption among smokers. In contrast, among non-smokers greater frequency of alcohol consumption was associated with an increase in caffeine consumption. One hypothesis to explain these findings is that alcohol may attenuate the induction of CYP1A2 enzyme activity by cigarette smoking. Smokers who drink alcohol less frequently may have a faster rate of caffeine metabolism that results in greater caffeine intake compared to smokers who drink alcohol more frequently.

Title: Subjects with hazardous alcohol consumption but not alcohol dependence present lower beta mean frequency than subjects with alcohol dependence

Authors: *L. NUÑEZ-JARAMILLO[1], W. V. HERRERA-MORALES[2], L. RAMÍREZ-LUGO[3], J. V. REYES-LÓPEZ[4];

Abstract: Harmful alcohol use is among the top five risk factors for disease, disability and death worldwide. Hazardous alcohol consumption is a pattern of alcohol consumption that increases the risk of harmful consequences for the user or others, and has been linked with risky behaviors, accidents and injuries. It is noteworthy that hazardous alcohol consumption does not necessarily implies alcohol dependence. While there is a large body of research on the neurophysiological correlates of alcohol dependence there is little information so far about neurophysiological correlates of hazardous alcohol consumption. It has been reported that subjects with hazardous alcohol consumption but not alcohol dependence present increased beta absolute power (AP) at centro-parietal region, and decreased beta mean frequency (MF) in frontal and centro-parietal regions. While increased beta absolute power has been already reported in alcohol dependent subjects, no report has addressed beta MF in these subjects, thus it is not yet known whether this decrease in beta MF is a feature correlated specifically with hazardous alcohol consumption or is also related with alcohol dependence. Herein we performed qEEG analysis of beta MF in subjects with alcohol dependence and in subjects with hazardous alcohol consumption but not alcohol dependence in 19 leads of the international 10/20 system. We found decreased Beta MF in in centro-parietal region in subjects with hazardous alcohol consumption, but not in subjects with alcohol dependence. Our results suggest that differences exist in the neurophysiological correlates of alcohol dependence and hazardous alcohol consumption, supporting the hypothesis that there are differences in the neurophysiological mechanisms underlying these two conditions

Title: A high-fructose diet alters brain insulin signaling, incentive motivation and dopamine reuptake

Authors: *A. R. KOSHELEFF[1], L. TSAN[2], Y. ZHUANG[3], F. GOMEZ-PINILLA[3], S. B. OSTLUND[4], N. P. MURPHY[2], N. T. MAIDMENT[2];

[1]Psychology, [2]Psychiatry & Biobehavioral Sci., [3]Integrative Biol. & Physiol., UCLA, Los Angeles, CA; [4]Anesthesiol. & Perioperative Care, Univ. of California Irvine, Irvine, CA

Abstract: Rewards such as food or drugs increase dopamine (DA) signaling in mesolimbic regions of the brain. With repetition, such increases in DA transmission become associated with proximate cues (e.g., jingles, slogans, paraphernalia), cues that can then trigger further reward-seeking, such as that seen in overeating and drug relapse. Dopamine transporter (DAT) is positively regulated by insulin, such that increasing insulin signaling facilitates DAT activity, thereby promoting DA reuptake and decreasing DA transmission. Conversely, decreasing insulin signaling (e.g., during fasting or due to insulin resistance), downregulates DAT activity. Diets high in sugars and refined carbohydrates impair insulin signaling in the periphery (e.g., Type II Diabetes), and recent evidence suggests insulin resistance can also occur in neuronal tissue. We hypothesize that neuronal insulin resistance due to chronic fructose exposure persistently downregulates DAT activity, leading to reduced extracellular DA clearance, resulting in increased DA signaling that manifests as hypersensitivity to reward-paired cues. Here, we use a commercially available high-fructose pellet chow (66% fructose) known to quickly produce insulin resistance in the periphery. In Exp. 1, we found that, within 3 weeks, this high-fructose diet significantly impaired insulin signaling in the ventral midbrain. In Exp. 2, we compared fructose-exposed with fructose-naïve rats in a Pavlovian-to-instrumental transfer paradigm, a behavioral model of incentive motivation (i.e., cue-induced reward-seeking) for a food reward, where we found increased incentive motivation for a food reward in fructose-exposed rats. In Exp. 3, using in-vivo fast-scan cyclic voltammetry, we found altered electrically-stimulated DA reuptake in the ventral striatum in fructose-exposed rats. These data highlight a potential role for diet and insulin dysfunction in potentiating hypersensitivity to reward-paired cues, an action that may be due to aberrant DAT function.

Title: Enhanced dopamine synthesis capacity in gambling addiction predicts drug-induced increase in reward learning

Authors: *R. COOLS[1,2], R. J. VAN HOLST[1,4], L. K. JANSSEN[1], M. JANSSEN[3], A. BERRY[5], W. JAGUST[6], G. SESCOUSSE[1];
[1]Radboud Univ. Nijmegen, Donders Inst. (RU/DI-BCB), Nijmegen, Netherlands; [2]Dept. of Psychiatry, [3]Dept. of Radiology and Nuclear Med., Radboud university medical center, Nijmegen, Netherlands; [4]Academic Med. Center, Univ. of Amsterdam, Amsterdam, Netherlands; [5]Lawrence Berkeley Natl. Lab., Berkeley, CA; [6]Helen Wills Neurosci. Institute, Univ. of California, Berkeley, CA

Abstract: The dopamine hypothesis of gambling addiction is pervasive. Particularly compelling is the clinical observation that patients with Parkinson's disease may develop gambling addiction symptoms following the onset of their dopaminergic therapy (Dagher et al 2009). Moreover, pathological gamblers respond abnormally to dopaminergic drugs (Boileau et al. 2014; & Janssen et al 2015; Zack & Poulos 2007). However there is little to no direct evidence for a categorical difference between pathological gamblers and controls in terms of dopamine transmission at baseline (in a drug-free state). In fact, multiple attempts to provide evidence for the hypothesis that gambling addiction, as in the case of drug addiction (Lee 2009, Martinez 2005, Volkow et al 2011), is accompanied by lower D2 receptor availability than controls have failed (Boileau et al 2014, Clark et al 2012, Joutsa et al 2012, Linnet et al 2010). Here we provide direct evidence for the dopamine hypothesis of gambling addiction by focusing on a different aspect of dopamine transmission. Specifically, we assessed dopamine synthesis capacity with PET 6-[^{18}F]fluoro-L-DOPA (FDOPA) dynamic scans in 15 controls and 15 pathological gamblers. Moreover, we investigated whether differences in dopamine synthesis capacity between gamblers and controls can account for their differential cognitive response to dopaminergic drug administration (Janssen et al 2014). Dopamine synthesis capacity in the striatum was enhanced in pathological gamblers compared with controls. Furthermore, this enhanced dopamine synthesis capacity predicted the effect of the D2 receptor antagonist sulpiride (400mg oral) on reward (versus punishment) learning. Across both gamblers and controls, individuals with high dopamine synthesis capacity exhibited drug-induced enhancement of reward learning, while individuals with low synthesis capacity exhibited attenuation of reward learning. These data provide strong empirical evidence for the pervasive but hitherto unsupported dopamine hypothesis of gambling addiction. They also reinforce the baseline-dependency principle of dopaminergic drug effects, thus demonstrating the importance of a dimensional as opposed to a categorical approach to dopaminergic treatment in psychiatry.

Title: Transgenerational effects of paternal nicotine exposure on fear response and cholinergic function

Authors: ***M. G. KUTLU**, R. COLE, J. M. TUMOLO, V. PARIKH, T. J. GOULD; Temple Univ., Philadelphia, PA

Abstract: Tobacco use is the leading cause of preventable death in the US as it directly leads to various negative health consequences including cardiovascular diseases and cancer. In addition, numerous studies have indicated a relationship between smoking and mental health problems such as anxiety and stress disorders. Recent developments in genetics have revealed that the effects of exposure to addictive drugs such as cocaine and nicotine are not confined within the same generation but transgenerationally transmitted through epigenetics mechanisms. However, effects of paternal nicotine exposure on pathogenesis of fear and anxiety-related disorders in subsequent generations are virtually unknown. Therefore, in order to investigate the transgenerational effects of paternal nicotine exposure on fear learning and anxiety, we conducted a series of experiments where male adult C57BL6/J mice received either chronic nicotine (28 days, 12.6 mg/kg/d) or chronic saline exposure. The offspring of nicotine (Nic-Sired) and saline (Sal-Sired) exposed mice were tested in contextual and cued fear conditioning. Our results demonstrated that paternal nicotine exposure resulted in augmented cued and contextual fear learning in the subsequent (F1) generation compared to Sal-Sired mice. This effect was reversed when F1 generation mice received acute nicotine injections. The paternal nicotine exposure-induced augmentation of fear learning also persisted in the F2 generation. Moreover, Nic-Sired mice also showed more pronounced spontaneous recovery of fear when re-tested following extinction. Importantly, Nic-Sired mice exhibited normal memory function in the non-affective Novel Object Recognition paradigm, suggesting the effect of paternal nicotine is specific to fear learning. In additional experiments, we did not find any effect of paternal

nicotine exposure in the elevated plus maze or open field tasks, which excluded the possible confounding effects of anxiety and locomotor activity. Finally, using an electrochemical recording technique, we also measured potassium and nicotine-evoked acetylcholine release in the dorsal and ventral hippocampus. Our results showed reduced ventral, but not dorsal, hippocampal cholinergic function in the Nic-Sired mice. In parallel, we also found increased DNA methylation in the ventral hippocampi of the Nic-Sired mice whereas this effects was absent in the dorsal hippocampus. Together, our results suggest that paternal nicotine exposure may result in alterations in the epigenome, which, in turn, leads to exaggerated fear learning and abnormal cholinergic function in subsequent generations.

Title: Aberrant cerebral functional and structural characteristics of methamphetamine abuser

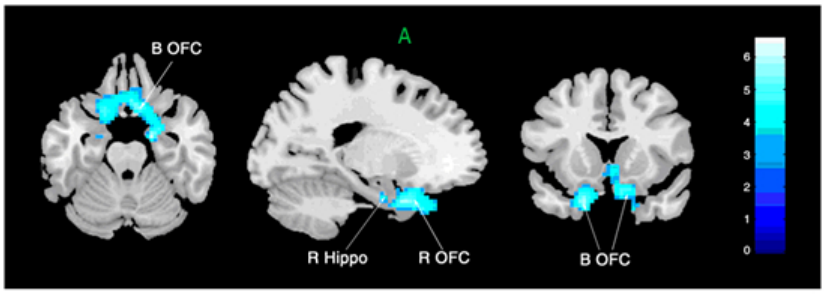
Authors: L. LU, M. ZHOU, L. ZHANG, J. LIU, X. HU, *X.-Q. HUANG;
West China Hosp. of Sichuan Univ., Sichuan, China

Abstract: Purpose
Methamphetamine (MA) is currently a world-widely used addictive psychostimulant. Clarifying the neural mechanisms underlying this problem with MRI can inform more effective treatment.
Method
50 male subjects (mean age=28.74±7.64) met the diagnosis of substance abuse according to DSM-IV and 32 healthy male controls (mean age=33.84±7.22) were recruited and scanned for structural MRI (sMRI) and resting state fMRI (rs-fMRI). ReHo map and subcortical volume of each subject were calculated with DPARSF and Freesurfer software respectively. Between group comparison of ReHo maps were performed using two sample t-test with FWE-correction. The volume of subcortical structures was analyzed using general linear model (GLM) with age and intracranial volume(ICV) as covariates. Relationship between withdraw time and significant regions of sMRI and rs-fMRI were performed with Pearson correlation.
Result

Compared with healthy controls, MA abusers showed lower ReHo in bilateral orbital frontal cortex and right hippocampus(Figure A). MA abusers also showed decreased volume in the right hippocampus, specially, the volume of right hippocampus positively correlated with the withdrawal time(r=0.328,p=0.02). (Figure B)

Conclusion

In present study, we confirm the specific role of hippocampus in MA abusers shown as deficit in regional functional connectivity and volume decrease in the right hippocampus, This is to our knowledge the first study using the ReHo to explore the regional connectivity changes in MA abusers, in additon, we combine sMRI and fMRI to demonstrate the specific role of hippocampus in MA abusers,which had been detected in animal studies before.



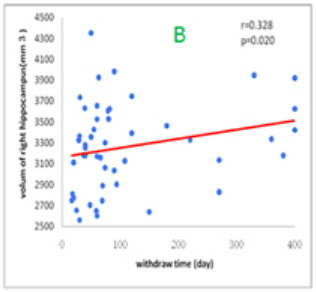


Figure A. Regions showed lower ReHo in MA abusers. B OFC , bilateral orbital frontal cortex (right x=18, y=-3, z=-27, t=6.58, P=0.002;left x=-18, y=15, z=-30 t=5.76,p=0.001) ; R Hippo, right hippocampus (x=6, y=21, z=-18, t=5.89 , P=0.001) .

Title: Feedback processing during risky decision making in cocaine relapse

Authors: *I. VERVEER[1], R. MARHE[2], D. REMMERSWAAL[1], F. M. VAN DER VEEN[1], I. H. A. FRANKEN[1];

[1]Fac. of social sciences, Erasmus Univ. Rotterdam, Rotterdam, Netherlands; [2]Child and Adolescent Psychiatry, VUmc, Amsterdam, Netherlands

Abstract: Background
Approximately two thirds of substance dependent individuals relapse within months after initiating treatment. This estimation suggests that current treatment interventions in addiction are of limited efficacy. In order to develop more effective interventions, it is important to understand the psychological and biological processes underlying relapse.
Neurobiological substrates that are related to cognitive control problems seem to play an important role in the aetiology and maintenance of substance use disorders (SUD). Therefore, neurocognitive measures of cognitive control functioning in addiction (i.e. event related potentials) may be helpful in predicting relapse and in developing more effective interventions. The current study explored whether the feedback related negativity (FRN) and P3 during risky decision making could predict relapse in cocaine addicted patients.
Method
The FRN and P3 were measured in 21 cocaine dependent patients and 25 healthy controls during the balloon analogue risk taking (BART) task by means of positive (earning money) and negative (balloon pops) feedback. The patient group was tested during their first week of detoxification. Relapse was measured at 3 months follow-up by means of self-reported cocaine use in the last month verified by urine screening (relapse n = 11).
Results
Differences between groups were found in P3 amplitudes related to negative (F (2,43) = 3.930, p = .027) and positive feedback processing (F (2,43) = 3.585, p = .036). Simple contrast analysis revealed reduced P3 amplitudes during negative feedback processing in the relapse group compared to both the non-relapse and the control group (p = .028 and p = .011 respectively). During positive feedback processing, P3 amplitudes were reduced in relapsers compared to the non-relapse group (p = .010). For the FRN, no differences between groups were found. Also, behavioural measures of risk-taking (i.e. number of pumps on the BART task) did not differ between groups.
Conclusions
Reduced feedback related P3 amplitudes measured during the first week of detoxification were associated with relapse at three months follow-up. However, no differences were found in behavioural measures of risk-taking. The results of this study emphasize the importance of neurocognitive measures as possible predictors of relapse and treatment outcome. Future research may therefore focus on treatment interventions modulating neurocognitive measures. Specifically, interventions in addiction that seem to operate by modulating brain activity, like the electrical neurostimulation technique tDCS, are interesting to explore in this respect.

Title: Taar1 agonists reduce nicotine related behaviors in rats

Authors: *J. LIU[1], J.-X. LI[2];
[1]Pharmacol. and Toxicology, Univ. at Buffalo, SUNY, Buffalo, NY; [2]Dept. of Pharmacol. and Toxicology, SUNY at Buffalo, Buffalo, NY

Abstract: Trace amine-associated receptor 1 (TAAR1), a G protein coupled receptor, modulates the dopaminergic system and dopamine related behaviors. Selective TAAR1 agonists could inhibit the rewarding effects of stimulants, e.g. methamphetamine and cocaine, reducing drug intake and relapse in animal drug addiction model. However, nothing is known about the role of TAAR1 in nicotine addiction or its underlying mechanism. In the present study, we tested the effects of selective TAAR1 full agonist RO5166017 and partial agonist RO5263397 on nicotine related behaviors. First, we tested the effect of both agonists on the maintenance of nicotine taking. Rats were trained to self-administer nicotine (0.003, 0.01, 0.03, and 0.1 mg/kg/infusion) for 1 hr per day under a fixed ratio 3 schedule of reinforcement followed by a 30-s time-out period. Infusions were accompanied by a 5-s illumination of the stimulus light above the active lever and the house light was extinguished for the duration of the time-out period. The results showed that nicotine self-administration followed an inverted U-shaped pattern, with the peak number of injections (about 9-10 injections in 1 hr) maintained by 0.03 mg/kg/infusion. Pretreatment with RO5166017 (5.6 and 10 mg/kg, i.p.) and RO5263397 (3.2 and 5.6 mg/kg, i.p.) 10 min before nicotine self-administration each day dose-dependently decreased the dose-effect curve of nicotine injections and total nicotine intake. We then tested whether activation of TAAR1 would affect the reinstatement of nicotine-seeking behavior. Rats were trained for nicotine self-administration for 15 days in total. The response requirement was gradually increased from FR 1 to FR 3 over a period of 7 days, and then maintained for 8 days under FR 3. Rats were then given six daily extinction sessions, during which lever presses had no consequence (no drug or cues). RO5166017 (10 mg/kg, i.p.) was administrated 10 min before cue- or drug (0.3 mg/kg nicotine, i.p.)-induced reinstatement of nicotine-seeking. Both cue- and drug-induced reinstatement of nicotine-seeking were significantly inhibited by RO5166017. These results indicate that activation of TAAR1 plays an essential role in nicotine-related behaviors, suggesting that TAAR 1 may represent a novel target for the treatment of nicotine addiction.

Title: The role of endogenous pituitary adenylyl cyclase activating polypeptide (PACAP) in the motivational effects of nicotine

Authors: ***O. FARHAD**, A. TSENG, P. SINGH, P. MARQUEZ, A. HAMID, K. LUTFY; Pharm., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Nicotine addiction is a major public health and socioeconomic issue. While the pleasurable effect of low doses of nicotine is thought to play an important role in the initiation of nicotine addiction, the negative affective state that develops following nicotine withdrawal is known to promote relapse. However, the underlying mechanisms of motivational effects of nicotine have not been characterized. The pituitary adenylyl cyclase activating polypeptide (PACAP) and its receptors are widely expressed along the stress and reward circuits, raising the possibility that this system may be involved in the motivational effects of nicotine. The present study sought to determine the role of endogenous PACAP in the aversive and reinforcing effects of nicotine. We used place conditioning and two-bottle choice (TBC) paradigms to assess the role of PACAP in these effects of nicotine. In the TBC paradigm, PACAP knockout and wild-type mice were housed individually while they had access to two water bottles for a week. Mice were then given a choice between water and nicotine (20μg/mL) for the following week. The concentration of nicotine was increased two-fold on each subsequent week. Our results revealed that wild-type mice failed to show any preference for the nicotine solution over the water. On the other hand, mice lacking PACAP consumed more nicotine compared to water. In the place conditioning paradigm, mice lacking PACAP and their wild-type littermates/controls were tested for basal place preference toward the conditioning chambers on day 1. Mice were then injected with either saline or nicotine (1 mg/kg) and confined to either the vehicle-paired chamber or drug-paired chamber, respectively. In the afternoon, animals received the alternate treatment and were confined to the opposite chamber for 15 min. This twice daily conditioning lasted for 8 days. Mice were then tested for postconditioning place preference on day 10. On each test day, mice were placed in the neutral chamber of the CPP apparatus and allowed to explore all the three CPP chambers. The amount of time that mice spent in each chamber was recorded. Our

results showed that wild-type mice spent significantly more time in the saline-paired versus nicotine-paired chamber, showing that wild-type mice exhibited a significant aversion toward the nicotine-paired environment. On the other hand, this aversive effect of nicotine was absent in mice lacking PACAP. Together, these results suggest that endogenous PACAP may mediate the aversive effects of nicotine, and PACAP and its receptors may be a novel target for the development of medications for smoking cessation and nicotine addiction.

Title: Menthol interaction with nicotine to enhance nicotine reinforcement and increase dopamine level in the nucleus accumbens of rats

Authors: Y. GONG, E. HARRISON, L. BISWAS, J. LAGE, *X. LIU;
Pathology, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Increasing clinical observations suggest that menthol may promote tobacco smoking and nicotine dependence. However, it is not yet clear whether menthol enhances the reinforcing actions of nicotine and interacts with nicotine at neurochemical level. This study employed rat models of nicotine consumption to examine effect of menthol on nicotine self-administration and used intracranial microdialysis to determine influence of menthol on nicotine-induced dopamine release in the nucleus accumbens. Male Sprague-Dawley rats were trained in daily 1-h sessions to press a lever for self-administration of intravenous nicotine at 0.015 mg/kg/infusion, a dose on the ascending limb of the inverted “U” shaped nicotine dose-response curve. Menthol (5 mg/kg) or its vehicle was given intraperitoneally 5 min prior to the test sessions. In separate sets of rats, dopamine levels in the right nucleus accumbens in response to administration of nicotine, menthol, and both were measured using microdialysis coupled with HPLC assay. In the behavioral tests, menthol increased self-administration of nicotine in a dose-dependent manner. In the neurochemical assay, menthol, albeit did not produce an effect on its own, enhanced dopamine release induced by nicotine administration. These data demonstrate a facilitative effect of menthol on nicotine reinforcement and an interaction of menthol with nicotine to enhance

dopamine release in the nucleus accumbens. These findings may shed a light on our understanding of the influence of menthol on smoking and its underlying neurobiological mechanisms.

Title: Interoceptive conditioning and reversal learning with the nicotine and varenicline stimulus

Authors: *B. M. THOMPSON, S. T. BARRETT, J. R. EMORY, C. E. LARSEN, A. M. PEER, S. T. PITTENGER, R. A. BEVINS;
Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Nicotine, the primary psychoactive chemical responsible for the use and addiction to tobacco smoking, has the ability to control behavior. The CDC (2014) estimates that 16.8% of people in the US, roughly 40 million, are smokers. Varenicline (Chantix™) is a smoking cessation drug that works on nicotinic acetylcholine receptors and can reduce the tenacity of the nicotine addiction and facilitates cessation for some smokers. With high relapse rates in individuals who wish to quit, a better understanding of the behavioral and neuropharmacological processes involving nicotine and treatment-related compounds like varenicline will eventually help inform cessation approaches. We have shown that the nicotine stimulus can acquire control over goal-tracking behavior when nicotine predicts intermittent access to brief sucrose rewards. Questions of whether appetitive learning can be reversed or whether varenicline could act as a substitute for nicotine in these situations has not been asked. Male Sprague-Dawley rats were trained to use nicotine (0.4mg/kg subcutaneous) as a conditioned stimulus for access to sucrose (CS+); 36 sucrose deliveries (4 sec each) in 20-min sessions. Conversely, on interspersed days when saline was administered, sucrose was withheld (CS-). Nicotine significantly increased anticipatory food-seeking behavior, measured using dipper entries per sec before the first reinforcer presentation (or equivalent time in CS- sessions). Following this discrimination training, rats were separated into four groups defining the next phase of training: 1) nicotine was maintained as a CS+ (i.e., no change from training); 2) reversal training where nicotine now

serves as a CS- (i.e., saline sessions now predict sucrose access); 3) varenicline replaces nicotine and serves as a CS+; 4) varenicline replaces nicotine in the reversal learning protocol (CS-). Rats that were kept in the drug (nicotine or varenicline) as CS+ groups maintained high levels of goal-tracking to the drug stimulus compared to saline. However, dipper entries per second were lower for rats in the varenicline CS+ group compared to those in the nicotine CS+ group. Early in the reversal learning phase, responding in the now reinforced saline sessions increased to levels controlled by the drug stimuli. With continued reversal training, responding to the non-reinforced drug stimuli began to decrease providing the first evidence of reversal learning in this task.

Title: Insulin normalizes the strong rewarding effects of nicotine observed in hypoinsulinemic rats.

Authors: *B. CRUZ[1], J. A. PIPKIN[1], R. MARTINEZ[1], C. A. HINOJOSA[1], O. V. TORRES[1,2], A. NAZARIAN[3], L. E. O'DELL[1];
[1]Psychology, Univ. of Texas At El Paso, El Paso, TX; [2]Psychology, San Diego Mesa Col., San Diego, CA; [3]Dept. of Pharmaceut. Sci., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Introduction: Previous research has demonstrated that hypoinsulinemic rats display enhanced rewarding effects of nicotine. However, it is unclear whether the strong rewarding effects of nicotine observed in these rats are modulated via insulin. To address this issue, the present study examined whether insulin replacement in streptozotocin (STZ)-treated rats would 1) normalize the rewarding effects of nicotine and 2) reverse the alterations in insulin-signaling proteins observed in the brains of STZ-treated rats. **Methods**: A rodent model of hypoinsulinemia was used involving STZ administration, which is a drug that is toxic to the insulin-producing cells of the pancreas. Male rats received STZ (45 mg/kg, sc) or vehicle. Half

of the animals were then implanted with an insulin pellet or received a sham surgery. The rats were then given 23-hour access to nicotine self-administration using an escalating dose regimen (0.03, 0.06 and 0.09 mg/kg/0.1 ml infusion). In a follow up study, western blot analyses were performed in a separate cohort of STZ-treated rats that received insulin replacement. Brain tissue was collected 2 weeks after STZ administration, in order to examine alterations in insulin-signaling proteins at a corresponding time point to our behavioral studies. Tissue was collected from the nucleus accumbens (NAc) for the analysis of the insulin-signaling proteins, IRS-2 and IGF-1Rβ. **Results**: Our behavioral results revealed that insulin replacement normalized the rewarding effects of nicotine in STZ-treated rats. Our protein analysis revealed that the levels of IRS-2 and IGF-1Rβ were increased in STZ-treated rats, and this effect was normalized to control levels in the NAc of rats that received insulin treatment. **Conclusion**: These observations indicate that insulin systems play an important role in modulating the strong rewarding effects of nicotine in hypoinsulinemic rats. Taken together, these results have implications for the development of tobacco intervention approaches in patients with metabolic disorders such as diabetes that suppress insulin signaling.

Title: Adolescent rats display stress- and stress+cue-induced reinstatement after cigarette smoke extract or nicotine self-administration

Authors: *C. GELLNER, A. S. ALVELA, H. L. HU, J. D. BELLUZZI, F. M. LESLIE; Pharmacol., Univ. of California, Irvine, Irvine, CA

Abstract: The nearly 90% of people who begin smoking in their teens have a harder time quitting and are more likely to relapse. Therefore, it is important to understand relapse to smoking during this developmental period. To investigate the role of non-nicotine constituents in relapse to smoking, we have established a model of intravenous self-administration comparing cigarette smoke extract (CSE) to nicotine alone. Previous research in our lab has shown that adult male rats that self-administer CSE extinguished more slowly and were more sensitive to

stress-induced reinstatement. We now test the hypothesis that adolescent rats will exhibit similar patterns of behavior. Adolescent rats, aged postnatal day (P) 25, were trained to lever press on a FR5TO20 schedule (1 food pellet per 5 lever presses with a time out period of 20 seconds). After rats reached the reinforced lever press threshold (R=35), they underwent surgery to implant a catheter in their right jugular vein. After three days recovery, rats (P35) began 1-hour drug self-administration sessions with nicotine or CSE (15 µg/kg/infusion nicotine content). Once rats reached stable responding for drug, drug was removed and drug-seeking behavior was extinguished. Extinguished drug-seeking behavior was reinstated with stress, cues, or a combination of stress and cues. Preliminary results suggest that baseline responding for CSE and nicotine groups is similar. When drug is removed, CSE and nicotine seeking rats display similar extinction rates. Adolescents also exhibit similar levels of stress- and stress+cue-induced reinstatement of CSE and nicotine seeking behavior. Therefore, these preliminary findings suggest that the non-nicotine constituents in cigarette smoke do not influence adolescent responding for drug, extinction or reinstatement of drug-seeking behavior.

Title: Role of the ventral tegmental area and prefrontal cortex in nicotine-enhanced responding for conditioned reinforcement

Authors: *R. TABBARA[1,3], P. FLETCHER[1,3,2];
[1]Psychology, [2]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [3]Biopsychology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Tobacco dependence is a leading cause of preventable death worldwide. Nicotine, the main psychoactive ingredient in tobacco products, possesses several reinforcing properties that may contribute to tobacco dependence. For example, preclinical studies have shown that nicotine enhances locomotor activity, supports self-administration behavior, and induces conditioned place preference. Nicotinic acetylcholine receptors (nAChRs) in the ventral tegmental area (VTA) have been implicated in mediating these reinforcing properties. Nicotine also enhances

responding for sensory cues that function as conditioned reinforcers (CRfs). It is unknown if nAChRs in the VTA are implicated in nicotine-enhanced responding for a CRf. Furthermore, given that responding for sensory cues requires subjects to attend to them, nicotine may enhance their reinforcing value via a prefrontal attentional mechanism. This work examined the role of nAChRs in the VTA and the prelimbic (PrL) area of the prefrontal cortex in nicotine-enhanced responding for a CRf. Male Long-Evans rats were implanted with a bilateral guide cannula aimed at the VTA or the PrL cortex. Next, water-deprived rats received a nicotine injection (0.4 mg/kg; s.c.) prior to 12 sessions of Pavlovian conditioning. Each session consisted of 30 trials wherein a 5-sec tone-light conditioned stimulus (CS) was paired with 0.05 ml of water. Tests of responding for a CRf were then conducted during which presentation of the CS alone (now acting as a CRf) was contingent upon pressing one of two levers (CRf lever). Pressing the other lever had no consequences (NCRf lever). To determine if nAChRs in the VTA or the PrL cortex mediate nicotine-enhanced responding for a CRf, the selective α4β2 nAChR antagonist Dihydro-β-Erythroidine (DHβE; 10 nmol/0.5 μL) was infused into the respective areas prior to a nicotine injection (0.2 mg/kg; s.c.). DHβE infused into the VTA, but not the PrL cortex, attenuated nicotine-enhanced responding for a CRf. Next, to confirm that nAChRs in the VTA mediate nicotine-enhanced responding for a CRf, nicotine (8, 16, or 32 nmol/0.5 μL) was infused into this area. Nicotine infused into the VTA elicited a dose-dependent selective enhancement in responding for a CRf. These findings suggest that nicotine acts within the VTA, but not the PrL cortex, to produce its reinforcement-enhancing effects.

Title: Modeling gene x environmental effects in the mouse: the multigenerational phenotypes of the interaction of the rs16969968 SNP with developmental nicotine exposure.

Authors: *H. C. O'NEILL, C. WAGEMAN, S. R. GRADY, M. J. MARKS, J. A. STITZEL; Univ. of Colorado Boulder Inst. for Behavioral Genet., Boulder, CO

Abstract: We have long known of the deleterious effects of developmental nicotine exposure. Recently, a non-synonymous SNP in the a5 nicotinic receptor subunit gene was shown to have

an impact on nicotine addiction; these studies seek to investigate the interaction of this risk allele with exposure to nicotine during development. Female mice with the rs16969968 SNP (hereafter D397 for wild type; N397 for risk allele), were given 100 μg/ml nicotine in a 0.2% saccharin solution 30 days prior to breeding to allow acclimation, and maintained exposure through weaning of pups to reduce the risk of withdrawal. We investigated dopaminergic (DA) release mediated by nicotinic receptor function in the striatum (in isolated synaptosomes) and found DA release is decreased in N397 mice exposed to developmental nicotine (dev nic), suggesting the potential for altered reward. To investigate the rewarding properties of nicotine, we used the two-bottle nicotine choice and conditioned place preference (CPP) paradigms, revealing nicotine aversion in D397 dev nic mice in both studies. N397 dev nic mice, in contrast, consumed the greatest amount of nicotine at high concentrations as compared to all other groups and also showed preference for nicotine in the CPP model. In conjunction with altered DA release, these data combined may suggest increased drive to attain reward in the N397 dev nic mice. We also measured homecage activity and found a significant increase in activity in the N397 mice as compared to the D397 vehicle groups. Both D397 and N397 dev nic mice were significantly more active than their vehicle counterparts during their normal active cycle. All N397 mice also appeared to have sleep disturbances in the homecage setting. Increased activity and possible decreased sleep may contribute to increased nicotine intake if it confers an anxiolytic effect on the N397 mice. We bred D397 and N397 dev nic females to nicotine naïve males creating an F2 generation, and found D397 F2 mice had dramatically increased activity in homecage. Combined, these generational models will allow investigation of structural and functional changes resulting from either direct developmental or germline exposure to nicotine.

Title: Chronic intravenous nicotine self-administration alters the expression of choroid plexus RNA in rats

Authors: *V. OCHOA, C. D. FOWLER;
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Tobacco dependence is a leading preventable cause of disease and death worldwide. Given the recent identification of circulating micro-RNAs (miRNAs) in the cerebrospinal fluid (CSF) and documented effects of nicotine on the secretion of protein from the choroid plexus, we sought to investigate whether the expression of RNA becomes altered with chronic intravenous nicotine self-administration. Adult, male Wistar rats were first trained to respond for food pellets in an operant box under a fixed ratio 5, time out 20 sec schedule of reinforcement. Thereafter, rats were implanted with intravenous catheters and randomly assigned into two groups: nicotine or saline (control) self-administration. Following eight days of intravenous self-administration, rats were anesthetized, and CSF was extracted from the cisterna magna. Brains were removed immediately thereafter, and the choroid plexus was microdissected from three distinct anatomical locations in the lateral, third and fourth ventricles. Extracted RNA was analyzed with a microarray and select targets were subsequently verified with RT-qPCR. To further investigate how nicotine may be acting on the choroid plexus, we then assessed the expression of various nicotinic acetylcholine receptor subunits across the ventricular sites. Together, these data support the hypothesis that nicotine acts directly on nicotinic acetylcholine receptors in the choroid plexus to alter RNA expression and release into the CSF.

Title: Comparison of the reinforcing effects of nicotine versus heroin, remifentanil and cocaine with rat intravenous self administration

Authors: *S. L. SMITH, E. JOHNSON, J. SLADE, S. HOLLAND, M. HALLAM, D. HEAL; Renasci Ltd, Nottingham, United Kingdom

Abstract: The relative reinforcing effect of nicotine was compared with three highly abused Controlled Drugs (CDs). They were the opiates, heroin and remifentanil, and the psychostimulant, cocaine. The relative reinforcing effect of the drugs was determined using a progressive ratio (PR) schedule where the rats press operant levers on an escalating response requirement within sessions to receive intravenous drug rewards.
Male Sprague Dawley rats (175-225g on arrival; Charles River, UK) were mildly food restricted and trained to press levers for food rewards. Once responding was stable, animals were implanted with a jugular vein catheter. After nicotine acquisition (0.03mg/kg/infusions [inf], iv)

and saline extinction, a dose-response test was performed for nicotine (0.0075, 0.015, 0.03, 0.06 mg/kg/inf) on fixed ratio 5 (FR-5) schedule in 2 hr sessions. When stable (inf did not vary by >20% over the last 3 sessions) and where each drug dose was positively reinforcing (mean >12 inf/session over the last 3 sessions), the break-point of operant responding was determined in a 4 hr PR session. The break-points for responding for heroin (0.025 mg/kg/inf), remifentanil (0.015 mg/kg/inf) and cocaine (0.29 mg/kg/inf) were determined on a PR schedule. These doses were the most reinforcing on PR schedule in previously performed dose-response tests.
On FR-5, all doses of nicotine were positively reinforcing (inf/session ± SEM: 18.8±1.7 for 0.0075 mg/kg/inf, n=6; 19.8±0.3 for 0.015 mg/kg/inf, n=8; 19.0±0.7 for 0.03 mg/kg/inf, n=8; 18.1±1.4 for 0.06 mg/kg/inf, n=7; 3.7±0.4 for saline; n=8; all doses $p<0.001$ vs. saline).
On a PR schedule, the break-points (lever-presses/infusion) for nicotine were 42.3±0.7 for 0.0075 mg/kg/inf; (n=6), 73.4±14.8 for 0.015 mg/kg/inf (n=8), 48.8±10.0 for 0.03 mg/kg/inf; n=8) and 67.2±10.1 for 0.06 mg/kg/inf; n=7). The break-points for highly reinforcing doses of heroin (61.8±17.7 for 0.025 mg/kg/inf; n=8) and remifentanil (48.1±18.2 for 0.015 mg/kg/inf; n=5) were not different from the most reinforcing dose of nicotine (0.015 mg/kg/inf). The break-point for nicotine was significantly higher than for cocaine (46.6±4.2 for 0.29 mg/kg/inf; n=9; $p<0.05$).
Using an ascending PR schedule, heroin, remifentanil and cocaine were robust positive reinforcers, reflecting their known profiles as highly abused drugs in humans. The relative reinforcing effect of nicotine did not differ from heroin and remifentanil, but was significantly greater than cocaine. In summary, although nicotine is a legally available and widely used drug, it has equivalent or greater reinforcing effect in this model than three Schedule II CDs.

Title: Tobacco flavor additives established as conditioned reinforcers promote nicotine self-administration in rats.

Authors: A. L. SMITH, E. A. WILLIAMS, C. A. BRADLEY, S. G. MALONE, A. K. PATTERSON, E. M. SANDERS, *M. I. PALMATIER;
East Tennessee State Univ., Johnson City, TN

Abstract: All tobacco products include flavor additives to enhance flavor and create a unique brand experience. Many additives are conditioned reinforcers (CRs) - they are found in sweet or caloric food and drinks such as candy and ice cream. For example, all Marlboro cigarette products include licorice extract (LE) in the ingredients list. These additives may interact with the effects of nicotine (NIC) to promote tobacco use. For example, NIC is a weak primary reinforcer but potently enhances the reinforcing effect of non-drug CRs, including flavors previously paired with sucrose. The purpose of this study was to investigate whether a ubiquitous cigarette additive (LE) would enhance intravenous NIC self-administration (IVNSA) in rats. We hypothesized that LE would enhance IVNSA if it was established as a CR, but not if it was a neutral stimulus. Male rats (n=34) were randomly assigned to one of two LE groups (CR or Neutral) and one of two LE concentrations (0.1% or 1%, v/v). Rats were allowed to drink solutions containing LE with 20% sucrose (w/v, CR groups) or unsweetened (Neutral groups) for 24 days (40 min per day). Following conditioned reinforcement training, rats were instrumented for IVNSA and allowed to recover. In subsequent IVNSA tests, operant lick responses at two sipper tubes (water or LE) were reinforced with presentations of oral solutions delivered to the sipper tube (0.12 ml). Meeting the schedule of reinforcement on the LE sipper tube delivered the assigned LE flavor (unsweetened) and IV NIC (7.5 ug/kg/infusion). Meeting the schedule of reinforcement on the water sipper tube delivered tap water but did not result in an IV infusion. The schedule of reinforcement was shifted from a fixed ratio of 2 (FR2) to FR5 and FR10 across testing sessions. After responding under the FR10 stabilized, NIC infusions were replaced with 0.9% saline (SAL). During acquisition, only rats in CR groups acquired NIC self-administration; rats in the Neutral groups responded equally at the LE and water sipper tubes. In addition, the stronger LE flavor (1%) was a more robust CR and robustly increased NIC intake, relative to the weaker flavor (0.1%). During SAL substitution, responding at the LE sipper tube declined to the same level as responding at the water sipper tube, but only in the 0.1% CR group. Responding at the LE sipper declined in the 1% CR group, but was statistically higher than responding at the water sipper throughout the SAL substitution phase. In conclusion, flavor additives can interact with NIC to potentiate self-administration and perseveration of operant behaviors after NIC has been removed. These additives may promote exposure and subsequent dependence on tobacco and vapor products.

Title: Adolescent diet and nicotine treatment interact to affect anxiety-like behaviors in mice

Authors: *L. K. SILVA, D. H. BRUNZELL;
Dept. of Pharmacol. and Toxicology, Virginia Commonwealth Univ. Hlth. Syst., Richmond, VA

Abstract: Disease resulting from obesity and cigarette smoking are the leading causes of preventable death in the United States. Adolescents often consume high fat diets and diets with low nutritional content, which have been shown to negatively impact development of the body and brain. Overweight adolescents typically become overweight adults while smokers who initiate use during adolescence report greater consumption and increased difficulty quitting. Additionally, although smokers tend to have lower BMI than non-smokers, heavy smokers are more likely to be obese and obese smokers have more difficulty quitting. Further, high fat diet has been shown to increase β2 subunit containing nicotinic acetylcholine receptors (β2*nAChR), which are known to be necessary for nicotine reward. However, little is known regarding how dietary choices may impact nicotine use vulnerability in adolescents. Nicotine effects on behavior are dose-sensitive, with low doses decreasing anxiety-like behavior, intermediate doses promoting reward and high doses increasing anxiety-like behavior. To study the impact of diet on nicotine reward and anxiety-like behaviors, adolescent C57BL/6J mice (postnatal day (P) 26-47) were maintained on one of three diets: a regular nutrient diet (10% kcal from fat, RND), an identical but reduced vitamin diet (LND), and a high fat (60% kcal from fat, HFD). Mice were tested using doses of nicotine shown to decrease anxiety-like behavior (0.03 mg/kg i.p.) and promote nicotine reward (0.1 mg/kg i.p.) in adult mice. Nicotine conditioned place preference (CPP) was tested from P33-37 and a battery of ethological tests of rodent anxiety-like behaviors was studied from P40-44. Regardless of diet, adolescent mice failed to show CPP at any dose studied. Interestingly, adolescents showed increased anxiety-like behavior at doses shown to promote anxiolysis and reward in adult C57BL/6J mice. RND mice showed elevated anxiety-like behavior in the open field at 0.1 mg/kg i.p. nicotine; HFD mice were left-shifted, showing anxiogenesis behavior at 0.03 mg/kg i.p. nicotine. In the elevated plus maze, LND mice showed reduced time in the open arms at both doses of nicotine, while RND and HFD mice were unaffected by nicotine treatment in this measure. Together, these data suggest that adolescents differ from adults in their response to nicotine and reveal that diet can interact with nicotine to

alter anxiety-like behaviors. Further studies will assess the effect of diet on nicotinic acetylcholine receptor expression and body composition.

Title: Incentive effects of acute or chronic nicotine on acquisition and extinction

Authors: *L. A. ORTEGA MURILLO[1], M. R. PAPINI[2], D. RAMIREZ[1];
[1]Fundacion Universitaria Konrad Lorenz, Bogota, Colombia; [2]Texas Christian Univ., Fort Worth, TX

Abstract: Current research has focused on learning and motivational processes for nicotine proposed to be critical for the development and maintenance of tobacco addiction. In particular, nicotine administration has been associated with the enhancement of nonassociative incentive and reinforcing properties of naturally rewarding stimuli. In the present studies, the role of acute and chronic nicotine was assessed on acquisition and extinction, using an autoshaping task with a natural unconditioned stimulus (food pellets). In Experiment 1, subcutaneous acute nicotine (0.4 mg/kg, dose reported as free base) or the appropriate vehicle control was administered during early acquisition or early extinction. Acute nicotine had no noticeable effects on autoshaping acquisition performance, but it retarded autoshaping extinction. In Experiment 2, chronic nicotine (3.6 mg/kg/day; dose reported as free base) or vehicle was administered using mini-osmotic pumps inserted subcutaneously under anesthesia. Contrary to acute nicotine effects, chronic nicotine enhanced autoshaping acquisition performance, but had no noticeable effects on extinction performance. Together, these findings suggests a differential effect of nicotine on autoshaping acquisition and extinction depending upon the type of nicotine administration, acute or chronic. As chronic, but not acute, nicotine administration is associated to upregulation of nicotinic cholinergic receptors, these findings also suggests differential brain mechanisms underlying the specific effect of chronic nicotine on acquisition. Future studies on this differential effect may help understand the mechanisms underlying the complex and varied incentive and reinforcing effects of nicotine on natural stimuli.

Title: Effects of genetic manipulation of metabotropic glutamate receptor 7 on nicotine self-administration in rats and mice

Authors: ***X. LI**, A. MARKOU;
Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: The reinforcing properties of nicotine are associated with increased glutamate transmission in the mesocorticolimbic circuit. Decreasing glutamate transmission by targeting metabotropic glutamate receptors (mGluRs), such as mGluR2/3 and mGluR5, inhibited nicotine taking. Our recent studies showed that activation of mGluR7 by the only commercial available agonist AMN082 attenuated nicotine reinforcement. However, findings indicated that some effects of AMN082 were not mediated by mGluR7, but rather by monoamine reuptake inhibition induced by an AMN082 metabolite, making the AMN082-induced effects difficult to interpret. The present study was aimed to assess the role of mGluR7 in nicotine reinforcement in mGluR7 null mutant mice and in mGluR7 overexpression rats. We found that mGluR7 null mutant mice showed increased nicotine self-administration, but had no change in food self-administration, compared to their wildtype littermates. AMN082, at middle dose (3 mg/kg), inhibited nicotine self-administration in wildtype, but not mGluR7 gene knock, mice. However, high dose of AMN082 inhibited nicotine taking in both wildtype and gene knock mice. Moreover, overexpression of mGluR7 in the ventral tegmental area (VTA), an important brain area involved in drug addiction, decreased nicotine self-administration, but had no effect on food-self-administration in rats. These findings in genetic manipulation animals are consistent with those of our previous findings with pharmacological manipulations, further suggesting the critical role of mGluR7 in nicotine reinforcement. Therefore, mGluR7 may be a promising target for the treatment of nicotine addiction.

Title: ChAT-BAC-Cre and ChAT-IRES-Cre mouse lines exhibit differential patterns of intravenous nicotine self-administration

Authors: A. LOEFFLER, E. CHEN, J. P. FOWLER, F. NOSRATI, N. P. GRIMES, *C. D. FOWLER;
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: The recent development of transgenic mouse lines expressing cre in a cell-specific manner, along with advances in engineered viral vectors, has permitted increased investigation into neural circuit function. However, emerging evidence has indicated that some transgenic mouse lines may introduce limitations into experimentation based on the method of development. For instance, it has been recently reported that ChAT-ChR2-EYFP transgenic mice that express channelrhodopsin under the ChAT promoter exhibit increased baseline cholinergic tone (Kolisnyk et al., 2013, *J Neurosci*). In the current investigations, we sought to characterize both the ChAT-BAC-Cre line created with the bacterial artificial chromosome method (GENSAT) and the ChAT-IRES-Cre line generated with the internal ribosome entry site method (Jackson Laboratory). Adult male and female mice were first trained in the food self-administration paradigm under a progressive fixed-ratio schedule to achieve a fixed-ratio 5, time out 20 sec schedule of reinforcement. Both lines exhibited no deficits in the acquisition of food responding across sessions, indicating an ability to learn and perform an operant task similar to their wildtype littermate controls. Thereafter, mice were surgically implanted with intravenous catheters into the right jugular vein. After a recovery period and reinstatement of food responding, the mice were transitioned to intravenous self-administration at the 0.03 mg/kg/infusion training dose of nicotine. At this dose, ChAT-BAC-Cre mice quickly attenuated their level of responding and did not sustain consistent nicotine self-administration behavior,

whereas ChAT-IRES-Cre mice exhibited sustained nicotine self-administration at a level similar to wildtype controls. Given the dense expression of acetylcholine in the medial habenula-interpeduncular pathway and the role of this structure in mediating nicotine aversion, we then investigated whether the mouse lines differed in their expression of the vesicular acetylcholine transporter and cre protein in the medial habenula and interpeduncular nucleus. Together, these data suggest that ChAT-BAC-Cre, but not ChAT-IRES-Cre, mice exhibit altered cholinergic signaling that results in increased sensitivity to the aversive properties of nicotine. As such, investigations with these mice should proceed with caution in consideration of this altered phenotype.

Title: Role of a3b4 nicotinic acetylcholine receptors in drug- primed reinstatement of Cigarette Smoke Extract (CSE)- and nicotine- seeking behavior

Authors: *D. REYNAGA[1], N. ZAVERI[2], F. LESLIE[3];
[1]Univ. of California Irvine, Irvine, CA; [2]Astraea therapeutics, Mountain View, CA; [3]Univ. of California, Irvine, Irvine, CA

Abstract: Cigarette smoking is difficult to treat and the majority of those who try to quit relapse within the first year. Many smoking cessation therapies fail at the clinical phase of drug development. One explanation for this may be that the majority of preclinical tests use nicotine alone, ignoring ~8,000 constituents also found in tobacco smoke. In prior studies, we have shown that rats that self-administered cigarette smoke extract (CSE), an aqueous solution containing nicotine and other smoke constituents, were more sensitive to stress- induced reinstatement of drug seeking behavior than were those that self-administered nicotine alone (Costello et al. 2014). Furthermore, AT-1001, a functional antagonist of α3β4 nicotinic acetylcholine receptors (nAChRs), was less effective in blocking self-administration of CSE than nicotine alone. We have now examined whether rats that self-administer CSE are also more

sensitive to drug- primed reinstatement than those that worked for nicotine alone, and whether AT-1001 has differential effects on drug- primed reinstatement in the two groups. Upon stable self-administration and extinction of CSE or nicotine responding (15 μg/kg/infusion nicotine content, i.v.), all animals were tested for reinstatement in a randomized design with the following 5 conditions: cues alone, nicotine priming (0.15mg/kg; i.p), CSE priming (0.15mg/kg nicotine content; i.p), and both drug priming conditions with cues. To test attenuation of reinstatement, AT-1001 (0, 0.75, 1.5, 3 mg/kg; s.c.) was given before the test followed by reinstatement testing with a priming dose of the previously self-administered drug (CSE or nicotine; 0.15 mg/kg nicotine content; i.p) paired with cues. We found that both animals that self-administered CSE or nicotine reinstated when drug priming was paired with cues. However, only animals that self-administered CSE reinstated when drug priming was given without cues. Furthermore, animals that self-administered CSE reinstated more robustly than animals that self-administered nicotine alone when given a priming dose of nicotine. AT-1001 dose dependently reduced drug- primed reinstatement both in animals that self-administered CSE and nicotine, with a trend toward higher potency in animals that self-administered nicotine. The results suggest that the non-nicotine constituents in CSE, contribute to the increased propensity for reinstatement, likely through nAChR sensitization. The attenuation of nicotine- and CSE- seeking behavior by AT-1001 suggests that α3β4 nAChR functional antagonism may be a suitable treatment approach to reduce nicotine and CSE craving during smoking cessation treatment.

Title: Bimodal modulation of social factors on nicotine aversion in rats: Focus on sex difference, pair housing and oxytocin

Authors: H. LEE, M. JANG, *J.-H. NOH;
Dankook Univ., Suji-Gu, Yongin-Si, Gyeonggi-Do, Korea, Republic of

Abstract: Tobacco smoking is controlled in diverse social circumstances. Social therapy is generally used to stop smoking, while peer interaction is insisted as a crucial factor which triggers initial tobacco use in adolescent. To determine the roles of social factors on nicotine dependence, we compared single and pair housed rats in dose escalating voluntary oral nicotine consumption. There were no differences in body weight and food intake among all assigned rats. Importantly, pair housed female rats showed alleviated nicotine consumption for both high and low dose of nicotine solution. On the other hand, pair housed male rats showed only reduced consumption in high dose nicotine solution compared to single housed rats. Moreover, in male rats, aversive response to nicotine was contrastively disappeared in pair housed rats in low dose of nicotine consumption. To demonstrate the other social factor which can mitigate nicotine aversion in male rats, we observed oxytocin-injected male rats on voluntary oral nicotine consumption against nicotine solution. As a result, oxytocin-injected rats showed enhanced nicotine consumption compared to saline-injected rats. Taken together, it provides a widen perspective on social interaction as a therapeutic strategy on nicotine addiction related behaviors. We suggest that revealing distinct roles of behavioral and physiological social factors have fascinating potentials for inoculating nicotine addiction. Nebraska DHHS - LB506 2015 "Nicotine Enhancement of Alcohol Seeking"

Title: Nicotine alters demand for alcohol reinforcement in male and female Sprague-Dawley and Wistar rats.

Authors: *S. BARRETT, B. M. THOMPSON, S. T. PITTENGER, C. E. LARSEN, J. R. EMORY, R. A. BEVINS;
Univ. of Nebraska - Lincoln, Lincoln, NE

Abstract: Nicotine and alcohol dependence are highly correlated: up to 80% of alcohol-dependent persons in the US smoke regularly, and risk of alcohol dependence is four times

higher among people who are nicotine dependent. Additionally, differences in the prevalence and nature of nicotine and alcohol dependence exist between the sexes. Women are less likely to attempt smoking cessation and more likely to relapse after quitting. Women also show greater sensitivity to the intoxicating effects of alcohol, slower alcohol metabolism, and greater risk for adverse health consequences of alcohol use. Understanding the behavioral processes that underlie alcohol and nicotine dependence and their high comorbidity will require consideration of the multifaceted causes that include an individual's sex.Increasing evidence suggests that the reward-enhancing effects of nicotine synergistically enhances behavior directed at obtaining other rewards, and this reward-enhancement effect holds promise in deciphering the mechanisms that drive nicotine dependence. That is, nicotine administration that occurs in the same context as the reception of other rewarding stimuli or may enhance their rewarding effects, and this enhancement may drive motivation to abuse nicotine. Recently, we demonstrated that experimenter-administered nicotine alters alcohol consumption in Wistar rats and that this effect depends in part on the response cost to obtain alcohol reinforcement. Briefly, 0.4 mg/kg nicotine decreased alcohol intake when alcohol delivery was relatively affordable but increased alcohol consumption when alcohol presentation was relatively expensive. Additionally, sex differences were observed in alcohol reinforcement under saline-control conditions, and nicotine administration modulated these differences. In the present study, we assessed the effects of nicotine across a range of doses (0.05, 0.1, 0.2, and 0.4 mg/kg) on 15% ethanol self-administration in male and female Sprague-Dawley and Wistar rats. Rats we trained to self-administer ethanol using an extended sucrose fading procedure to ensure high intake. Subsequently, the response cost (FR schedule) per 0.1 mL delivery of 15% ethanol was increased over blocks of 10 sessions, and ethanol consumption was assessed as a function of response cost. A behavioral-economic reinforcer-demand model was applied to the data and separate demand curves were constructed for each nicotine dose between sex and strain conditions. The effects of nicotine to alter ethanol reinforcement value were analyzed using the Q_0 and *essential value* parameters generated by these demand curves.

Abstract: Nicotine is a key compound having reinforcing effects on initiation and maintenance of tobacco dependence through potentiation of dopaminergic and glutamatergic neurotransmission. Non-nicotine alkaloids in tobacco also contribute to tobacco dependence by activating cholinergic system. However, glutamatergic neurotransmission in the dorsal striatum associated with psychomotor sensitization in response to cigarette smoking has not been determined. In this study, we investigated alterations in glutamate response in the dorsal striatum related to behavioral alterations after repeated administration of cigarette smoke condensate (CSC). The results demonstrated that repeated administration of three types of CSCs (3R4F, KCP-A and KCP-B) significantly increased extracellular glutamate concentrations as compared with repeated nicotine administration alone. Paralleled to the hyperactivity of the glutamate response, repeated administration of these CSCs occurred a prolonged hypersensitization of psychomotor activity including locomotor activity and stereotypy movement. These findings suggest that non-nicotine constituents in cigarette smoke synergistically upregulate the reinforcing effects of nicotine on glutamatergic response in the dorsal striatum, which seems to be a necessary neurochemical event leading to tobacco dependence.

Title: Nicotine consumption is strongly influenced by social interactions in male, but not female, adolescent mice

Authors: A. D. HUDSON, R. L. MURPHY, *K. J. FRYXELL;
Sch. of Systems Biol., George Mason Univ., Manassas, VA

Abstract: Studies of human teenagers have shown that social isolation and emotional stressors increase the likelihood of smoking initiation. Early smoking initiation and/or symptoms of emotional stress, including depression and anxiety, are correlated with increased rates of smoking. In rodent models, previous studies have shown that unpredictable chronic mild stress increased the sensitivity of adolescent male rats to the lowest nicotine doses, but reduced their preference for higher nicotine doses. In another study, chronic isolation (a form of mild stress) of adolescent mice from weaning to adulthood did not increase subsequent cocaine self-administration. However, the rewarding properties of adolescent peer interactions differed between adolescent male and female rats, and prior isolation dramatically increased social reward only in adolescent males, as shown by an assay of conditioned place preference. Here we show that social isolation (vs. pair housing) of adolescent male mice during a test of voluntary oral nicotine consumption dramatically increased the amounts of nicotine chosen by adolescent male C57BL/6J mice. Adolescent female C57BL/6J mice also increased their nicotine consumption under conditions of social isolation (vs. pair housing), but the increase was much smaller than males. Moreover, isolated adolescent males showed significantly elevated nicotine consumption immediately after their first access to nicotine, suggesting that social reward (and/or anxiety) modified drug-seeking on a short-term basis, particularly in adolescent males. These observations, particularly the effectiveness of social isolation only when it occurs simultaneously with prolonged access to nicotine, is consistent with a “reward deficit” model in which the rewarding properties of adolescent social interactions partially substitute for (and hence reduce the need for) nicotine reward. It is also consistent with previous observations on adolescent male rats, showing that nicotine injections interacted synergistically with the rewarding properties of social interactions in a conditioned place preference assay, but only if those two treatments were delivered simultaneously.

Title: Modeling habitual nicotine-seeking in rats

Authors: ***A. J. LOUGHLIN**[1,2], K. COEN[1], D. FUNK[1], A. D. LÊ[1,2,3];
[1]Campbell Family Mental Hlth. Res. Institute, Neurobio. of Alcohol Lab., Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Dept. of Pharmacol. and Toxicology, [3]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Addiction to nicotine, usually in the form of smoked tobacco, can persist in spite of repeated attempts to quit. A possible reason for this is that repeated voluntary intake of nicotine may lead to a rapid transition from goal-directed to habitual behavioral control. Although accelerated habit formation with self-administered ethanol and cocaine has been previously demonstrated, this phenomenon has not been extensively studied with nicotine. To examine the liability of nicotine self-administration to become habitual, male rats were allowed to lever-press for intravenous nicotine for 10 consecutive days, under a fixed-ratio 1 (FR-1) schedule. As a control, these same rats also lever-pressed for oral saccharin solution in separate daily sessions. In the first experiment, nicotine or saccharin were devalued by pairing with the aversive agent lithium chloride; this treatment specifically reduced responding for both nicotine and saccharin in subsequent reacquisition tests, indicating both rewards could be successfully devalued. In the second experiment, the contingency between lever pressing and delivery of nicotine or saccharin was degraded during six sessions, across which lever responding declined for non-contingently delivered saccharin, but not for non-contingently delivered nicotine. Prior to reacquisition testing (Experiment 1) but following contingency degradation (Experiment 2), animals were also tested under extinction conditions. During these extinction tests, responding on the lever previously associated with saccharin delivery was reduced by both devaluation and contingency degradation, suggesting that the lever pressing for saccharin was goal-directed. In contrast, pressing on the lever previously associated with nicotine delivery was not affected by either devaluation or contingency degradation, suggesting that responding for nicotine was habitual. These results suggest that 10 days of FR-1 training produced habitual responding for nicotine, but goal-directed responding for saccharin, and therefore demonstrate that operant responding for intravenous nicotine may become habitual more rapidly than responding for oral saccharin. This augmented development of habitual responding for nicotine may help to account for the persistence of tobacco use.

Title: Disgust (but not fear) graphic warning labels reduce EEG-indexed cognitive processing of smoking-related visual cues

Authors: *J. COCHRAN[1], M. J. LEE[1], N. WALKER[2], R. KYDD[1], N. CONSEDINE[1];
[1]Psychological Med., [2]Univ. of Auckland, Auckland, New Zealand

Abstract: Smokers exhibit cognitive biases in the processing of smoking-related stimuli that are thought to facilitate the detection of smoking cues and play a perpetuating role in addiction. Graphic warning labels (GWLs) are being added to cigarette packaging in the hope that they will reduce smoking; yet, the ability of these images to discourage continued tobacco use is still being debated. Historically, research has assessed the impact of GWLs using attentional (eye tracking) paradigms and done so in images that mix fear- and disgust-inducing elements. The current study had smokers view categorized fear and disgust images while an EEG was recorded. It was hypothesized that both the fear and the disgust GWLs would distract and disrupt attention-related cognitive processing of the smoking cue, as indexed by reduced P3 and LPP activations, but that disgust's effects would be larger.

In the current study, 61 smokers participated in an oddball paradigm consisting of 3 counterbalanced blocks of visual stimuli while an EEG was recorded. Each block (100 trials each) used the same positive smoking cue as the oddball image (20%) while the frequent image differed in each block: neutral, GWL-fear, or GWL-disgust image. The P300 (P3) and the Late Positive Potential (LPP) components of the event-related potential (ERP), which index the deployment of attentional resources to motivationally relevant stimuli such that they are enhanced by motivationally relevant stimuli and reduced when attention is directed elsewhere, were assessed.

Analysis revealed that, as expected, the P3 (250-600ms) and the LPP (500-1000ms) varied between stimuli blocks at Cz. Somewhat consistent with expectation, post-hoc comparisons revealed that the disgust GWLs led to reduced area activation in the P3 and LPP compared to the fear GWLs and neutral blocks; there were no differences in P3 or LPP between the neutral and fear GWL blocks. These results extend prior work by separating fear and disgust elements in GWLs and in providing preliminary support for the suggestion that GWLs on cigarette packaging may reduce attention to smoking related cues. Disgust (but not fear) GWLs appear to disrupt attention-related cognitive processing of smoking cues and may represent a fruitful target in cessation efforts.

Title: Paternal nicotine self-administration is associated with increased nicotine taking and anxiety-like behaviors in offspring

Authors: *J. J. MAURER, C. A. TURNER, J. D. WOLFHEIMER, C. A. PIERCE, M. E. WIMMER, H. D. SCHMIDT;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Human epidemiological studies indicate that children of parents who smoke tobacco have a higher incidence of developing nicotine dependence, cognitive deficits and anxiety. These findings suggest that nicotine may reprogram the germline epigenome to produce aberrant behavioral phenotypes in subsequent generations. The goal of this study is to establish a novel animal model of the inter-generational effects of voluntary preconceptional nicotine taking. Male Sprague Dawley rats were allowed to self-administer nicotine (0.03 mg/kg/infusion) on a fixed-ratio 1 (FR1) schedule of reinforcement for 60 consecutive days. Each nicotine-experienced rat was paired with a yoked saline control rat that received the same number and temporal pattern of infusions. Following nicotine self-administration, nicotine-experienced and yoked saline control rats were allowed to mate with drug-naïve dams. At P60, acquisition of nicotine self-administration was assessed in the drug-naive offspring (F1 generation). Both female and male nicotine-sired offspring self-administered significantly more nicotine than saline-sired offspring. These effects were specific to nicotine, as sucrose taking and cocaine self-administration were not altered in the offspring of nicotine-exposed sires. Memory formation and anxiety-like behaviors were measured in separate cohorts of F1 littermates. Our preliminary results indicate that male and female nicotine-sired offspring had increased anxiety-like behavior in the novelty-induced hypophagia (NIH) and shock-probe defensive burying (DB) paradigms compared to saline-sired controls. Taken together, these data are consistent with human epidemiological studies and indicate that voluntary paternal nicotine taking produces heritable addiction-like and anxiety-like phenotypes. To identify potential mechanisms underlying the inter-generational effect of nicotine, future studies will profile transcriptomes in brain regions known to regulate the effects of nicotine on behavior as well as epigenetic modifications within gametes. Identifying the mechanisms underlying transmission of enhanced vulnerability nicotine and

mood disorders could aid in the development of novel pharmacotherapies for individuals at risk for developing chronic smoking behavior and mental disorders.

Title: Sex differences in stress-induced reinstatement of nicotine seeking in a mouse conditioned place preference model

Authors: ***A. M. LEE**, Y. S. MINEUR, M. R. PICCIOTTO;
Yale Univ., New Haven, CT

Abstract: Clinical and epidemiological research indicate that stress contributes to smoking relapse and that women are particularly vulnerable to this effect. Further, research in human smokers has shown that targeting the noradrenergic system with guanfacine, an alpha2-adrenergic agonist, can reduce stress-precipitated smoking in a laboratory setting. Therefore, pharmacological interventions that can successfully target this stress response may be especially beneficial for women in reducing relapse to smoking. Preclinical models of behaviors related to nicotine addiction have demonstrated stress-induced reinstatement of nicotine seeking and attenuation of stress-induced reinstatement through noradrenergic manipulations. Furthermore, sex differences in catecholaminergic and cholinergic systems and in nicotine-seeking behavior have been observed in rodent models. However, sex differences in stress-induced reinstatement of nicotine seeking, specifically, or its modulation using adrenergic agents has not been studied in rodents. We developed a behavioral protocol based on the conditioned place preference (CPP) model of drug seeking to investigate this phenomenon in C3H/HeJ mice. We administered nicotine (0.5, 0.75, or 1.0 mg/kg) subcutaneously during the conditioning phase and observed a dose-dependent preference for the nicotine-paired chamber that differed in male and female mice. We also observed sex differences in the preference for the nicotine-paired chamber after a period of abstinence. Both sexes subsequently demonstrated successful extinction learning after

repeated exposure to the CPP chambers in the absence of nicotine, and reinstatement of preference for the nicotine-paired chamber following a forced swim stress. Interestingly, our preliminary data suggest that guanfacine (0.15 mg/kg, intraperitoneal) blunts this stress-induced reinstatement in a sex-dependent manner. Therefore, this behavioral paradigm may be a valuable tool in studying nicotine-seeking behavior in male and female mice, especially in response to stress. Genetic, molecular, and cellular techniques can then be applied in this paradigm to investigate the neurobiological mechanisms underlying sex differences in stress-induced reinstatement of nicotine seeking and its attenuation with adrenergic agents.

Title: Activation of locomotor activity by imposed inhalation of nicotine

Authors: *R. C. ZEPEDA[1], T. MOLINA[2], G. ROLDÁN-ROLDÁN[3], Á. DE FELIPE[1], E. MEZA[1], M. CABA[1], C. JUÁREZ-PORTILLA[1];
[1]Univ. Veracruzana, Xalapa, Mexico; [2]Dept. de Biología de la Reproducción, Univ. Autónoma Metropolitana, Ciudad de México, Mexico; [3]Univ. Nacional Autónoma de México, Ciudad de México, Mexico

Abstract: The establishment of animal models has contributed to advances in the understanding of the neural basis of nicotine addiction. These models include self-administration and experimenter-administration (imposed), through intraperitoneal and subcutaneus pathways. These techniques imply an important manipulation of the subjects causing stress, besides, distant from the typical way of nicotine intake in humans by inhalation. Administered by either method, it is expected that the nicotine acts over neural regions of the limbic system, related to drugs intake. The activation of this circuit is behaviourally expressed in an increase of locomotor activity and some somatic signals, depending on the dose. In addition, novel drug administration methods have been reported, as imposed nebulization of methamphetamine. However, this latter has not been explored using other drugs as nicotine, so required concentrations to get the behavioral effects observed under traditional methods are unknown. This is relevant since nebulization protocol simulates the human intake condition. The goal of this study was to

standardize and validate the imposed nebulization of nicotine as an effective nonivasive protocol of intake. Wistar male rats were housed under light-dark conditions 12-12 h, food and water intake ad libitum. Locomotor activity was evaluated using the open field test at eight experimental conditions: 1) 0.35mg/kg of nicotine s.c., 20 min nebulization of: 2) distilled water, 3) 0.5 mg/ml, 4) 1.0 mg/ml, 5) 1.5 mg/ml, 6) 2.0 mg/ml, 7) 2.5 mg/ml, and 8) 3.0 mg/ml of nicotine solution. Results indicate that locomotor activity increased in subjects nebulized with 2.5mg/ml nicotine solution similar to that reported using subcutaneus administration of 0.35mg/kg of this drug. We conclude that this dose is useful for the imposed nebulization protocol to study the effects of nicotine in a more effective model that simulates human condition of intake.

Title: Chronic stress enhances nicotine-seeking behavior in an animal model of addiction

Authors: *J. J. CORTRIGHT, A. MILLER, E. ANDERSON, H. KLIMEK, A. JANKE, T. HARMAN;
Psychology, Univ. of Wisconsin River Falls, River Falls, WI

Abstract: Drug addiction is a major public health and serious economic concern in the United States costing taxpayers billions of dollars annually. Experimental evidence shows that exposure to stress is not only a factor in the development of addiction; but also a trigger for drug relapse, or reinstatement. As tobacco use has been linked to a number of cancers and represents the leading cause of preventable death in the United States, elucidation of the effects of stress on nicotine-seeking behavior and relapse is critical. A critical role of chronic stress in the compulsion to seek tobacco and other nicotine delivering products has long been suspected. Although many studies have provided compelling evidence for a role of chronic stress in the enhanced sensitivity to cocaine-seeking behavior and relapse, few have assessed the contribution of chronic stress on nicotine-seeking behavior. In fact, stress induced cross-sensitization to nicotine remains controversial. Additionally, there have been no studies investigating the effects of chronic stress on nicotine-seeking relapse, or reinstatement. Thus, these experiments assess the ability of repeated exposure to variable stress to augment nicotine-seeking behavior and

relapse in an animal model of drug addiction. Male Long-Evans rats were exposed to variable stress that consisted of the exposure to different stressors once a day in random order for 20 days. During this period the control group was left undisturbed except for cage cleaning. Rats were allowed to self-administer nicotine (0.03 mg/kg/infusion) under fixed ratio schedules of reinforcement across 15 consecutive daily sessions. Responding under a progressive ratio schedule of reinforcement was assessed over the following six daily sessions. This schedule allows for break points to be analyzed, a measure that reflects the motivation to self-administer nicotine. Following up to 20 days of extinction training, rats were tested for nicotine-seeking behavior reinstatement by a non-contingent injection of nicotine (0.4 mg/kg, IP). Rats exposed to chronic stress acquired nicotine self-administration at a faster rate relative to controls, exhibited enhanced motivation to obtain the drug, and were more resistant to nicotine extinction. Further, exposure to chronic variable stress led to enhancements in nicotine-primed reinstatement, or relapse. Collectively, these findings indicate that chronic stress can enhance the motivational effects of nicotine.

Title: Persistent activity of prefrontal neurons as a source of confidence in working memory

Authors: *A. TANAKA, S. FUNAHASHI;
Kyoto Univ., Kyoto, Japan

Abstract: The prefrontal cortex has been thought of as an important structure for working memory processes. Previous neurophysiological studies have repeatedly shown that prefrontal neurons exhibit stimulus-selective persistent activity during a period after the offset of a sensory stimulus, which has been considered as a neural correlate of the short-term maintenance of information. In the present study, we examined whether and how this prefrontal persistent activity is related to subjective confidence in working memory. Two macaque monkeys were

trained on a modified oculomotor delayed response task. In this task, the subject was required to remember the location of a visual cue toward which it had to make a saccade after a several-sec delay period as a memory test. Task difficulty was controlled by varying the number of distractors that were presented during the delay and response periods. After the delay period but before the response period, the subject was sometimes allowed to choose to take or decline the memory test and sometimes forced to take the test. A correct response to the test was rewarded with a drop of juice, while no reward was given for an incorrect response. Declining the test led to a simple visually guided saccade task, but only 30 to 50% of correct saccades were rewarded. Under these conditions, monkeys' performance on the memory test was significantly higher when they chose to take the test than when they were forced to do so, which suggests that the monkeys tended to decline the test when the cued location was not remembered. While the monkeys were performing this task, a number of prefrontal neurons exhibited persistent activity that was tuned to particular spatial locations during the delay period. Importantly, the spatial selectivity of this delay-period activity was significantly weaker when the monkeys chose to decline the memory test than when they chose take the test. This reduction in spatial selectivity was not due to a decrease in responses to preferred directions but due to an increase in responses to nonpreferred directions. In other words, the monkeys tended to decline the memory test in trials in which the responses of neurons whose preferred directions differed from the cued location were failed to be inhibited. Thus, the quality of spatial information represented by prefrontal neuronal activity was related to the subject's choice to take or decline the memory test. We propose that the spatially selective persistent activity of prefrontal neurons serves as a source of confidence in visuospatial working memory and that this memory-related signal would be transmitted to a neural circuit that is responsible for computing the degree of confidence.

Title: The neural representation of large numerosities in the corvid nidopallium caudolaterale

Authors: H. M. DITZ[1], *A. NIEDER[2];
[1]Univ. of Tuebingen, Tuebingen, Germany; [2]Univ. Tuebingen, Tuebingen, Germany

Abstract: Number recognition is widespread throughout the animal kingdom, and found, for instance, in insects, fish, amphibians, and birds. So far, most studies exploring the neural code of number investigated non-human primates. It remains elusive how large numerosities beyond five items are represented in animals lacking a prefrontal cortex. In this study, we investigated how large numerosities are represented in birds with independently developed endbrain structures that enable intelligent behavior. The telencephalic nidopallium caudolaterale (NCL) is considered to be the avian homologue of the prefrontal cortex. We trained two Carrion crows (Corvus corone corone) to differentiate dot arrays with 1 to 30 dots (controlled for total dot area and dot density) in a delayed match-to-sample task while we recorded single cells in the NCL. We recorded a total of 325 neurons. About a fifth of those neurons were significantly tuned to numerosity during sample presentation and during the 1-sec memory delay. Neural preference for a certain numerosity was distributed over the whole shown numerosity range. The neuronal tuning curves exhibited a peak in activity for their preferred numerosity and a systematic drop-off in activity the further the shown numerosity was numerically distant to the preferred one (distance effect). In addition, the tuning functions grew broader with increasing preferred numerosity (magnitude effect). Analysis of the tuning functions revealed that both small and large numerosities are both best described by a logarithmic scale as predicted by the Weber-Fechner law. The existence of the distance and magnitude effects together with logarithmic number scaling indicates the presence of an underlying analogue magnitude system to encode numerosities.

Title: Laminar-specific coding of working memory in frontal cortex

Authors: *A. BASTOS, R. LOONIS, E. K. MILLER;
Picower Inst. For Learning and Memory, Cambridge, MA

Abstract: All cortical areas have some degree of laminar anatomical organization, which is characterized by different local and long-range inputs and outputs, expression levels of different molecular markers, and cell types. These distinctions have inspired many theories about the putative functions of different layers, but little physiological data exists to support these claims.

In particular, the role of the different cortical layers for cognition remains relatively unexplored. To address this, we recorded spike and LFP data from the frontal cortex (area PMd and SEF) of a macaque monkey with multiple 16 and 24 channel linearly-spaced multicontact probes as the animal performed a visual working memory (WM) task. As previously observed in visual cortex, LFP power in gamma frequencies (40-100 Hz) was strongest in superficial layers (L1-3), and alpha frequencies (8-12 Hz) predominated in deep layers (L5-6), suggesting some degree of functional compartmentalization by layers. We next examined the role of different frequency bands and layers for encoding WM information during the delay period of the task. We found that brief, punctate bursts of gamma-band activity in superficial layers reliably encoded the spatial position held in WM, but deep layers and other frequencies carried either very little or no information about WM contents. Deep and superficial layers synchronized their LFPs at sub-gamma frequencies, with spectral peaks in the alpha and beta frequency (~20-25 Hz) bands. Granger causality analysis revealed that this alpha-beta interaction was primarily unidirectional, with deep layers driving superficial. Finally, cross-frequency coupling analysis showed that the phase of delay period alpha oscillations in deep layers modulates the gamma amplitude of superficial layers. These analyses suggest a modulatory role for deep layers in WM maintenance, and an active role for superficial layers which encode WM contents in information-rich bursts of high-frequency gamma activity.

Title: fMRI assessment of anesthesia-induced learning deficiency

Authors: ***D. P. AKSENOV**, M. MILLER, L. LI, A. WYRWICZ;
NorthShore Univ. HealthSystem, Evanston, IL

Abstract: Each year approximately 6 million children in the USA alone undergo anesthesia in the course of surgeries and other diagnostic procedures. A growing body of literature has indicated that early exposure to general anesthesia can affect neuronal development, leading to deficits in learning and memory. It was found that children who underwent anesthesia were more than twice as likely to exhibit behavioral/developmental deficits in young adulthood. Animal

studies enable a more well-controlled analysis of anesthesia-related effects and allow for more precise comparisons between anesthetized subjects and controls. A variety of animal models have been used to study the effects of inhaled anesthetics and have revealed associations between early anesthesia exposure and developmental pathologies including increased cell apoptosis, defects in myelination, hippocampal and cortical cell loss and disruption of associative learning in adult subjects. The functional changes in the brain associated with such impairments have not been directly characterized. Previously, we have used blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) to examine the learning-related functional changes that occur during eyeblink classical conditioning (ECC) in awake, behaving rabbits. In ECC the subject learns to associate a neutral conditioned stimulus (CS) with a behaviorally salient unconditioned stimulus (US). fMRI allowed us to evaluate the functional state of the sensory system before learning, and together with ECC provides a non-invasive, easily quantifiable approach for characterizing the impact of anesthesia on learning. This study evaluated the effects of anesthesia exposure during infancy on learning-induced functional activity in the cortex during young adulthood. Infant rabbits were exposed to isoflurane anesthesia using a common surgical protocol and then received training with a trace ECC paradigm at three months of age. fMRI experiments were performed to measure the BOLD response to the whisker vibration CS before and after learning. Using awake rabbits allowed us to compare directly the results in anesthesia-exposed animals versus unanesthetized controls. Our findings revealed significant learning impairment for the trace ECC paradigm in rabbits exposed to anesthesia during infancy, as well as significant functional changes in the cortex.

Title: Dynamics of prefrontal, medial temporal lobe, and caudate networks in context-specific associations

Authors: *M. MOAZAMI GOUDARZI, S. L. BRINCAT, E. K. MILLER;
MIT, Cambridge, MA

Abstract: Flexible, context-specific retrieval and expression of learned information is a hallmark of intelligent behavior. Multiple brain regions—including prefrontal cortex (PFC), the medial temporal lobe (MTL), and the caudate nucleus (Cd)—have been implicated but neural information processing within and network-level interactions between these areas are not well understood. We recorded spiking and local field potentials (LFPs) from up to 104 electrodes in the PFC, MTL (hippocampus and perirhinal cortex), and the caudate tail of monkeys performing a context-specific association task. One of four object cues was shown in one of four locations. Half of the 16 resulting object/location pairs mandated a leftward saccadic response following a brief delay, while the other half mandated a rightward saccade. Thus, the correct behavioral response required the integration of object and its location context. In PFC and Cd, information about both object identity and its spatial context were encoded in both multiunit spiking rates and evoked potential amplitudes. At a slightly longer latency, both signals in these regions also reflected the saccade direction imposed by the object/location pair. In contrast, the MTL regions encoded object identity and location only in their LFPs, but not in spiking activity, while the saccade was reflected in both signals. As LFPs are thought to primarily reflect feedforward input, and spikes reflect outputs, the MTL may be integrating feedforward object and spatial information to compute the associated saccade. We also used representational similarity analysis to examine interactions between these regions. Analysis of band-limited LFP signals showed the strongest interactions in the beta band (~10-25 Hz) with peaks during the pre-cue and delay periods and a trough during the cue period itself. These beta-band interactions were broadly similar between all pairs of brain regions. In contrast, analysis of the raw LFP signals revealed a cue-period peak at approximately the same time as the beta-band trough. CA3-PFC and Cd-PFC interactions exhibited only this phasic peak, while CA1-PFC interactions were sustained though the entire delay period. These results indicate widespread network interactions with more focused sustained interactions between CA1 and PFC.

Title: Multiple tasks reveal the neural basis of implicit and explicit learning

Authors: *R. LOONIS[1,2], E. G. ANTZOULATOS[3], S. L. BRINCAT[1], E. K. MILLER[1];
[1]The Picower Inst. for Learning and Memory and Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Dept. of Anat. and Neurobio., Boston Univ., Boston, MA; [3]Ctr. for Neuroscience, Dept. of Neurobiology, Physiology, and Behavior, Univ. of California, Davis, CA

Abstract: Learning can be explicit (hippocampal-dependent, and conscious) or implicit (non-hippocampal dependent, and unconscious). We found neural evidence for both in a meta-analysis of six different monkeys performing three different learning tasks: (1) an object paired-associate matching task, (2) a category-saccade association task, and (3) a category matching task. All involved trial and error learning. Correct responses produced reward (positive feedback) and incorrect responses produced a visual signal and a time-out (negative feedback). Category-saccade learning is likely to be more implicit as it involved learning a motor response. The learning of category-saccade associations was primarily driven by reward, and monkeys reverted to chance performance following an incorrect response. This behavioral pattern suggests implicit learning, because amnesiacs who by definition employ implicit strategies learn better when positive feedback is emphasized. On the other hand, the paired-associate and category matching tasks are likely to be more explicit as they involved matching judgments. Learning the correct matches involved both positive and negative feedback, and behavior improved after both. The implicit (saccade) task and the explicit (matching) tasks had different patterns of within- and cross-area synchronizations during the feedback period. During category-saccade learning, there was theta band (2-7 Hz) synchrony on correct trials within and between prefrontal cortex and striatum. This weakened with learning and then, late in learning, appeared on incorrect trials. By contrast, during the matching tasks, there was beta band (10-25 Hz) synchrony on correct trials and that, in the category-matching task, also weakened with learning. Thus, theta and beta synchrony may help drive the plastic changes underlying implicit vs explicit learning, respectively.

Title: Training in a working memory task affects neuronal activity differentially along the anterior-posterior axis of the primate prefrontal cortex

Authors: *M. RILEY, X. QI, C. CONSTANTINIDIS;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The prefrontal cortex (PFC) is a brain area critically involved in working memory (WM) and executive function. A functional gradient of specialization along the anterior-posterior axis of the PFC has been speculated, with posterior areas representing more faithfully the properties of stimuli, and anterior areas activated by more abstract operations, but little neurophysiological evidence exists to support it. To address this idea, we trained monkeys in a spatial WM task requiring subjects to determine if a stimulus was either in the same spatial location as a previously presented stimulus or not. We then examined the effects of training on 3 prefrontal regions: a posterior dorsal region, including area 8A, a mid-dorsal region including area 8B and area 9/46, and an anterior dorsal region, including area 9 and area 46 of Petrides and Pandya. A total of 669 neurons were recorded in 4 monkeys after training and were compared to 1046 neurons recorded while the same monkeys were exposed to these stimuli passively before training in any WM task. After training, a greater proportion of anterior-PFC neurons were activated by the stimuli during the delay period than before training (before 7%/after 36%, a 4.1 fold increase). This increase was less pronounced for posterior regions (posterior-PFC: before 18%/after 40%; mid-PFC: before 24%/after 36%). Among responsive neurons, a greater increase in firing rate to the stimulus was also seen in the anterior prefrontal cortex after training (before: 4.4/after: 9.3 spikes/s) compared to posterior (before: 7.6/after: 6.8 spikes/s) and mid-PFC (before: 4.6/after: 5.3 spikes/s). Similarly, mean stimulus selectivity among neurons active during the trial, quantified with a selectivity index as (Max-Min)/(Max+Min), was low in the anterior areas before training and increased appreciably following training, whereas it changed little or declined after training for the mid- and posterior-PFC regions (posterior-PFC, before: 0.78/after: 0.51; mid-PFC, before: 0.58/after: 0.55; anterior-PFC, before: 0.44/after: 0.64; 2-way ANOVA, $p<0.0001$, for interaction). The percentage of explained variance for the spatial location of stimuli exhibited a similar pattern (posterior-PFC, before: 25.5%/after: 11.0%; mid-PFC, before: 13.4%/after: 13.1%; anterior-PFC, before: 4.7%/after 17.0%; 2-way ANOVA, $p<0.0001$, for interaction). Our results provide neurophysiological evidence that anterior PFC neurons are more plastic with respect to a task being executed, and their functional properties change to a greater extent than posterior/middle PFC neurons, providing evidence of specialization along the anterior-posterior axis of the PFC.

Title: Delay period activity in dorsolateral prefrontal cortex related to working memory capacity

Authors: *H. TANG, X. QI, M. R. RILEY, C. CONSTANTINIDIS;
Dept Of Neurobio. & Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The capacity of information that can be stored in human working memory is severely limited, typically to approximately 4 items. Studies in non-human primates have also obtained estimates of limited capacity. Little is known about how neural activity relates to working memory capacity and the nature of this severe limitation. To investigate this question, we trained one monkey to perform a spatial working memory task, requiring memory for the locations of multiple stimuli. The monkey viewed a sample display with 1 to 5 white squares presented for 0.5 s. The stimuli could appear at one of 24 locations arranged on a circle, at an eccentricity of 10 degrees of visual angle. After a delay period of 1 s, a second display appeared with the same number of stimuli and with all the items appearing at the same locations as in the sample or with one of the squares appearing at a different location. Two choice targets appeared subsequently, one of them green and the second blue. The monkey was required to saccade to the green target if the two stimulus displays were identical, and to the blue target if they were not. The monkey's behavioral performance was determined as a function of the number of stimuli. As expected, overall performance declined as the number of stimuli increased. The subject's estimated capacity in the task reached an asymptote at approximately K=3.5 items. After the monkey was trained in the task, we recorded from a total of 104 neurons in the dorsolateral prefrontal cortex. We focused particularly on neurons with significant selectivity for different stimulus locations (ANOVA, $p<0.05$). If prefrontal delay period activity represents the stimuli stored in memory, we reasoned, then as additional items are stored overall activity would be expected to increase across the population. When the capacity limit is exceeded, delay period activity representing some of the stimuli decays, and the items cannot be recalled at the end of the delay period. Addition of more stimuli should no longer produce increases in mean activity across the population. Indeed, we observed that delay period activity increased as a function of number of stimuli, for up to 3 items. For displays with 4 or more stimuli, which exceeded the subject's behavioral capacity, persistent activity decreased, a statistically significant difference across conditions (ANOVA, $p<0.01$). These results suggest that prefrontal delay period activity is

predictive of the subject's capacity limit. Our findings provide mechanistic insights on the working memory capacity limitation.

Abstract: The ability to group and organize patterns of sensory input into categories is a hallmark of cognition. Sometimes category members can look physically similar. Other times, however, categories are highly abstract and the individual exemplars can look quite different (e.g. "tools").
We compared category selectivity in the prefrontal cortex (PFC) of rhesus macaque monkeys at different levels of category abstractness using a dot-pattern categorization task (Posner & Keele, 1968). Abstractness of category exemplars was varied by the degree of spatial distortion of the dot pattern from the category prototype. Thus, low distortion exemplars look similar to members of the same category and different from the other category. Under high distortion, exemplars from the same category can look very different and thus require greater abstraction of the "essence" of the category prototype. Monkeys performed a delayed-match-to-category task that required judgments of whether two exemplars (sample – test) were from the same category. For each recording session, monkeys learned to distinguish between two novel categories. We recorded local field potentials (LFPs) from multi-electrode arrays in ventrolateral and dorsolateral PFC (VLPFC, DLPFC).
Behavioral results yielded the expected effects of better categorization with lower levels of distortion. Category selectivity was seen in the stimulus-evoked LFP signal in DLPFC and in beta frequency-band power in VLPFC. During sample exemplar presentation, category information in the evoked LFP was equally strong for high and low-level distortions in DLPFC. However, during the memory delay and subsequent category match judgment of the test stimulus, it showed less information about the sample category for more distorted exemplars.

Similarly, VLPFC beta power (25-30 Hz) during the delay period only showed category information for low-distortion exemplars. Multivariate pattern category decoding in DLPFC was above chance when trained on one distortion level and tested on the other. Thus, the PFC seemed to abstract the same essential category information across the different distortion levels. In sum, PFC activity could signal category membership at high levels of abstraction (distortion) but this selectivity was weaker, mirroring the monkey's greater difficulty for more abstract categorization.

Title: Investigating the role of CHD7 in glutamatergic synaptic development

Authors: ***A. P. ARANDA**, F. L. W. LIEBL, T. DELANEY;
Biol. Sci., Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: The nervous system depends on the proper development and function of synapses. Glutamatergic synapses are essential for multiple processes including learning and memory. We have found that the chromodomain helicase DNA (CHD) binding protein, Kismet (Kis), regulates glutamate receptor localization and synaptic transmission at the *Drosophila* neuromuscular junction. One of the mammalian orthologs of *kis*, *CHD7*, is important for early neurodevelopmental events including migration of neural crest cells. Mutations in *CHD7* lead to CHARGE Syndrome, which is characterized by delayed neurodevelopment and sensory abnormalities. The synaptic role of CHD7, however, is largely unexplored. We are using the *Gal4-UAS* expression system to express a *Drosophila*-optimized *CHD7* in controls and *kis* mutant flies to assess the functional redundancy between Kis and CHD7.

Title: Synchronous beta rhythms of frontoparietal networks support only behaviorally relevant representations

Authors: *E. G. ANTZOULATOS[1,2], E. K. MILLER[2];

Abstract: Executive functions of the primate brain have been associated with distributed networks spanning several brain areas, including the prefrontal cortex (PFC) and the posterior parietal cortex (PPC). Both the PFC and PPC have been previously shown to play roles in rule-based categorization. Although category-selective spiking activity in these areas has been established, the frequency-dependent dynamic interactions of frontoparietal networks are largely unexplored. We trained monkeys to perform a delayed-match-to-spatial-category task while recording spikes and local field potentials (LFPs) from the PFC and PPC with multiple electrodes. We found category selective beta- and delta-band synchrony between and within the areas; different pairs of sites showed greater synchrony for one or the other category. However, in addition to the categories, delta synchrony and spiking activity also reflected irrelevant stimulus dimensions. By contrast, beta synchrony only conveyed information about the task-relevant categories. Further, the spikes of category-selective PFC neurons were synchronized with PPC beta oscillations. PFC neurons that carried irrelevant information were not. These results suggest that long-range beta-band synchrony could act as a filter that only supports neural representations of the variables relevant to the task at hand.

Title: Influence of prefrontal and posterior parietal delay period activity on the accuracy of spatial working memory

Authors: *X. QI[1], X. ZHOU[2], S. LI[1], C. CONSTANTINIDIS, 27103[1];
[1]Wake Forest Univ. Sch. of Med., Winston Salem, NC; [2]Stanford Univ., Stanford, CA

Abstract: The dorsolateral prefrontal (dlPFC) and posterior parietal cortex (PPC) are involved in cognitive operations such as working memory and executive function. Only subtle differences in firing rate have been observed between neurons recorded in the two areas, across various cognitive tasks. Here we addressed differences between the two areas on how their activity influences working memory performance on a single trial basis. We trained two monkeys in the Oculomotor Delayed Response task which requires the monkey to saccade to the remembered location of a stimulus, after a delay period. The accuracy of working memory recall was evaluated based on the distance of the saccadic end point from the true location of the stimulus. Neurophysiological recordings were performed in areas 8a and 46 of the dlPFC and 7a and LIP of the PPC. We selected neurons with significantly elevated activity and significantly different responses to different stimulus locations (ANOVA, $p<0.05$) during the delay period. We collected 170 such neurons from PFC and 63 from PPC. We first compared the tuning strength of neurons in each area. Neurons in dlPFC showed a significantly higher tuning strength, indicating stronger selectivity for the location of the stimuli during the delay period, compared to the PPC (t-test, $p<0.05$). We then examined the correlation between delay period activity and the accuracy of the saccadic end point across trials. Prefrontal neurons showed significant correlations between firing rate and saccadic deviation for stimulus locations appearing at the flank of their tuning curve, but not for locations at the tail of the tuning curve. Parietal neurons also showed a correlation during the delay period for flank locations but also for tail locations, particularly later in the delay period. This correlation rose with increasing tuning strength for dlPFC and PPC. Tuning curves constructed based on the firing rate recorded in trials with saccadic endpoints deviating clockwise or counterclockwise from the true stimulus location exhibited a slight difference, or tuning bias, for neurons in both areas. The tuning bias was higher overall for dlPFC neurons than PPC neurons. The results indicate that the activity of neurons

both in prefrontal and in posterior parietal cortex influences the accuracy of spatial working memory recall, but that systematic differences exist between areas.

Title: Working memory load may modulate neuronal coupling

Authors: ***D. PINOTSIS**[1], T. J. BUSCHMAN[2], E. K. MILLER[1];
[1]MIT, Cambridge, MA; [2]Princeton Neurosci. Inst. and Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: There is a severe limitation in the number of objects that can be held in working memory. However, the neurophysiological origins of cognitive capacity remain unknown. In this work, we focus on the biophysical correlates of the bandwidth limit of conscious thought and ask whether this might be explained by differences in load-specific neuronal coupling. We develop a theoretical model based on Predictive Coding and use it to analyze local field potentials (LFPs) recorded with multiple electrodes in prefrontal cortex (PFC), frontal eye fields (FEF) and lateral intraparietal area (LIP), while monkeys performed a multiple object working memory task (Buschman et al., 2011). In previous work (Kornblith et al.,2015), we calculated the power of oscillatory responses recorded from this task and found that it depends crucially upon the number of maintained objects. Interestingly, power increases with memory load beyond behavioral capacity; however, it is unclear how increasing load affects neuronal coupling and whether the capacity limit can be explained by changes in the extrinsic and intrinsic connectivity in the PFC-FEF-LIP network. Our model attempts to address these questions based on Predictive Coding and the data from Buschman et al. (2011). This is a theory of brain function which suggests that brain regions are hierarchically organized and interact in both feedforward and feedback directions. It also presumes that the activity of deep and superficial pyramidal cell populations reflects the processing and maintenance of visual stimuli. Motivated by these considerations, our model predicts that top down signals maintaining sensory predictions would result in increased

feedback connectivity from PFC to FEF and LIP and an increase in the gain of deep pyramidal cell populations with varying memory load. Here we test these predictions and investigate whether the memory encoding of visual objects can be explained by load-specific differences in extrinsic and intrinsic cortical connectivity. In brief, our study provides new insights into the neuronal underpinnings of behavioral capacity and how effective connectivity in a distributed working memory network is affected by a different number of remembered stimuli.

Title: Effects of D-serine on visual working memory in macaque monkey

Authors: *M. KUSI, J. MANJUNATH, C. CRANDELL, V. BARRETTE, M. PARÉ;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Working memory is a limited-capacity cognitive process that retains information for short periods of time to guide thoughts and behavior. A neural correlate of working memory has been postulated in the persistent activity of neurons in the cerebral cortex during the memory retention intervals of various behavioural tasks. Modeling and behavioral work suggests that this persistent activity depend on NMDA receptor (NMDAR) activation. Indeed, we have previously shown that the NMDAR antagonist ketamine induces deficits in visual working memory (VWM) that are dependent on both dose and memory load in monkeys. NMDAR hypofunction is now a dominant hypothesis to explain cognitive symptoms in schizophrenia, and the NMDAR co-agonist site has become a target for therapy tested in clinical trials. Here, we tested the effects of orally administered doses of the NMDAR co-agonist D-serine (acute 1-1000 mg/kg; sub-chronic 100mg/kg/day-6 weeks) on the VWM ability of three adult female rhesus macaques. We also tested the effects of D-serine (acute 100 mg/kg) on rescuing impaired VWM ability following ketamine (acute 0.5 mg/kg). Animals performed a sequential comparison task which required them to identify the location of a color change within an array of 2-5 colored stimuli following a retention interval (Heyselaar et al., 2011). We predicted that D-serine would improve performance on the VWM task and that the effects of D-serine would scale with memory load as well as being dose-dependent for acute treatment and time-dependent for sub-chronic treatment. Contrary to our predictions, we found that none of the tested doses of D-serine had an effect on the accuracy or latency of task responses at any memory load. We also found that D-serine did

not significantly improve task accuracy when ketamine was administered prior to D-serine administration. These findings suggest that targeting the NMDAR co-agonist site has a limited role in benefiting VWM.

Title: Activity of medial prefrontal and striatal neurons in primates while remembering faces and vocalizations.

Authors: *B. PLAKKE, L. M. ROMANSKI;
Dept. of Neurobio. & Anat., Univ. of Rochester Sch. of Med. and Dent., Rochester, NY

Abstract: Our previous work has shown that ventrolateral prefrontal cortex (VLPFC) integrates face and vocal information and is necessary for audiovisual working memory. However, visual working memory relies on many cortical and subcortical regions including the medial prefrontal cortex (mPFC) and dorsal striatum. Moreover, mPFC is involved in conflict detection, audio-vocal control and receives strong inputs from higher order auditory processing regions within the temporal lobe. There are few studies which have examined the roles of these regions in audiovisual processing and memory. Here, we recorded from mPFC and striatal neurons while macaques performed an audiovisual nonmatch-to-sample task. Subjects attended an audiovisual movie clip of a face-vocalization as the Sample and detected the occurrence of a Nonmatch (when the face or vocalization differed from the Sample movie). Neurons within the mPFC and striatum were task related and were active for key periods of the task including the sample, the delay, the match, and the nonmatch epochs. In contrast to previous findings from VLPFC, both mPFC and striatal neurons were more active during decision-related epochs of the task, such as detecting the Nonmatch or suppressing a response during a Match presentation than during the Sample or Delay. These decision related units were more commonly found in mPFC than in the

striatum. This data suggests mPFC and the striatum are part of a neuronal circuit underlying audiovisual working memory in the primate brain.

Title: Low-beta oscillations turn up the gain during category judgments

Authors: *D. A. STANLEY[1], J. E. ROY[2,3], N. J. KOPELL[1], E. K. MILLER[2,3];
[1]DEPARTMENT OF MATHEMATICS AND STATISTICS CAS/BU, Boston Univ., Boston, MA; [2]The Picower Inst. for Learning and Memory, [3]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Synchrony between local field potential (LFP) rhythms is thought to boost the signal of attended sensory inputs. Surely, other cognitive functions could benefit from such gain control. One is categorization where decisions can be difficult if categories differ in subtle ways. Monkeys were trained to flexibly categorize smoothly varying morphed stimuli, using orthogonal boundaries to carve up the same stimulus space. First, we found evidence for category-specific patterns of low-beta (16-20 Hz) synchrony in the prefrontal cortex. This synchrony was stronger when a given category scheme was relevant. Second, during sample presentation, we observed an overall increase in low-beta LFP synchrony for stimuli that were near the currently relevant category boundary and thus more difficult to categorize. We could identify single unit correlates of category sensitivity but not of the boundary effect. We also found that the category response showed up in partial FFC measurements, but the boundary response was almost completely abolished. Based on this, we propose that the category and boundary responses represent two distinct low-beta oscillations that work together; one local and the other system-wide. Increases in low-beta synchrony may then reflect recruitment of additional cortical resources for categorizing challenging stimuli, perhaps serving as a form of gain control.

Title: The use of zebrafish to identify genes affecting working memory and age-related cognitive decline.

Authors: *A. J. BROCK, A. SUDWARTS, C. H. BRENNAN;
SBCS, Queen Mary, Univ. of London, London, United Kingdom

Abstract: Aim
To identify genes influencing cognitive performance (memory and learning, impulse control) using zebrafish as a model system.
Method
GBT Screen: We screened lines of mutant zebrafish at 3 months for performance in behavioral tasks that assess aspects of cognition. So far we have screened over 50 gene-break transposon (GBT) lines (n=4 for each line) as well as wild-type (n=20) in a 5-choice serial reaction time task (5-CSRTT) starting at the 3-month stage. The 5-CSRTT system is fully automated as designed by Parker et al. (2012).
Development of MTS system: In collaboration with Bill Budenburg (Zantiks Ltd, Cambridge, UK) we have developed an automated, scalable system for measuring a number of behaviors including matching-to-sample (MTS), a measure of memory. The system is designed along the lines of a 'Skinner Box' for zebrafish can currently be used to measure 2-5 choice discrimination as well as MTS. Stimuli are presented using a computer screen positioned beneath the holding tank.
Results
GBT Screen: We have identified several lines of interest that show significantly altered performance from controls. When measuring the mean number of correct responses in the task, 2 lines ($p=0.03$ & $p=0.001$) clustered to the right of the distribution. There were 2 lines ($p=0.02$ & $p=0.05$) showing faster response when assaying latency to approach the stimuli. When using trials to steady state as a measure of learning rate 2 line ($p=0.03$ & $p=0.05$) show faster learning rates and one line ($p=0.01$) slower. Work is ongoing to rescreen the siblings from these families and characterize the mutations involved.
Automated Operant system: Using this system, we have trained adult 4 month (at start)

zebrafish to perform 3-choice discriminations to over 80% accuracy within 3 weeks, 5-choice discriminations to 70% accuracy within 5 weeks and 3-choice matching-to-sample to over 60% accuracy within 8 weeks.

Discussion Recently a number of high profile publications have suggested that zebrafish can also be used to explore the genetics and aetiology of behavior including complex behavioral phenotypes associated with psychiatric disease. However, progress has been limited. This is partly due to the lack of an automated system that can be used for analysis of cognitive behaviors in large-scale genetic or pharmaceutical screens.

We demonstrate that in our old 5-CSRTT system using a population screen approach, differing lines can be shown to cluster on either side of a distribution curve, demonstrating the ability to pick out genes affecting aspects of cognition. By developing the new operant system which is capable of measuring MTS we will be able to screen current GBT lines for their performance in this task.

Title: Spaced context exposure enhances context fear memory and hippocampal context coding

Authors: *A. F. LACAGNINA[1], C. A. DENNY[2], M. R. DREW[1];
[1]Dept. of Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Dept. of Psychiatry, Columbia Univ., New York City, NY

Abstract: Spaced training is superior to massed training in many learning paradigms. Although the spacing effect has been studied in *in vitro* hippocampal preparations, its mechanisms *in vivo* are not well understood. We examined the effects of spaced versus massed context exposure in one-trial contextual fear conditioning (CFC), a hippocampus-dependent learning paradigm that depends on two learning processes: 1) forming a mental representation of the context and 2) associating that representation with an aversive stimulus. Theories of CFC posit that such mental representations can be acquired during passive exploration of an environment and are essential

for conditioning but do not make strong predictions about how varying the interval between context preexposure and conditioning will affect learning. Because the two learning processes can be separated in time, we predicted that introducing a delay between context preexposure and conditioning would strengthen CFC. We found that context preexposure 72 h or 24 h before single-shock CFC produced stronger conditioned fear than did preexposure 1 min before or no preexposure. A series of behavioral experiments revealed the effect of spaced context exposure was not explained by (1) a change in the susceptibility to extinction, (2) artifacts related to experiencing a novel context prior to conditioning, or (3) modulation of memory retrieval by primacy or recency. The results instead suggest that spaced context exposure strengthened context fear memory. To understand the neural activity patterns corresponding to the stronger conditioned fear following spaced preexposure, we used ArcCreER^{T2} x ChR2-eYFP mice to indelibly tag neurons activated during CFC. Mice were preexposed to the conditioning context 72 h or 1 min prior to one-trial CFC. Mice received an injection of 4-OHT prior to CFC acquisition, thereby labeling neurons active during CFC acquisition with eYFP. Five days later, mice were re-exposed to the shock-paired context and euthanized 90 min later. We compared neurons active during acquisition (eYFP+) to those activated by memory retrieval (cFos+). Mice that received preexposure 72 h prior to conditioning displayed an increased percentage of reactivated (cFos+/eYFP+) cells in CA3 compared to mice receiving preexposure 1 min prior. Moreover, the percentage of reactivated cells correlated with fear expression. In summary, spaced context exposure enhances CFC acquisition and increases the reactivation of CA3 neural ensembles associated with acquisition. These data demonstrate that trial spacing can modulate CFC and identify a neural correlate of the spacing effect in hippocampal CA3 related to memory strength.

Title: Switching from normal to PTSD-related fear memory is associated with epigenetic modifications in the hippocampus-amygdalar circuit

Authors: ***C. BOUARAB**[1,2], M. MENNESSON[3], C. GUETTE[1], D. N. ABROUS[1], A. MARIGHETTO[1], M. KOEHL[1,2], N. MONS[2,4], A. DESMEDT[1,2];

[1]Neurocentre Magendie, Bordeaux, France; [2]Univ. de Bordeaux, Bordeaux, France; [3]Univ. of Helsinki, Helsinki, Finland; [4]Inst. des Neurosciences Cognitives et Intégratives d'Aquitaine, Bordeaux, France

Abstract: Posttraumatic stress disorder (PTSD) is characterized both by hypermnesia for simple salient trauma-related stimuli and amnesia for peri-traumatic contextual cues. In human, this disorder is associated with hippocampal hypofunction but amygdalar hyperfunction, which may contribute to such paradoxical memory impairment. We recently showed that PTSD-related memory could be mimicked in mice in which the erroneous selection of a salient tone stimulus instead of the context as predictor of the threat is observed in association with an altered pattern of neural activation within the hippocampal-amygdalar network. On this basis, the molecular changes underlying this system dysfunction can now be investigated.
Here we show that, compared to normal fear memory, PTSD-like memory is associated with a switch from H3K9 hyperacetylation to H3K9 hypermethylation in hippocampal CA1 as well as a significant reduction of H3K27 trimethylation (non-permissive) resulting to an increase of transcription in the amygdala. In addition, we show that prenatally stressed mice exposed to a stressful event in adulthood develop a PTSD-like memory and display a similar histone H3 dysregulation pattern. Altogether, these results indicate that an altered histone H3 acetylation/methylation balance within the hippocampal-amygdalar network may contribute to the switch from normal to pathological memory.

Title: Social defeat-induced changes in network oscillations in the rat hippocampus

Authors: ***R. NAKAYAMA**, S. OKADA, T. SASAKI, Y. IKEGAYA;
Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Chronic social defeat is a widely used animal model with high etiological and discriminative validity that evokes profound behavioral phenotypes, including increased anxiety and depression-like syndromes. Many studies have revealed the effects of social defeat stress on molecular and cellular functions of various organs. In this study, we examined how social defeat stress alters physiological activity in freely moving rats. To this end, we developed a new recording technique that can simultaneously monitor ongoing bioelectrical signals from the brain and peripheral organs. The recording system integrates local field potential signals from the cortex, heartbeat signals (electrocardiograms), and skeletal muscle signals (electromyograms) into an electrical interface board that is mounted on an animal's head. We applied this method to intruder rats that were subject to a social defeat paradigm using an aggressive resident rat and analyzed their cortical activity patterns by comparing a variety of physiological body states. After receiving a physical attack from the resident rat, the heart rate of the intruder animals was transiently increased and then decreased when they started to show freezing behavior, a sign of subordination. During the freezing period, hippocampal ripple events, which represent synchronous firing of hippocampal pyramidal cells, were prominently abolished. This result is in contrast to the general notion that hippocampal ripples preferentially occur during rest/immobility periods and suggests that the social defeat-induced freezing behavior does not include ripple-dependent memory processing such as consolidation and retrieval. During periods without freezing, the frequency of hippocampal ripples was negatively correlated with the heart rate. We will further analyze whether other types of cortical oscillatory activity is related to body states. The evidence will advance the understanding of the neurophysiological correlate of mind-body associations during mental stress exposure.

Title: Hippocampal-retrosplenial connectivity is necessary for memory retrieval after contextual fear conditioning

Authors: *K. A. CORCORAN, B. J. FRICK, A. L. GUEDEA, J. RADULOVIC;
Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Memory retrieval requires activity in a number of brain regions. We have previously demonstrated essential roles for both dorsal hippocampus (DH) and retrosplenial cortex (RSC) in contextual fear conditioning, though little is known about how these two structures interact to mediate the retrieval of conditioning memories. Here, we used an adeno-associated viral vector to deliver inhibitory DREADDs to specific excitatory projections from DH to RSC in mice. After contextual fear conditioning, mice were tested for memory retrieval after intra-RSC infusions of aCSF and clozapine-n-oxide (CNO), the synthetic ligand that activates the DREADDs in order to inhibit neural activity. By delivering the DREADDs to DH and CNO to RSC, we were able to specifically inhibit activity in hippocampal axon terminals in RSC and disrupt hippocampus-retrosplenial communication. CNO reduced freezing to the conditioning context without causing hyperactivity, suggesting that excitatory DH-RSC projections mediate retrieval of contextual fear conditioning memory. In a second experiment, DREADDs were again delivered to DH, and insulated silver wires were implanted in DH and RSC. We recorded local field potentials (LFPs) and measured intra-regional power and inter-regional coherence of oscillatory activity in the delta (1-4Hz), theta (4-12Hz) and gamma (30-80Hz) frequency bands from both regions during novel context processing and memory retrieval. By combining targeted inhibition of specific excitatory inputs and in vivo electrophysiology, we can begin to understand the nature of the inter-regional structural and functional connectivity that underlie memory retrieval.

Abstract: Patients suffering from stress-related disorders, in particular post-traumatic stress disorder (PTSD), commonly have dissociative symptoms related to their inability to properly recall the traumatic event. These trauma-related memories are not forgotten, but only

inaccessible under normal conditions. Instead, these memories are state-dependent, such that they can be retrieved when patients are in a similar psychological or physiological state as when the trauma occurred. Dissociative amnesia is highly correlated with deficits of social functioning, including abnormal social cognition and inability to maintain interpersonal relationships. Dissociative amnesia occurs at similar rates in males and females, however, it is well established that males and females cope with traumatic events differently, with a female bias towards affective PTSD symptoms. We therefore investigated phenotypic sexual dimorphism and circuit mechanisms of social and affective behaviors in a mouse model of state-dependent memory, including sociability, social recognition, and light-dark emergence. We demonstrated that state-dependent contextual fear conditioning mediated by pharmacological excitation of extrasynaptic gamma-aminobutyric acid receptors type A ($GABA_AR$) impairs sociability, successfully recapitulating the pairing of dissociative symptoms with social deficits observed in humans. Identifying the effects of state-dependent memory on social and affective behaviors is important for understanding the role of inaccessible stress-related information on behaviors executed in alternative brain states. Title: PACAP alters fear-related behavior and increases activity-regulated cytoskeleton-associated protein (Arc) expression in the central nucleus of the amygdala after fear conditioning in rats

Authors: *E. G. MELONI, K. T. KAYE, W. A. CARLEZON, Jr;
Psychiatry, McLean Hosp., Belmont, MA

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) is a highly conserved neuropeptide, with shared amino acid sequence homology among rats, mice, and humans. Alterations in the PACAP system are associated with stress and may play a role in psychiatric

conditions such as post-traumatic stress disorder (PTSD). We have previously shown that PACAP modulates learning and memory and induces both amnestic (early) and hypermnestic (late) behavioral phenotypes in animals treated with PACAP prior to fear conditioning (Meloni et al., 2015). In those studies, immunohistochemistry for the immediate early gene c-Fos revealed PACAP-dependent effects in the central nucleus of the amygdala (CeA), but not basolateral amygdala (BLA) or dorsal hippocampus (DH), brain areas implicated in consolidation of fear learning. Here, we examined PACAP's effects on synaptic plasticity in these brain areas by measuring changes in activity-regulated cytoskeleton-associated protein (Arc) expression, a biomarker of synaptic activity that could uncover plasticity-dependent effects not revealed by c-Fos in earlier studies. Male Sprague-Dawley rats were implanted with intracerebroventricular (ICV) cannula for infusion of either vehicle (VEH) or PACAP-38 (1.5 ug) followed 30 min later by fear conditioning; rats received two pairings of a 30 s, 75 dB tone co-terminating with a 0.6 mA footshock. Rats were perfused 1 hour after conditioning, and brain sections were processed for Arc immunoreactivity. There was a highly significant increase in Arc-labeled neurons in the CeA but not the bed nucleus of the stria terminalis (BNST) or DH (dentate gyrus) in PACAP-treated animals. In the CeA, double labeling immunohistochemistry indicated no co-localization between Arc and corticotropin releasing factor (CRF)-containing neurons in PACAP-treated animals. Arc staining in the BLA or dendritic fields of the CA1-CA3 of the DH were not significantly different between VEH and PACAP-treated rats. These results indicate that the CeA is a primary brain area involved in PACAP's modulation of neuronal plasticity induced during fear conditioning. Because the CeA receives heavy PACAPergic innervation from the brainstem, stress-induced elevations in this neuropeptide - as is seen in some patients with PTSD (Ressler et al., 2011) - may facilitate consolidation of emotional memories through Arc-dependent pathways. Hence, understanding the neurobiology of PACAP systems may help reveal how stressful experiences such as exposure to trauma promote psychiatric illness, and facilitate the development of more effective strategies to treat or prevent stress-related disorders.

Title: p38 mitogen-activated protein kinase activation in amygdala mediates κ opioid receptor agonist U50,488H-induced conditioned place aversion.

Authors: *J.-G. LIU, G. ZAN;
Shanghai Inst. Materia Medica, Shanghai, China

Abstract: κ Opioid receptor agonists produce aversive effects in rodents, however the underlying mechanisms remain unclear. Activation of p38 mitogen-activated protein kinase (MAPK) has been discovered to play a critical role in the modulation of affective behaviors. The present study was undertaken to detect the possible involvement of p38 MAPK in the aversive effects induced by κ opioid receptor activation. We found that the κ opioid receptor agonist trans-(±)-3,4-Dichloro-N-methyl-N-[2-(1-pyrrolidinyl)-cyclohexyl] benzenacetamide methanesulfonate salt (U50,488H) produced significant place aversion in mice as measured by the conditioned place preference procedure, accompanied with significant p38 MAPK activation in the amygdala, but not in the nucleus accumbens and hippocampus. Stereotaxic microinjection of the p38 MAPK inhibitor 4-(4-fluorophenyl)-2-(4-methylsulfonylphenyl)-5-(4-pyridy-l)-1H-imidazole (SB203580) into amygdala significantly inhibited p38 MAPK activation and completely blocked the conditioned place aversion in mice. Thus, these results suggested that activation of p38 MAPK in the amygdala was required to mediate κ opioid receptor-induced aversive behavior.

Title: Inducible protein synthesis inhibition in the amygdala.

Authors: *P. M. HERRERO-VIDAL[1], P. SHRESTHA[1], P. AYATA[2], A. GASTONE[1], N. HEINTZ[2], E. KLANN[1];

Abstract: Extensive studies support the role of the amygdala as a major hub for integration, processing and consolidation of auditory fear conditioned responses. Hence, this brain region has been widely used for studying learning and memory processes at a molecular and cellular level. Although excitatory neurons of the lateral amygdala are thought to be the cellular substrate for fear memory formation, new evidence supports the importance of different types of interneurons in this process for which *de novo* protein synthesis appears to be necessary. Prior research using pharmacological protein synthesis inhibitors, such as cyclohexamide or anisomycin, have indicated that translation is required for long term fear memory formation. However, there is still considerable controversy regarding the relevance of these findings given the possibility that the observed results may be due to drug secondary effects. Here, we introduce a novel method to block general translation in an inducible and reversible manner as an alternative approach to study the role of newly synthesized proteins in this process. Initiation is a tightly regulated step in translation and depends on eukaryotic initiation factor 2α (eIF2α). In response to cellular stress, eIF2α is phosphorylated at the amino acid residue Serine 51 and results in inhibition of general protein synthesis. Making use of this molecular mechanism, we have modified the eIF2α kinase domain of PKR to be both drug-inducible and cell-type specific. First, we tested the system both *ex vivo* and *in vivo* in a Nestin-cre pan neuronal mouse line crossed to our inducible iPKR line using the drug, Asunaprevir, and obtained a significant and reversible translation block. We next confirmed our results by shutting down the protein synthesis wave following fear conditioning in amygdala and blocking the formation of the auditory fear memory. Administration of the drug resulted in reversible block of cued freezing response after drug administration. Finally, we immunohistochemically observed the activation of protein signaling cascades in the major interneuron cell types in the amygdala, Parvalbumin, Somatostatin and Protein Kinase C- delta expressing cells. The use of our cell-type specific pharmacogenetic system selectively expressed could therefore be used to ascertain the differential role of *de novo* protein synthesis in inhibitory neuron populations for the modulation of the cued fear memory.

Title: c-Fos in the central amygdala in appetitively and aversively motivated learning

Authors: *T. LEBITKO[1], H. MADEJ[1], T. JAWORSKI[1], A. SUSKA[1], K. KONDRAKIEWICZ[2], E. KNAPSKA[2], L. KACZMAREK[1];

Abstract: The central nucleus of the amygdala (CeA) is well known for its involvement in aversively motivated learning, e.g. in fear conditioning. However, neurons in the CeA are also essential for reward learning. Before, we reported that matrix metalloproteinase-9 (MMP-9, extracellularly operating enzyme) in the CeA is crucial for appetitive, but not for aversive, learning. Since in activated neurons MMP-9 is c-Fos/AP-1 regulated at the transcriptional level, we hypothesized that appetitively motivated learning depends also on learning-driven c-Fos expression in the CeA. To test this hypothesis we injected CeA with a short-hairpin (sh) RNA in a lentiviral vector. Blocking *c-fos* expression resulted in impairment of appetitively but not aversively motivated discrimination learning and significantly reduced motivation to seek for a reward. To further characterize c-Fos dependent motivational changes we optogenetically stimulated CeA neurons involved in reward learning. Animals were injected with genetic construct, in which channelrhodopsin is placed under the control of a *c-fos* promoter and trained in the operant conditioning chamber to associate an auditory stimulus with contiguous food reinforcement. Learning was defined as an ability to modify the bar-pressing responses during exposure to the signaling stimulus. Subsequent activation of the CeA neurons during the signaling stimulus presentation amplified incentive motivation for food reward reflected by an increase in the number of bar-pressing responses. Such stimulation did not change behavioral responses in the absence of a signaling stimulus. Taken together, the results show that c-Fos expression in the CeA is necessary for learning motivated by alimentary rewards. In particular, *c-fos*-expressing neurons modulate incentive motivation to pursue an associated reward.

Title: Neural ensemble coding of nociceptive information in the amygdala drives innate pain affective behavior

Authors: *G. F. CORDER, B. AHANONU, B. GREWE, C. SOTOUDEH, M. SCHNITZER, G. SCHERRER;
Stanford Univ., Palo Alto, CA

Abstract: Pain is a cohesive multidimensional experience arising from sensory and emotional processes. Qualitative categorization of nociceptive sensory information as 'unpleasant' is essential for protective learning, behavior selection, and survival. Injury-induced plasticity within emotional valence circuits, such as the basolateral amygdala (BLA), may lead to a miscoding of sensory information concomitant with the emergence of chronic pain. To determine how the BLA encodes nociceptive information and how this activity changes during the development of chronic neuropathic pain, we manipulated nociresponsive BLA neural ensembles and followed their dynamics for multiple weeks after the induction of a peripheral nerve injury. To do this, we selectively expressed the inhibitory DREADD(hM4) receptor in a functionally-defined population of BLA nociresponsive neurons. Chemogenetic manipulation of the BLA nociceptive network in mice with nerve injury did not alter reflexive pain behavior. Strikingly, affective pain behaviors following noxious stimulation, such as attending to the injured paw and escape-avoidance, were dramatically reduced. To further characterize how BLA ensemble dynamics represent noxious stimuli before and after nerve injury, we conducted long-term *in vivo* Ca^{2+} imaging of $CaMKII^{+}$ BLA neurons using the miniature integrated fluorescence microscope and the Ca^{2+} indicator GCaMP6m. Prior to nerve injury, multidimensional and population vector analysis of sensory-evoked Ca^{2+} transients revealed that the BLA uniquely represents noxious and innocuous stimuli (*e.g.* sharp pin *vs*. light touch), as well as distinct sensory modalities (*e.g.* mechanical *vs*. thermal). After the establishment of neuropathic pain, the neural ensemble representations of prior innocuous and noxious stimuli became more similar. Overall, we have identified unique network representations of noxious information in the BLA; these representations facilitate the innate, negative affective qualities of the pain experience and drive appropriate motivated behaviors. Further, our findings demonstrate how BLA ensemble activity evolves under chronic pain states to assign negative valence to previously innocuous stimuli, possibly contributing to pathological sensory dysfunctions such as allodynia, and to psychological co-morbidities such as depression.

Title: Functional effects of age on NR2A and NR2B containing NMDA receptors in interneurons and pyramidal cells of the rat medial prefrontal cortex

Authors: *K. B. KELLY[1], J. L. BIZON[2], C. J. FRAZIER[1];
[1]Dept. of Pharmacodynamics, [2]Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Biochemical studies from our group and others have shown that NMDA receptor subunit expression is decreased in the aged prefrontal cortex and suggested these changes are associated with specific impairments in cognitive function. This study was designed to carefully evaluate age related changes in NMDA receptor mediated currents in both interneurons and pyramidal cells found in layer 2/3 of the rat medial prefrontal cortex (mPFC). Whole cell patch clamp recordings were used, in combination with selective antagonists, to isolate NMDAR-mediated currents carried by either NR2A or NR2B containing NMDA receptors. We found that the majority of NMDA current was carried by NR2A containing receptors in both interneurons and pyramidal cells from young (4-6 month old) animals, we carefully quantified the percentage of cells that exhibited detectable NR2B mediated currents, we calculated the ratio of NR2A:NR2B current in cells that displayed both components, and we evaluated the extent to which these values are altered by age. We found that ~40% of cells layer 2/3 interneurons tested in young animals had detectable NMDA current carried by NR2B containing NMDARs, which represented ~40% of total NMDA receptor mediated current in those cells. Interestingly, neither the percentage of NR2B positive interneurons, nor the NR2B:NR2A current ratio in those interneurons was altered in aged (20-24 month old) rats. In contrast, we found that the vast majority of young layer 2/3 pyramidal cells exhibited detectable current carried by NR2B containing NMDA receptors (representing ~34% of the total NMDAR mediated current), and that the percentage of NR2B positive pyramidal cells was significantly reduced by age. Interestingly, in aged cells that retained detectable NR2B current, the overall NR2A:NR2B ratio was not altered by age ($p=0.79$). Overall these observations indicate a prominent role for NR2A

containing NMDA receptors in cortical function, and are consistent with an age related loss of NR2B containing receptors in layer 2/3 of the rat mPFC that is largely restricted to a subset of cortical pyramidal cells.

Title: Stress reactivity predicts impaired working memory in aging: Vulnerability of GABAergic synapses

Authors: *J. A. MCQUAIL[1], M. M. BRUNER[1], C. M. HERNANDEZ, III[1], E. G. KRAUSE[2], B. SETLOW[3], D. A. SCHEUER[4], J. L. BIZON[1];

Abstract: Normal aging is associated with impaired cognition, including working memory supported by the prefrontal cortex (PFC). Our prior work strongly implicates altered PFC glutamatergic and GABAergic signaling in age-related working memory impairment. Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis also accompanies the aging process and it has been proposed that the cumulative effects of stress and concomitant glucocorticoid exposure over the lifespan exacerbate neural changes that mediate the emergence of cognitive deficits. As the PFC is enriched in glucocorticoid receptors, the present study tested the hypothesis that age-related differences in HPA function predict working memory ability and that psychogenic stress recapitulates adverse effects of aging on PFC glutamatergic and GABAergic signaling protein expression. First, we evaluated the relationship between working

memory and circulating corticosterone (CORT) in aged rats. Young adult (4-6 mo) and aged (22-24 mo) rats were characterized for working memory ability using a delayed response task. As in our previous work, working memory in aged rats was less accurate than young, although aged performance spanned a broad range with some aged rats performing similar to young (unimpaired) and others performing worse than young (impaired). Basal CORT measured across the diurnal cycle was greater in aged rats than in young but this elevation was not associated with working memory. When challenged with a stressor (1 h restraint), stress-induced CORT was positively correlated with working memory performance of aged rats. Next we determined the extent to which chronic variable stress alters expression of excitatory and inhibitory synaptic proteins in the PFC. Young adult rats were subjected to a 14-day randomized schedule of twice-daily stressors including insulin-induced hypoglycemia (Day 1 only), forced swim, novel environment, restraint stress and exposure to predator urine. While markers affiliated with excitatory signaling (NMDARs, VGluT1) were not reliably changed by stress, expression of GABA(B)R1a, a presynaptic GABA autoreceptor, and VGAT, the presynaptic vesicular GABA transporter, were significantly reduced in the PFC of stressed rats. Collectively, our findings reveal important interrelationships between aging, stress and PFC function and, further, identify a causal role for stress in PFC GABA signaling alterations that could contribute to impaired working memory. Ongoing studies will evaluate age- and stress-related changes in glucocorticoid receptors as well as the effects of synthetic glucocorticoid receptor agonists on working memory function.

Title: Velocity modulated hippocampal local-field potential across hippocampal lamina

Authors: *A. P. MAURER[1], C.-H. ELVIRA-MARTIN[1], S. N. BURKE[1], A. SHEREMET[2]; [1]Evelyn F. McKnight Brain Inst., [2]Univ. of Florida, Gainesville, FL

Abstract: The anatomy of the hippocampus is characterized by a laminar organization such that afferent input and intrinsic fiber projections are isolated in discrete layers. The layers of CA1, for example, are divided into stratum oriens, stratum pyramidale, stratum radiatum and stratum lacunosum-moleculare. The stratum lacunosum-moleculare region of CA1 neurons receives input from the layer III of the entorhinal cortex (Witter et al., 1988), nucleus reuniens (Wouterlood et al., 1990) and amygdala (Pikkarainen et al., 1999), while the stratum radiatum and oriens receive CA3 Schaeffer collateral and commissural fibers (Hjorth-Simonsen, 1973; Ishizuka et al., 1990). Moreover, different populations of interneurons target distinct hippocampal lamina with parvalbumin positive cells synapsing in the stratum pyramidale and oriens while the somatostatin positive cells target the stratum lacunosum-moleculare (Freund and Buzsaki, 1996) Theoretically, this anatomical organization should manifest as physiological differences in the local field potential. Using 32-site linear arrays, we investigated the rhythmic activity of the local-field potential as a function of depth in rats that were trained to perform a spatial alternation task. Specifically, as a function of the animal's running velocity we investigated theta (8 Hz), the theta harmonics (phase locked integer of the hippocampal theta rhythm; Sheremet et al., 2016), and the individual gamma rhythms (Colgin et al., 2009; Belluscio et al., 2012). Finally, we extended these analyses to determine the nature of cross-frequency coupling of oscillations both within and across hippocampal subregions.

Title: Broad neuronal population coding in hippocampus relative to piriform cortex during difficult olfactory discriminations

Authors: *S. A. JOHNSON[1,2], W. M. YODER[3], K. N. LUBKE[2], J. P. LISTER[6], A. P. MAURER[4], J. L. BIZON[2], S. N. BURKE[2,5];

Engin. and Neurosci. / McKnight Brain Inst., [5]Inst. on Aging, Univ. of Florida, Gainesville, FL; [6]Dept. of Pathology & Lab. Med., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The ability to discriminate between similar stimuli is fundamental to accurate encoding and retrieval of episodic memories. For visual and spatial domains, this ability has been linked to activity within hippocampal circuits. However, it is not yet known whether the hippocampus and its cortical inputs perform this role across all sensory modalities. The current study sought to determine the extent to which neuronal populations in perirhinal cortex (PRC) and CA3 are engaged by olfactory discrimination, relative to piriform and lateral entorhinal cortical regions associated with olfactory processing (Chapuis & Wilson 2013). Male F344 rats (N=6) were trained to perform a go/no-go olfactory discrimination task using aliphatic alcohols and aldehydes (C3-C8) as stimuli. We have previously shown performance on this task is inversely related to structural similarity of odorant molecules, such that difficulty of discriminations increases as difference in carbon chain length between odorants decreases (Yoder et al. 2014). Neuronal populations active during easy versus difficult discriminations were identified with cellular compartmental analysis of temporal activity by fluorescence *in situ* hybridization (catFISH), from which the activity history of neuronal ensembles can be inferred based on subcellular distribution of Arc mRNA (Guzowski et al. 2005). After initial training, rats performed similarly on easy (85.7% correct, SD=7.7%) and difficult trials (83.3%, SD=9%). Overall, more neurons were active during olfactory discrimination in the PRC (17.5%, SD=2%; $P < 0.006$) and CA3 region (21.8%, SD=5.8%; $P < 0.007$) relative to piriform cortex (11.3%, SD=2.7%). In the piriform cortex and PRC, the difference in proportion of neurons active during difficult relative to easy trials was not significantly greater than zero (piriform: $P = 0.08$, PRC: $P = 0.30$). Conversely, in CA3 there were more neurons active during difficult trials relative to easy trials (Difference in % Arc+ neurons=6.24, SD=2.7; $P < 0.05$). Our results demonstrate that the relative size of neuronal ensembles recruited across the piriform, PRC, and CA3 increases when rats are accurately discriminating between similar, but not distinct, odorants. These findings are consistent with prior implications of hippocampal activity in olfactory working memory (Kesner et al. 2011; Weeden et al. 2014), and support the hypothesis that the hippocampus is critical for the encoding of distinct representations of similar stimuli across multiple sensory modalities.

Title: The medial prefrontal cortex is critical for the flexibility necessary for adaptive risky decision-making.

Authors: *C. A. ORSINI[1], S. C. HESHMATI[2], S. C. WALL[2], J. L. BIZON[2], B. SETLOW[2]; [1]UNIVERSITY OF FLORIDA, Gainesville, FL; [2]Univ. of Florida, Gainesville, FL

Abstract: Previous research shows that prefrontal cortex (PFC) damage mimics decision-making deficits observed in individuals suffering from substance use disorder (SUD). Thus, it is conceivable that impaired decision-making in SUD is due to alterations in PFC integrity. While the role of the medial PFC (mPFC; homologous to the primate dorsolateral PFC) has been elucidated in some forms of decision-making, its contributions to decision-making under risk of explicit punishment is unknown. To this end, we assessed the effects of mPFC manipulations in a rat model of risky decision-making [the "Risky Decision-Making Task" (RDT)], in which rats chose between a small, "safe" food reward and a large, "risky" food reward accompanied by ascending probabilities of mild footshock punishment. In Exp. 1, well-trained rats were tested in the RDT following mPFC inactivation with muscimol/baclofen (M/B) or vehicle. In Exp. 2, effects of intra-mPFC M/B or vehicle were assessed on a modified version of the RDT in which reward magnitudes associated with each lever were equated (such that rats chose between a small, safe reward and a small, risky reward). To determine whether effects of mPFC inactivation were due to behavioral inflexibility, a new cohort of rats was trained in a "descending" RDT in which the probabilities of punishment decreased across the session (Exps. 3-5). In Exp. 3, rats received intra-mPFC M/B or vehicle. In Exp. 4, rats received intra-mPFC amphetamine (AMPH; 0, 2, 10, 20 µg). Finally, in Exp. 5, rats received systemic injections of AMPH (0.0, 0.3, 1.0, 1.5 mg/kg). mPFC inactivation increased choice of the large, risky reward in the ascending RDT. When reward sizes were equated, choice behavior was not affected by mPFC inactivation, indicating no effects on sensitivity to punishment. In the descending RDT, mPFC inactivation decreased choice of the large, risky reward. Together, Exps. 1-3 suggest that the mPFC is necessary for adjusting choice behavior in response to changing punishment probabilities. In Exp. 4, similar to mPFC inactivation, intra-mPFC AMPH decreased choice of the large, risky reward in the descending RDT, suggesting mPFC monoamine neurotransmission is critical for flexible decision-making. Finally, and consistent with prior work in the ascending

RDT, systemic AMPH decreased choice of the large, risky reward in the descending RDT. Thus, it is also possible that enhancing mPFC monoamine neurotransmission potentiated the salience of punishment, causing a decrease in risk-taking. Future studies will dissociate these two interpretations and determine the roles of specific monoamine systems (dopamine vs. norepinephrine) to risky decision-making.

Title: Stimulus modality affects recognition behavior during spontaneous object recognition and crossmodal object recognition tasks

Authors: *L. S. GAYNOR[1,2], J. MIZELL[1], K. T. CAMPOS[1], L. SANTACROCE[1], C. MCEWEN[1], D. K. CHETRAM[1], A. P. MAURER[1], R. M. BAUER[2], S. N. BURKE[1]; [1]Dept. of Neurosci., [2]Dept. of Clin. and Hlth. Psychology, Univ. of Florida, Gainesville, FL

Abstract: The time a rodent spends freely exploring a novel object compared to a previously encountered object has been used to measure recognition abilities (Ennaceur & Delacour, 1988). More recently, differences in behavior on these spontaneous object recognition (SOR) tasks have been used to quantify age-related deficits in object recognition and discrimination (Burke et al., 2010). In rodents, this cognitive process likely relies on sensory information obtained from both visual and tactile modalities and declines with age. Rodents, however, have an aversion to lighted areas, exhibiting reduced exploration under these conditions (Crawley & Goodwin, 1980;

Belzung et al., 1987). Moreover, the spatial resolution of the rat somatosensory system, which is less than 100 um (Morita et al., 2011; PMID: 21673811), is well suited to support object recognition. Therefore, SOR behavior, as detected by a rat's preference for novelty, may be more readily observed when animals use tactile information relative to visual. We tested young and aged rats' preferences for novel compared to familiar objects in a visual and a tactile SOR task with a 5 min delay between sample and test phases. Furthermore, to examine interactions between these modalities we used the Crossmodal Object Recognition task (CMOR) with and without multimodal pre-exposure to the sample object (Winters & Reid, 2010). This task tests the ability of rodents to identify objects based on visual features after familiarizing themselves with the object based on tactile cues only. In all 4 tasks, there was not a significant effect of age with a 5 min delay ($p > 0.1$ for all comparisons). Together, the young and aged rats showed a significant novelty preference in the tactile SOR task ($t[26] = 6.23$, $p < 0.001$), but not in the visual SOR task ($t[29] = 1.73$, $p = 0.1$). Additionally, both young and aged rats showed a significant novelty preference in the CMOR task with multimodal pre-exposure ($t[29] = 4.36$, $p < 0.001$), but not in the CMOR task without pre-exposure ($t[29] = 1.37$, $p = 0.2$). Together these data suggest that the superiority of the rat somatosensory system compared to the visual system results in preferential use of tactile over visual cues to guide crossmodal object recognition. In the CMOR with pre-exposure condition, rats are given the chance to encounter the test object's visual and tactile cues simultaneously, conceivably allowing the rat to incorporate both into a single, polymodal object representation in advance of the sample and test phase.

Title: A rodent model of medial temporal lobe-dependent discrimination deficits in the elderly

Authors: *S. M. TURNER[1], L. A. SANTACROCE[1], S. A. JOHNSON[1], S. N. BURKE[1,3,4], A. P. MAURER[1,2];
[1]Neurosci., [2]Biomed. Engin., Univ. of Florida, Gainesville, FL; [3]Mcknight Brain Inst., Gainesville, FL; [4]Univ. of Florida, Inst. on Aging, Gainesville, FL

Abstract: Advanced age is associated with cognitive deficits that include impairments in object recognition and discrimination. In humans, the magnitude of these deficits is proportional to the difficulty of the discrimination. That is, elderly subjects show greater impairments when the stimuli to be discriminated have more features in common, relative to when they are more distinct (Yassa et al. 2011). The neurobiological underpinnings of these declines, however, have not yet been elucidated. This is due, in part, to the lack of rodent model for age-related discrimination deficits. The goal of these studies was to determine whether age selectively impairs the ability to distinguish between similar stimuli in a rat model of old age, and to test the role of the hippocampus. In order to systematically vary the difficulty of object discriminations, stimuli were created from LEGO© blocks. In experiment 1, young (6-10 m) and aged (26-30m) male Fischer 344 x Brown Norway hybrid rats were trained on an object discrimination task in which one pair of objects was visually distinct (easy), while the other pair shared features (difficult). Although young [$p<.05$] and aged [$p<.05$] rats took significantly longer to learn the difficult compared to the easy discrimination, the aged rats were selectively impaired relative to young on the difficult discrimination only [$p<0.01$]. In order to more closely replicate the experimental design of human studies, in experiment 2, rats were tested for their ability to correctly discriminate between a well-learned target object and 3 novel foil objects, each with increasing similarity to the target. Similar to the first experiment, aged animals were impaired relative to young on the difficult discriminations [$p<0.05$]. Finally, in experiment 3, a reversible inactivation in young rats was used to test the requirement of a functional hippocampus in performing the difficult discriminations. Inhibition of hippocampal neural activity resulted in a difficulty-dependent deficit similar to that observed in aged rats. These data suggest that advanced age impairs the ability to accurately discriminate between objects that share overlapping features, and this deficit may emerge from hippocampal dysfunction occurring in advanced age.

Title: The ketogenic diet as a therapeutic strategy for improving motor and cognitive functioning in a rodent model of senescence

Authors: *A. R. HERNANDEZ, K. CAMPOS, L. TRUCKENBROD, L. SANTACROCE, C. M. HERNANDEZ, Y. SAKARYA, J. A. MCQUAIL, A. P. MAURER, J. BIZON, C. CARTER, S. N. BURKE;
Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL

Abstract: The loss of independence in the elderly can result from both physical and cognitive decline. These declines may be a consequence of body weight fluctuations, decreased glucose utilization, and increases in damage from reactive oxygen species. Currently, limited treatment options are available to prevent the myriad of age-related deficits many individuals experience. We propose the use of a ketogenic diet as a metabolic intervention for alleviating the symptoms of several aspects of aging. This high fat, low carbohydrate diet elicits a shift in the body's main energy source away from glucose towards the use of ketone bodies. Previous studies have shown that the ketogenic diet can reduce inflammation, increase oxidative capacity, and reverse aberrant neural activity. The ability of aged animals to enter and maintain ketosis, and the impact of this diet on body composition, however, has not been systematically examined. In this study, young and aged Fisher 344 x Brown Norway Hybrid rats were given 51 kcal/day of a nutrient matched ketogenic or control diet for a duration of 12 weeks. Young and aged rats in the ketogenic group maintained significantly higher levels of β-hydroxybutyrate and lower levels of glucose relative to the controls. While all rats were modestly calorically restricted (by ~15%), rats on a ketogenic diet had significantly less visceral fat than control rats ($p < 0.007$). Moreover, both young ($p < 0.003$) and aged ($p < 0.001$) ketogenic rats had significantly less brown adipose tissue compared

to age matched controls. Additionally, TD-NMR was used to determine body composition, revealing that there was a significant increase in the ratio of lean to fat mass in the aged rats on the ketogenic diet ($p < 0.003$) but not in aged controls ($p = 0.119$). Finally, aged rats on the ketogenic diet maintained grip strength over a 10-week period, while aged rats on the control diet showed a significant decline ($p < 0.05$). Future studies will determine the extent that the ketogenic diet can improve performance on a motor-cognitive "dual-task" that requires walking while using working memory, which is particularly sensitive to dysfunction in advanced age.

Title: Group II and Group III metabotropic glutamate receptors are required for normal working memory and are reduced in the aged rat prefrontal cortex

Authors: ***M. R. SCHWABE**[1], C. M. HERNANDEZ[1], J. A. MCQUAIL[1], B. SETLOW[2], J. L. BIZON[1];
[1]Neurosci., [2]Psychiatry, Univ. of Florida Col. of Med., Gainesville, FL

Abstract: Working memory refers to the short-term maintenance of information and this process is thought to require the persistent activity of excitatory pyramidal neurons within the prefrontal cortex (PFC). Metabotropic glutamate receptors (mGluRs) are localized to pre- (Group II and III) and post- (Group I) synaptic sites in the PFC, where they modulate synaptic transmission and neuronal excitability. As the role of PFC mGluRs in working memory is still not well-defined,

separate cohorts of rats were used to evaluate the effects of antagonists targeting receptors within each of the three major classes of mGluRs: Group I (MTEP, mGluR5 antagonist), Group II (LY341495, mGluR2/3 antagonist) and Group III (MMPIP, mGluR7 antagonist). Following surgical implantation of guide cannula targeting the medial PFC (mPFC, the rat homologue of primate dorsolateral PFC), rats were trained to baseline performance on an mPFC-dependent delayed response task. Drugs were then administered acutely into mPFC using a within-subjects, Latin square design, such that all subjects within a cohort received vehicle and three doses of drug, with a 48 hour washout period between successive doses. Using this design, both the mGluR 2/3 antagonist (LY341495) and the mGluR7 antagonist (MMPIP) impaired working memory relative to vehicle, whereas the mGluR5 antagonist (MTEP) had no effect. A second series of experiments then used Western blotting to evaluate expression of mGluR2/3 and mGluR7 in the mPFC of young (6 mo, n=6) and aged (24 mo., n=12) rats to explore the hypothesis that age-associated changes in PFC mGluRs contribute to the well-described working memory impairments that accompany the aging process. Expression of both mGluR2/3 and mGluR7 receptor proteins was significantly reduced in aged mPFC relative to young adults. Collectively, these findings show that presynaptic mGluRs are critical for normal working memory, and further, that loss of presynaptic mGluRs in the mPFC could contribute to attenuated working memory abilities in aging.

Title: Differential effects of D2 and D3 dopamine receptor ligands on risky decision-making

Authors: *S. L. BLAES, C. A. ORSINI, M. SPURRELL, J. L. BIZON, B. SETLOW;
Univ. of Florida, Gainesville, FL

Abstract: Regulation of decision-making is integral to daily life, and dysregulation in this process is evident in many psychiatric conditions including ADHD, schizophrenia and substance use disorders. In addition to impaired decision-making, these disorders share the common feature of dysregulated dopamine signaling. Indeed, dopamine signaling plays a critical role in

regulating multiple forms of decision making; however, the specific dopamine receptor subtypes involved are still not yet clear. Previous work from our lab identified a role for D2-like, but not D1-like, dopamine receptors in modulating decision- making involving risk of explicit punishment. The goal of the current experiments was to differentiate the roles of D2-like receptors (specifically D2 and D3) in risky decision-making, using a behavioral pharmacological approach.
Adult male Long-Evans rats were trained on a Risky Decision Making Task (RDT) in which they made discrete-trial choices between two levers, one which delivered a small, safe food reward and the other which delivered a large food reward accompanied by ascending probabilities (0-100%) of mild foot shock punishment. Once rats attained stable performance on the task, they received i.p. injections of multiple doses of amphetamine (indirect dopamine agonist), bromocriptine (D2/3 agonist), sumanirole (D2-selective agonist) and PD128907 (D3-selective agonist). Each drug was tested in a separate experiment, using a randomized, within-subjects design such that each rat received each dose of drug.
Consistent with previous work from our lab, both amphetamine and bromocriptine caused a significant dose-dependent decrease in choice of the large, risky reward. Surprisingly, sumanirole produced a trend toward an increase in choice of the large, risky reward. PD128907 caused a decrease in choice of the large, risky reward, but as this effect was evident irrespective of the probability of punishment, it is likely that it was due at least in part to impairment in reward magnitude discrimination. The results of these experiments thus far suggest that both D2 and D3 receptors are important for modulation of risky decision-making. Future experiments will focus on replicating these findings, as well as determining the effects of D2 and D3 receptor antagonists.

Title: Age-related alterations in working memory and intertemporal choice in Fischer 344 x Brown Norway hybrid rats.

Authors: *L. M. VETERE[1], C. A. ORSINI[2], J. A. MCQUAIL[3], S. N. BURKE[3], B. SETLOW[2], J. L. BIZON[3];
[2]Psychiatry, [3]Neurosci., [1]Univ. of Florida, Gainesville, FL

Abstract: The ability to evaluate the benefits and potential consequences associated with a choice and to make effective decisions is critical for maintained independence across the lifespan. Poor decision making is associated with impaired prefrontal cortical-dependent cognition across a variety of clinical conditions. However, despite the fact that prefrontal cortical function declines in aging, aged individuals generally show an enhanced ability to delay gratification as is evident by less discounting of delayed rewards in intertemporal choice tasks. The current study was designed to evaluate relationships between two aspects of prefrontal cortical-dependent cognition (working memory and cognitive flexibility) and intertemporal choice in young (6 mo.) and aged (24-28 mo.) Fischer 344 X Brown Norway hybrid rats. First, young and aged rats were tested on a food-motivated intertemporal choice task in which they chose between a small reward available immediately and a large reward available following variable delays ranging from 0-60 seconds. Overall, aged rats showed attenuated discounting of delayed rewards in this task compared to young (i.e., enhanced preference for large, delayed over small, immediate rewards). These same rats were then tested on a delayed response working memory task in which they had to remember the location of a response lever over delays ranging from 0-24 seconds. Aged rats were significantly impaired on the delayed response task compared to young, although among aged rats, those with better working memory tended to show the greatest ability to delay gratification on the intertemporal choice task. Finally, the rats were tested on a set-shifting task in which they had to shift between two response rules in order to receive food rewards. Performance on the set-shifting task did not predict intertemporal choice among aged rats. These data indicate that impairments in working memory and cognitive flexibility cannot account for the robustly attenuated discounting of delayed rewards observed in aged subjects.

Title: Biochemical evidence for altered glutamatergic signaling in the aged prefrontal cortex: contribution to impaired behavioral flexibility

Authors: *C. M. HERNANDEZ, III[1], B. S. BEAS[1], J. A. MCQUAIL[1], B. SETLOW[2], J. L. BIZON[1];
[1]Neurosci., [2]Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: Behavioral flexibility, or the ability to adjust response strategies when faced with changes in the environment, is critical for normal adaptive behavior. Behavioral flexibility is mediated by the prefrontal cortex (PFC) and is compromised in schizophrenia and other clinical conditions characterized by cortical hyperexcitability. This aspect of PFC-mediated cognition can also become impaired in aging and previous work from our laboratory has identified attenuated GABAergic signaling as a contributor to impaired behavioral flexibility among aged rats. The goal of the current study was to extend these investigations to determine the relationship between age-associated alterations in medial PFC (mPFC) expression of proteins involved in glutamate signaling and impaired behavioral flexibility. Young (6 mo, n = 6) and aged (24 mo, n = 12) Fischer 344 rats were first trained on a mPFC-dependent set-shifting task that assesses behavioral flexibility. Two weeks after the conclusion of testing, the mPFC was micro-dissected, fractionated, and the expression of synaptic proteins involved in glutamatergic signaling was evaluated using Western blotting. Several presynaptic proteins important for the regulation of synaptic glutamate were significantly reduced in expression in the aged mPFC. These included Group II (Grm 2/3) and Group III (Grm4, Grm7) metabotropic glutamate receptors, as well as the excitatory amino acid transporter EAAT1. While expression of these presynaptic proteins did not reliably predict behavioral flexibility among aged rats, they were

suggestive of increased glutamate availability at mPFC synapses. Several post-synaptic proteins (NR1, PSD-95, and Grik2) were selectively reduced in aged rats exhibiting impaired behavioral flexibility relative to the young cohort. It is notable that attenuated expression of both NMDA and kainate receptors has been strongly linked to impaired cognition across a variety of conditions. Moreover, blockade of NMDARs in the PFC generally produces increased excitation, supporting the functional role of these receptors in regulating interneuron activity. As such, the overall pattern of changes in protein expression provides evidence for cortical hyperexcitability in aged rats with impaired behavioral flexibility.

Title: Neural population dynamics of contextual coding in LEC

Authors: *A. TSAO, L. LU, J. SUGAR, E. I. MOSER, M.-B. MOSER;
CNC/KAVLI, NTNU, Trondheim, Norway

Abstract: Recent work has demonstrated that lateral entorhinal cortex (LEC) is involved in encoding context. However, the details of how this occurs and the underlying mechanisms are not well understood. Here we take a population-level approach to understanding the details of how context is encoded in LEC, using tetrode recordings in rats across multiple experimental paradigms. In our first set of experiments, we change the wall color of the recording environment, which has been shown to induce rate-remapping in the hippocampus which is dependent on LEC function. In particular, we alternate between white and black walls 6 times in order to more fully capture contextual coding dynamics in LEC. In our second set of experiments, we introduce an object into the recording environment in the middle of the

recording session, in order to test the generality of contextual coding in LEC. Population-level analysis of LEC activity in both of these experiments reveals robust contextual coding, even in the relative absence of such information at the single-cell level, as context can be accurately predicted using a classifier trained on the entire recording population. In addition to context, trial order can also be accurately predicted, suggesting that LEC encodes both environmental and temporal context simultaneously. Population vector analysis verifies that temporal coding is not merely due to drift in the neural population. We are currently exploring the population dynamics present in these experiments, including those occurring at the contextual switches. In our final set of experiments, we train rats to perform a continuous-alternation task in order to test contextual coding in a behaviorally meaningful situation. We find that the neural trajectories for left- and right-turn trials are well-separated throughout the maze except for the last half of the central arm, and that the distance between left-and right-turn neural trajectories increases significantly at the turning points of the maze, suggesting that LEC codes for behavioral context by keeping track of the animal's actions.

Title: The impact of NMDA and NR2B antagonists on working memory and c-fos expression in rats.

Authors: *L. M. FLEMING[1], S. KRIEGER[2], R. FRAWLEY[2], T. SONGTACHALERT[2], L. LUNDEGARD[2], P. IVAIN[2], C. CHADWICK[2], K. FISCHER[2], F. MENNITI[3], R. GRAHN[2]; [1]Yale Univ. Neurosci. Program, New Haven, CT; [2]Connecticut Col., New London, CT; [3]MindImmune Therapeutics, Inc, Kingston, RI

Abstract: The NMDA receptor plays a role in mental processes ranging from mood regulation to memory formation. Ketamine, a non-selective NMDA antagonist, has both rapid antidepressant effects and side effects similar to the symptomology of schizophrenia. Another link between these disorders is working memory, which relies on the NMDA receptor and specifically NR2B-subunit function. We investigated the effects of acute and long-term administration of ketamine and an NR2B-specific antagonist (traxoprodil) on working memory in rats. Rats were tested with a spatial working memory procedure on the eight-arm radial arm maze after acute and repeated

doses of each drug. After the animals' final day of testing on the maze, brains were extracted for immunohistochemistry staining using a c-fos antibody. The results showed a trend indicating that animals repeatedly administered ketamine performed better on the working memory task than those administered saline or traxoprodil. The animals administered ketamine also showed significantly lower c-fos expression in areas of their frontal cortex compared to animals receiving saline and traxoprodil. These results indicate that the long-term effects of ketamine do not appear to be the results of its action on the NR2B subunit. These findings have positive implications for the therapeutic use of low doses of this drug class for depression and hints at dose-related differences in the effects of repeated ketamine administration.

Title: Evaluating the role of mGluR5 in post-cocaine working memory deficits and relapse

Authors: *C. M. GOBIN, M. SCHWENDT;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: Chronic cocaine abuse produces motivational and cognitive deficits that might be rooted in abnormal function of circuitry that includes the prefrontal cortex (PFC) and the nucleus accumbens (NAc). While diminished activity of the PFC during post-cocaine abstinence has been linked to deficits in working memory and cognitive flexibility, over activation of PFC-to-NAc glutamatergic pathway permits relapse to drug-seeking. Systemic administration of metabotropic glutamate receptor 5 (mGluR5) antagonists attenuate relapse, but prolonged blockade of mGluR5 might exacerbate post-cocaine PFC dysfunction. Conversely, mGluR5 agonists, while potentially beneficial for treating PFC dysfunctions, may increase the risk of relapse. Here we wanted to evaluate the effects of prolonged mGluR5 inhibition or activation on

working memory performance and reversal learning following cocaine or saline self-administration. We used a novel combination of cocaine self-administration followed by an operant delayed match/non-match to sample task (DMS/DNMS). In the DMS task, each trial consists of a sample phase, delay period and choice phase. In the sample phase, either the left or right lever results in a sucrose pellet. In the choice phase, choosing the same lever presented in the sample phase yields sucrose delivery. Performance with variable delays assesses working memory. In the DNMS task, the rule is switched in which choosing the opposite side lever as the one presented in the sample phase results in a reward. Upon reaching stable performance over a block of five days, rats received daily systemic injections of the mGluR5 antagonist MTEP or the mGluR5 positive allosteric modulator CDPPB over a block of five days followed by a washout period of five days. We found that MTEP significantly impaired, while CDPPB mildly enhanced, cognitive performance in saline self-administering rats. We predict that prolonged use of MTEP will be damaging to cognitive function, but CDPPB may treat cognitive deficits in rats with a history of cocaine without negatively affecting relapse.

Title: Effect of high-fat diet on consolidation of object location memory and hippocampal leptin receptor levels

Authors: T. OMURA, J. ZIONTZ, *A. L. TRACY;
Psychology, Grinnell Col., Grinnell, IA

Abstract: The increasing global prevalence of obesity in the 21st century has been associated with a variety of life-threatening diseases. In rodent models, obesity induced by a high-fat diet (HFD) has also been shown to impair learning and memory compared to lean animals. The hormone leptin, produced in adipose tissue, is primarily known as a regulator of food intake behavior in the hypothalamus but is also implicated in altering learning/memory behavior by affecting the hippocampus. In the present study, rats were fed either a HFD (40% fat, 4.54 kcal/g) or a standard chow diet (4.4% fat, 3.93 kcal/g) for 10 weeks. Spatial memory was assessed using an object location recognition (OLR) behavioral assay. Rats were first allowed to

explore the empty testing arena (habituation), and, in a separate training session, placed in the arena with two identical objects to investigate, positioned at locations A and B (acquisition). Rats were then removed and one of the objects was moved to novel location C while the other remained in its original location A. After a period of 5 minutes, animals were placed back into the arena and allowed to freely explore the objects in this configuration (first retention). After 1 hour, animals were placed a final time into the arena with objects now placed in original location A and novel location D (second retention). Interaction time with each object was measured and compared across diet condition and retention delay interval. After the first retention interval (t = 5 min), there were no significant differences in demonstrated learning between diet conditions. After the second retention interval (t = 1hr), only animals on a standard chow diet demonstrated learning by exploring the object in the novel location more than the object in the familiar location, while animals on the HFD not differentially explore the two objects. This impaired performance at a longer retention interval suggests that HFD-induced obesity impairs consolidation of spatial memory in a rodent model. Hippocampal leptin receptor was quantified via Western blot and correlated with OLR performance.

Abstract: Historically, the traditional medicine has been used significantly to preserve health, prevent and treat various diseases. The safety should be a decisive criterion in the selection of herbal medicines for use in health services. Whole plants, as well as each of its parts, natural extracts and pure phytochemicals should be subject to a selection process, chemical analysis, clinical trials and regulatory measures to evaluate its potential effect on the body. For pure phytochemicals, procedures should be an identical those who apply to synthetic drugs. The aim of this study was to evaluate the effect of the *Kalanchoe blossfeldiana (K.b)* on the neuronal density of the layer III of the cerebral prefrontal cortex (CCFP) correlative with the execution of

a test short-term memory. Three groups of male wistar rats were used; 1) control, 2) vehicle and 3) rats received 5g/kg of weight-*K.b*., Lyophilised natural juice of *K. blossfeldiana* was used for the behavioral evaluation in Biel's Labyrinth of firm ground. The CCFP was processed with the hematoxylin-eosin technique. The results show alterations in the execution of the task after receiving treatment, however histologically no changes which could result from possible physiological alterations at the molecular level change behavioral activity without getting to cause observable effects on cell histology.

Title: Corticostriatal contributions to working memory: single-unit and local field potential dynamics during working memory maintenance and updating

Authors: *D. HUIE[1], A. PAULK[2], T. M. HERRINGTON[3], E. ESKANDAR[2];
[2]Neurosurg., [3]Neurol., [1]Massachusetts Gen. Hosp., Boston, MA

Abstract: Background: Working memory is the capacity to briefly hold and manipulate information, which is robustly maintained against distraction, but may also be flexibly updated

when necessary. While working memory storage has primarily been ascribed to prefrontal cortex, the basal ganglia is thought to play a gatekeeping role, permitting certain stimuli to access and change working memory while protecting working memory from distracting input. Here, we recorded from neurons in the dorsolateral prefrontal cortex and caudate nucleus of two rhesus macaques while they engaged in two visual non-spatial working memory tasks.
Methods: Microelectrode recordings were performed in rhesus macaques within the anterior caudate nucleus and dorsolateral prefrontal cortex while subjects engaged in either a distractor chain task or one-back task. During task performance, the animal was first shown a cue indicating the task to be performed, followed by a variable, unknown-length series of non-repeating images drawn from a pool of 16 familiar images. Following a short delay, the subject was then shown two image choices. The correct answer was either the first image in the chain (distractor chain) or the last image (one-back).
Results: Preliminary field potential analysis demonstrates separable dynamics in the dorsolateral prefrontal cortex and caudate nucleus during the two tasks. We also found variation in spiking activity at the single-unit level that was dependent upon both image identity and position within the image chain, as well as the current task rule. Ongoing analyses will further investigate single-unit, field potential, as well as spike-field dynamics within the corticostriatal network during task performance.
Discussion: Our current results indicate that the varying demands of the one-back and distractor chain tasks result in measurable differences in neural activity within the dorsolateral prefrontal cortex and caudate nucleus. Ongoing analysis will further test the role of the corticostriatal circuit in working memory function.

Title: Real-time change of neural activity in hippocampal CA1 after the experienced episodes; restraint stress and first encounters with female, male, and object

Authors: *J. ISHIKAWA[1], D. MITSUSHIMA[2];
[1]Yamaguchi Univ. Grad Sch. Med., Ube, Japan; [2]Yamaguchi Univ. Grad. Sch. of Medicine., Ube, Japan

Abstract: The hippocampal CA1 is necessary to maintain experienced episode in many species including humans. To monitor the process of the episode, we used freely moving male rats to record neural activity of CA1 neurons before, during, and after a specific episode. The rats were experienced either the restraint stress, or the first encounter with a female, a male, or an object for 10 min. Although spontaneous firing rate was relatively low in their habituated home cage, we observed spontaneous high frequency firing (super burst: > 600 ms duration with 43 ~ 129 Hz frequency) during and soon after the episodes. The episodes with female or restraint consistently induced the super bursts, while the episode with male or object induced the events inconsistently. Then, minutes after the episode, CA1 neurons exhibited short term (≈ 50 ms) high frequency ripple-like synchronized firing. Each ripple-like event exhibited different shape, duration, and frequency, showing a wide diversity. Moreover, simultaneous monitoring of the firing with theta wave further revealed the phase-locked relation of ripple-like events with hippocampal theta wave ($\varphi \approx 180°$). Total duration of super bursts, the number of ripple-like firing, and the timing of increase in the ripple-like firing were different among the 4 different episodes. Moreover, the rats exhibited more and longer super bursts showed more ripple-like firing after the episodes. To further examine the synaptic plasticity after the episodes, we made acute brain slices 30 min after the episodes. Compared with inexperienced controls, the episodes with female, male, and restraint significantly increased the amplitude of miniature EPSCs and IPSCs, while the episode with novel object increased the amplitude of miniature IPSCs only. Karnel density estimation of further demonstrated that the different episode promotes different diversity at excitatory and inhibitory synapses. Experienced episode promotes a wide diversity of excitatory/inhibitory CA1 synapses that may depict neuron specific outputs to process the experienced episodes. Spontaneous super bursts and following ripple-like firing may be necessary for the processing of experienced episodes in male rats.

Title: Goal-directed firing of hippocampal cells in a two-dimensional open field

Authors: *Y. AOKI[1], H. IGATA[2], T. SASAKI[2], Y. IKEGAYA[2];
[1]Univ. Tokyo, Tokyo, Japan; [2]Lab. Chem. Pharmacol., Grad. Sch. Pharmaceut. Sci., Univ. Tokyo, Tokyo, Japan

Abstract: The hippocampus is composed of place cells that fire preferentially when an animal visits a restricted area of an environment. A widely used behavioral task for characterizing place cells is a foraging task in which rats freely explore an open two-dimensional space in search of randomly dispersed food. In this task, firing of place cells tends to show little dependence on moving direction. On the other hand, in spatial tasks on a radial arm maze and a linear track where animals develop goal-directed behavioral strategy, place-selective firing of hippocampal cells is strongly biased to a specific moving direction. Taken together, the hippocampal circuit employs distinct encoding modes for space depending on ongoing task demands and the presence of goals. In this study, we recorded firing patterns of hippocampal cells while rats performed a goal-related task and a random foraging task in an identical open field. In the goal-related task, rats were required to run toward a light-cued goal to obtain a food reward in the field. Enhancing the degree of freedom of moving directions by utilizing the two-dimensional space allowed us to analyze animal's trajectories from various provenance toward goals, including errors, which could not be parsed in a stereotyped one-dimensional path, such as a linear track. We found a certain population of hippocampal cells in the goal-directed task fired only at the time when rats approached to a future goal or left from a previous goal independent of moving directions. Some of the goal-directed place-selective firing patterns differed from those observed at the same locations in the foraging task. We will further analyze what proportion of the cells share distinct spatial coding patterns, to what extent their firing fields are affected by goal locations, and whether goal-directed firing patterns are associated with task performance. The evidence will advance our understanding of how place-selective firing of hippocampal cells is modified by goal-directed movement in an open field.

Abstract: Hippocampus plays an essential role in memory formation for space and events. However, it is not well understood how hippocampal microcircuits are reorganized during the formation and retention of memory for a particular place associated with value such as a reward event. Although it has been reported that an event-related memory can be recalled by activation of a sparse but specific ensemble of hippocampal neurons (Tonegawa *et al*., Nature, 2012), it remains a possibility that a temporal firing sequence within the event-specific ensemble can recall the event-related-memory robustly. Furthermore, the stability of these ensembles over days and changing event conditions should be investigated. To address these questions, we conducted calcium imaging of hippocampal CA1 neurons in mice that express the fluorescent calcium sensor protein G-CaMP7. During recording, mice were head-fixed under a two-photon microscope while performing a reward-related memory task in virtual reality. Three colored zones were placed along a virtual linear track and reward was given in one of them. Mice were required to remember the correct reward zone and learn to stay there for 2 seconds to receive reward, as a delay condition. With training, mice learned to stop and stay in the reward zone to get reward, eventually reaching a success rate up to 70%. In a single session, about 10-15% of recorded neurons demonstrated time-locked activity while the mice stayed at the reward zone. Among recording sessions over days, the temporal neural activity within the reward zone remained stable for a subpopulation of neurons. When the reward zone was changed among the three before mentioned zones, 2% of all identified cells kept responding in the previous reward

zone, while other subpopulations encoded the present reward zone with specific temporal firing pattern. Moreover, when the delay condition to the reward was omitted or when reward was not given, the temporal activity of neurons representing the reward event was suppressed. However, the activity pattern of some neurons recovered after the reward condition was reinstated. These results raise an intriguing possibility that an event such as reward is coded with sequential firing within groups of CA1 neurons, and suggest a probable mechanism for robust recall of event-related-memory.

Abstract: The hippocampus plays a crucial role for formation and consolidation of spatial memory, and location-specific activity of hippocampal neuronal populations provides a mnemonic representation of the animal's environment. Although previous studies have demonstrated that cells that encode locations of behavioral relevance, such as reward, are disproportionately overrepresented in hippocampal place maps, how this overrepresentation is established is poorly understood. Thus, we chronically imaged formation and stabilization of hippocampal CA1 place cell maps using two-photon calcium imaging in Thy1-G-CaMP7 transgenic mice during training on a linear track task in a head-fixed virtual environment. A salient visual landmark and reward delivery were associated as two types of behavioral relevance with two distinct locations in the virtual linear track. Fraction of time spent running and fraction of virtual place cells increased as training progressed. Overrepresentation of these locations was evident from the early phase of training, although place cell maps were highly variable during this period. These unstable maps were increasingly stabilized by repeated training to an extent correlated with behavioral performance. Cells that encoded these behaviorally relevant locations showed higher inter-session place field stability than place cells that encoded other locations, whereas net formation of place cells from non-place cells and recruitment of place cells that encoded other locations were not significantly biased toward these locations. These findings indicate that representations of behaviorally relevant locations form more persistent traces in hippocampal cognitive maps and that such preferential stabilization serves as an underlying mechanism for the hippocampal overrepresentation of these locations.

Title: Light modulates spatial learning and memory in a diurnal rodent, the nile grass rat (arvicanthis niloticus).

Authors: *J. E. SOLER, A. NÚÑEZ, L. YAN;
Michigan State Univ., East Lansing, MI

Abstract: The effects of light on cognitive function have been well-documented in human studies, with brighter illumination improving cognitive performance in schoolchildren, healthy adults and patients in early stages of dementia. However, the neural mechanisms through which ambient light modulates cognitive functions are not well understood. There are substantial differences in how light affects nocturnal and diurnal species e.g., light induces sleep in nocturnal mammals and wakefulness in diurnal ones. An animal model with a diurnal pattern of general activity, like that of our species, is critical for uncovering how light modulates cognition in humans. The present study utilized the diurnal grass rat (Arvicanthis niloticus) to investigate the effects of ambient light on hippocampal function. Grass rats were housed in either a 12:12hr bright light-dark (briLD, 1000 lux) or dim light-dark (dimLD, 50 lux) cycle. After 4 wks, the dimLD group showed impaired spatial memory in the Morris Water Maze (MWM) task, as revealed by increased latencies to locate the platform during the training period and less time spent searching for the platform in the goal quadrant during the testing period. When grass rats in the dimLD were rehoused under briLD condition for another 4 wks, their performance in MWM significantly improved. The results collectively suggest that light modulates hippocampal-dependent spatial memory in the diurnal grass rats. In addition to the behavioral analysis, hippocampal plasticity was also assessed by measuring brain-derived neurotrophic factor (BDNF) and dendritic spine density using immunohistology and Golgi staining, respectively. Grass rats in the dimLD condition exhibited reduced hippocampal BDNF expression, especially in the CA1 sub-region, and approximately a 50% reduction in dendritic spine density in CA1 apical dendrites. When dimLD animals were transferred to the briLD condition and kept there for 4 weeks, the hippocampal BDNF and dendritic spine density significantly increased. The results illustrate that not only does light intensity affect cognitive function, but that it also impacts hippocampal plasticity. These studies serve as a starting point to further understand the neural pathways mediating the effects of light on cognition.

Title: Optimal population coding by mixed-dimensionality neurons in the head-direction system of bats

Authors: *A. FINKELSTEIN[1], N. ULANOVSKY[1], M. TSODYKS[1], J. ALJADEFF[2]; [1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Univ. of Chicago, Chicago, IL

Abstract: Ethologically-relevant stimuli are often multidimensional. Recently we found that head-direction is encoded in the bat brain by two major neuronal classes: 'pure' 1D cells, which encode azimuth or pitch independently; and 'conjunctive' 2D azimuth-by-pitch cells, which encode head azimuth and pitch jointly. Together, these two populations form an apparently redundant representation. Here, we show that such mixed-dimensionality coding by pure and conjunctive populations is in fact advantageous for efficient representation of head-direction in different behaviorally-relevant regimes. Specifically, we found that encoding by conjunctive cells is more robust when the stimulus changes quickly, whereas pure cells represent the stimulus more efficiently on slower timescales. More generally, our results suggest that the optimal dimensionality of neuronal tuning-curves can strongly depend on population size and on the system's dynamic variables, such as the time available for decoding - which might explain why mixed-dimensionality representations are common in sensory, motor, and higher cognitive systems across species.

Title: Towards bat hippocampal recordings in large-scale environments

Authors: *T. ELIAV, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Over the last forty years, hippocampal electrophysiological research has typically focused on spatial representations in small laboratory environments. Nothing is known about hippocampal neural codes on large spatial scales - in environments spanning hundreds of meters or kilometers - the scales of natural navigation by rodents and other mammals. Here we aim for the first time to develop a unique recording setup, including a large-scale ethologically relevant environment, which will allow us to address this fundamental question. We are using the Egyptian fruit bat as our animal model, because (i) bats are excellent navigators over large natural spatial scales, and (ii) bats were shown to have rodent-like hippocampal spatial representations in small laboratory environments, during crawling and flight behaviors. So far, we took the following steps: First, we developed an on-board wireless neural-logging system, which allows recording single units over unlimited distances. Second, we built a 200-m long tunnel where bats can fly freely. Third, to track the bat's position we are utilizing an RF localization device that measures distances to an antenna-array - yielding spatial accuracy of ~10-cm, much better than GPS. Preliminary experiments showed that bats fly volitionally back-and-forth along the tunnel - up to 100 laps per session (20-km total flight distance) - exhibiting very high flight speeds of ~8 meters/sec. We hypothesize two possibilities for hippocampal coding of large-scale environments: (i) enlargement of place-fields to dozens of meters, versus (ii) hundreds of small place-fields for each place-cell. Here we will present the first neural recordings that directly test these hypotheses.

Title: 3D grid cells and border cells in flying bats

Authors: *G. GINOSAR, A. FINKESTEIN, A. RUBIN, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Grid cells exhibit spatially-periodic firing fields, and are thought to be important for navigation. When recorded in animals moving on a 2D plane, the cells fire when the animal passes through the vertices of a hexagonal grid spanning the 2D environment. Despite extensive research on 2D grid cells, there is an ongoing debate regarding the function of these fascinating neurons - namely, whether they encode the position of the animal or the distance it travelled. Moreover, many animals navigate through 3D space, but no studies to date have attempted to characterize the 3D volumetric firing of grid cells. Here, we conducted experiments in flying bats to elucidate the grid code in 3D - and found that our results provide also surprising insights into the debate on grid function in 2D. We trained Egyptian fruit bats (Rousettus aegyptiacus) to fly in a flight-room, while we wirelessly recorded single-neuron activity in medial entorhinal cortex. We found several classes of 3D spatially tuned neurons, including 3D border cells and 3D head direction cells. Importantly, these recordings revealed grid-like structures in the 3D firing-rate maps of some cells, which exhibited multiple firing-fields. The spacing between firing-fields was more variable than in perfect synthetic 3D lattices, but was substantially less variable than for randomly-distributed fields - namely, 3D grid-cells seem to exhibit a rather fixed distance scale, without forming a global lattice. These preliminary data shed new light on the function of grid cells, because the global lattice arrangement is a key requirement for representing position using the widely-proposed grid-based modulo code. Conversely, the fixed inter-field spacing observed in our data might be suitable for the encoding of distance travelled.

Title: Vectorial representation of spatial goals in the hippocampus of bats

Authors: *A. SAREL, A. FINKELSTEIN, L. LAS, N. ULANOVSKY;
Dept. of Neurobio., Weizmann Inst. of Sceince, Rehovot, Israel

Abstract: Navigation, the ability to reach a desired destination, requires the knowledge of the position and direction to the goal. Decades of research have focused on the representation of the current location and orientation of the animal, revealing place cells, grid cells and head-direction cells. However, a fundamental question that remains unanswered is how spatial goals are represented in the brain - which is crucial for understanding the neural basis of goal-directed

navigation. To address this question, we trained three Egyptian fruit bats to fly towards landing-sites (defined as 'goals'), while the activity of single neurons from hippocampal area CA1 was recorded. We found a subpopulation of hippocampal neurons that exhibited rather narrow angular tuning to the direction of the goal. This goal-direction tuning was highly stable, over both short and long timescales, and was independent of the place tuning. Further, in two of the three bats we conducted another session in which we positioned the goal behind a curtain, and found many neurons tuned to this hidden goal - suggesting that the goal-direction representation is memory-based rather than sensory-based. In addition, we also found hippocampal neurons that encoded the distance to the goal, often in conjunction with goal-direction tuning. Taken together, our results suggest the existence of goal-direction and goal-distance signals in the bat hippocampus - a vectorial representation that could support goal-directed navigation.

Title: Representation of conspecifics by bat hippocampal place cells

Authors: *D. B. OMER, N. ULANOVSKY, L. LAS;
Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: In animals living in social groups, learning can be facilitated by observing the behavior of conspecifics (observational learning). In particular, it is important for social animals to know the spatial location of conspecifics, both because they need to know the locations of socially-dominant animals, and for purposes of group navigation. How is the location of other animals represented in the brain? Here, we addressed this question by studying bats - highly-social flying mammals that excel in observational-learning and are also outstanding navigators. We designed an observational-learning task for Egyptian fruit bats (*Rousettus aegyptiacus*), where animals were trained in pairs: In each trial, one bat ('observer') had to observe and remember the flight-trajectory of the other bat ('demonstrator'). After a short delay, the observer had to imitate the demonstrator and fly along the same flight-trajectory to receive a reward- a spatial delayed match-to-sample task, which required the observer to pay close attention to the demonstrator's behavior. We recorded neurons in hippocampal area CA1 of the observer bat during this task, using a tetrode-microdrive and a miniaturized wireless electrophysiology system that allows recording individual neurons during flight. To control for the known spatial

properties of hippocampal place-cells, we did two things: first, the observer hung at a fixed position while observing ('space-clamp'); and second, we used an accelerometer to exclude neural activity due to head-movements. Our preliminary data suggest that some CA1 neurons in the observer's hippocampus represent both the bat's own position (place cells) as well as the position of the conspecific. Further, many of these cells were modulated by the direction of the conspecific's flight - similar to place cells that are modulated by the animal's own flight directionality. Taken together, these data indicate a possible role for the hippocampus in social-spatial cognition.

Title: Enhanced acquisition in reference memory due to social housing

Authors: *V. L. TEMPLER, K. PALFRAMAN;
Psychology, Providence Col., Providence, RI

Abstract: Studies with both humans and nonhuman animals suggest numerous effects of social living, such as stress and neuroprotective benefits, both of which may affect cognitive ability. The aim of this study was to determine the cognitive and behavioral impact of social vs. individual housing in rats. In order to best model disparate levels of sociality in human populations, 20 male Long-Evans rats were housed in enriched cages and were divided into two groups: 10 socially housed (SH) rats lived together in a large cage, and 10 non-socially housed (NSH) rats lived in individual cages where they could see, smell, and hear other rats but had no physical contact with them. These housing conditions were maintained throughout development

and into adulthood, at which point working memory, reference memory, and long-term memory were assessed in spatial contexts using multiple renditions of the Barnes Maze (BM) and Radial Arm Maze (RAM). SH rats displayed improved acquisition in reference memory, but not long-term memory performance, as compared to NSH rats in both the BM and RAM. At the end of acquisition in the RAM, when reference memory errors and exploratory behavior was equalized between groups, the SH animals also showed improved working memory as demonstrated in decreased working memory errors. However, after reference memory for the RAM was learned and over-exploratory behavior in SH rats was extinguished, group differences in both reference memory and working memory errors across groups disappeared. In order to further control for differences in locomotor behavior and examine overall levels of anxiety, subjects were also tested on the Elevated Zero Maze and Open Field Test, which revealed no group differences. We conclude that SH rats show enhanced learning in spatial memory tasks with increased opportunities to learn correct locations.

Title: Central cholinergic function: impact of limited environmental enrichment on spatial learning and memory deficits in the rat

Authors: *J. MANOR[1,2], M. L. PARMENTER[2], E. P. WIERTELAK[2,1];
[1]Psychology, [2]Neurosci. Studies, Macalester Col., Saint Paul, MN

Abstract: Alzheimer's disease is a neurodegenerative disease characterized by severe memory impairment and progressive deterioration in cognitive function. Research indicates that the blockade of central muscarinic ACh receptors results in learning and memory dysfunction. Scopolamine is an anticholinergic drug that targets and antagonizes muscarinic ACh receptors, which mirrors the aforementioned cognitive dysfunction and dementia symptoms. Studies have demonstrated that while scopolamine impairs memory and learning, environmental enrichment (EE) can reverse the learning and memory deficits. The present study examined the effects of one hour per day of EE on improving spatial learning and memory in rats, thereby reversing the anticholinergic effects of scopolamine. Subjects were grouped into a standard or enriched condition for the EE training. All subjects were housed in standard cages for three weeks, and the enriched group was removed once per day to receive one hour of play in an enriched

environment with four other conspecifics. All animals were assessed using the Morris water maze spatial navigation task (MWM). Half of the subjects in the enriched and standard condition were injected with scopolamine (0.6 mg/kg, s.c.) thirty minutes prior to testing in the MWM, and the other half of the subjects were injected with saline solution (vehicle control). Results indicate that subjects with one hour of enrichment per day showed significantly decreased latencies to reach a hidden platform compared to those in the standard condition for both drug conditions. These data provide evidence that environmental enrichment has the ability to improve cognitive functioning and potentially, may ameliorate dementia symptomology, by countering ACh deficits. Future research will examine more directly the effect EE may have on cholinergic circuitry.

Title: Investigation of the relation between rat`s navigation strategy and brain activity

Authors: *E. RAMA[1], G. CAPI[4], M. JINDAI[2], Y. FUJIMURA[1], N. TANAKA[3], S. KAWAHARA[3];
[1]Dept. of Electrical and Electronic Syst. Engin., [2]Dept. of Mechanical and Intellectual Systems Engin., [3]Grad. Sch. of Innovative Life Sci., Univ. of Toyama, Toyama, Japan; [4]Dept. of Mechanical Engin., Hosei Univ., Tokyo, Japan

Abstract: Robot self localization and goal directed navigation in a complex environment are still challenging tasks. It has been well known that rats accurately and rapidly navigate in a complex space by localizing themselves in reference to the surrounding environmental cues. As the first step to incorporate the rat's navigation strategy into the robot control, we analyze the rats' strategies while it navigates in a multiple Y-maze. In the present study, we analyzed the effects of distal and remote cues on rats navigation behavior by changing the lighting condition. The multiple Y-maze has a tree-like structure made of a four Y-junctions. Therefore, the rat has to follow the appropriate route to reach the target food location. During training each rat was placed on the starting position and allowed to navigate freely on the maze environment until it reaches the target food position, which was fixed throughout the experiment. To help the rat to localize

itself and to memorize the target route, in the surrounding walls were placed pictures of a different signs (distal cues). First the rats were trained to learn the maze in a lighted environment until they reached an asymptotic level of learning. Then the learned behavior was tested in dark environments. The learning performance was evaluated by percentage rate of selecting the correct route, time to reach the food location and running speed. We found that during the learning phase in a bright condition rats showed different navigation behavior. Some of the rats learned the task quickly and showed a stable performance, while other rats required more time to learn and showed an unstable behavior. When we performed the experiments in dark environment rats which learned the task faster, adapt also quickly with the new environment condition. Based on the behavior results we suggest that rats might use two different navigation strategies to solve the multiple Y-maze task: one dependent on the distal visual information and the other on the local or internal information. This is consistent with many other studies so far, which have demonstrated that hippocampus plays an important role in processing and/or storing spatial memory using distal cues while the striatum is involved in selecting the sequence of actions based on the internal and local cues. In order to verify our hypothesis, the same experiments, with recording electrodes for local field potential (LFP) in these brain regions, are performed. Now, the analysis of the LFP taken from the rat's brain is in progress. The preliminary results show interesting relation between recorded LFP and rats' navigation strategy.

Title: Training recurrent networks for neural solutions to realistic navigation tasks

Authors: *I. KANITSCHEIDER[1], I. R. FIETE[2];
[1]Dept. of Neurosci., [2]Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: Sensory noise and ambiguous cues make self-localization during navigation computationally challenging: Path integration causes location estimates to deteriorate quickly and landmarks are often spatially extended (e.g. walls) or look similar to other landmarks, thus providing only partial position information. Worse, in novel environments, landmark positions are unknown and must be learned while navigating. How brains perform these difficult computations is largely unknown. Engineering solutions require sophisticated probabilistic algorithms based on particle filters that update several hypotheses simultaneously over time, but are hard to map to biological neurons.
We define several problems that crystallize typical navigation challenges: Self-localization in a circular 1D environment with several indistinguishable landmarks, known circular and polygon-shaped 2D environments with extended, featureless boundary walls, and novel 2D polygon-shaped environments whose boundaries have to be learned during navigation. We take a model-free approach and generate neurally plausible solutions by training recurrent networks with hidden layers, then scrutinize their performance, errors, and dynamics.
The networks learn to update their estimates through velocity integration, integrate landmark information, and use memory of the last landmark encounter to choose between competing location hypotheses. The network performance matches the optimal particle filter (known environments) and substantially outperforms pure path integration (unknown environments), evidence that it can learn new maps. Reminiscent of remapping, the hidden units dynamically switch their tuning to code for the relevant statistics at a given time, such as location relative to the last observed landmark or to absolute location. These results demonstrate that hard navigation tasks can be solved by deterministic networks and provide predictions for neural representations during real-world navigational challenges.

Title: Deep brain two-photon calcium imaging of dentate gyrus granule cells in awake mice

Authors: *T. HAINMÜLLER, M. BARTOS;
Univ. of Freiburg, Freiburg I. Br., Germany

Abstract: The hippocampus is an essential brain center for the acquisition of conscious memories. Formation of functional neuronal ensembles in the dentate gyrus (DG), the input region to the hippocampus, is a critical step in the genesis of episodic memories (Denny et al., Neuron, 2014). Furthermore, activation of these ensembles can be used to manipulate existing memories in mice or to craft artificial ones (Liu et al., Nature, 2012; Ramirez et al., Science, 2013). In spite of this important function, the knowledge on how these neuronal groups emerge during memory acquisition is scarce.
The study of neurons in the DG is hindered by two factors: First, the activity of granule cells (GCs), the principal neurons of the DG, is extremely sparse, with most neurons being silent throughout behavioral recording sessions (Pernía-Andrade & Jonas, Neuron, 2014). Therefore, a large number of GCs must be observed simultaneously in order to record activity of the few coactive cells that form a functional memory ensemble. This is hard to achieve using standard electrophysiological recording techniques like tetrode-recordings. Second, the DG is located deep within the brain and therefore difficult to access for many of the current standard recording methods in neuroscience, such as patch-clamp recordings or two-photon imaging approaches.
To overcome these technical obstacles and record simultaneously from a large number of DG neurons, we have developed a novel approach to perform two-photon calcium imaging in the DG of awake, head-fixed mice performing behaviors in a virtual-reality environment (Dombeck et al., Nature Neurosci., 2010). We were able to simultaneously record the activities of a subset of DG neurons, including neurochemically identified cell types labelled with the fluorescent protein tdTomato. Our recordings revealed location related activity (‘place fields’) in some of these cells, including hilar non-GC neurons. In summary, our approach will enable the possibility to investigate the formation of functional DG neuron ensembles and their interactions with other cell types in the DG during memory related behaviors in a virtual environment.

Abstract: Constitutive neurogenesis occurs in the dentate gyrus (DG) of the mammalian hippocampus throughout life. Newborn granule cells integrate into local hippocampal circuitry and have been suggested to function in hippocampus-dependent learning, memory and affective behaviors. Immature granule cells show increased excitability and plasticity in acute hippocampal slice recordings, suggesting that these cells may be more active than mature granule cells. However, the electrophysiological properties of newborn neurons in vivo are not well-characterized due to the technical challenges of identifying the age of putative granule cells during extracellular single unit recordings. To identify and record newborn neurons in the intact brain, we established a novel inducible transgenic mice model to express the light-activated opsin channel, channelrhodopsin (ChR2), in a birthdated cohort of newborn neurons. Five days of systemic tamoxifen injections in Tbr2-CreERT2 mice selectively targets intermediate neural progenitors in the adult mouse hippocampus. Using this Tbr2-mediated genetic targeting strategy, ChR2 was systematically expressed in a highly specific and robust manner (i.e. approximately 1000 ChR2-YFP+ cells per dentate gyrus). At two weeks post tamoxifen injection, 99% of YFP+ cells expressed doublecortin (a marker of immature neurons). By combining optogenetics with in vivo extracellular recording, we identified several light-responsive units, with less than 5 msec latency after the onset of the light stimulation. We are currently optimizing the conditions to test the hypothesis that immature granule cells are more active than mature granule cells during exploratory behavior. Recording sessions in multiple distinct environments will allow the measurement of spatial selectivity and remapping properties of both immature and mature granule cells.

Title: Distinct spatial firing and remapping properties of cells in the granule cell layer and hilus of the dentate gyrus

Authors: *D. GOODSMITH[1], K. M. CHRISTIAN[2,3], S. KIM[2,3], H. SONG[2,3,4], J. J. KNIERIM[1,4];
[1]Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Inst. for Cell Engin., [3]Dept. of Neurol., [4]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The dentate gyrus (DG) was traditionally thought to perform pattern separation due to the projection of overlapping entorhinal inputs onto a larger, sparsely firing granule cell (GC) population, leading to the recruitment of independent ensembles of active GCs in response to small changes in input (Marr, 1969; McNaughton & Nadel, 1990). Although GCs make up the majority of cells in the DG, the hilus contains a number of other cell types, including excitatory mossy cells. Recent evidence suggests that DG cells with single or multiple firing fields correspond to different cell populations (Neunuebel & Knierim, 2012). It is unclear whether this heterogeneity in spatial firing properties can be attributed to anatomically distinct populations in the granule cell layer (GCL) and hilus.

We recorded from the DG and CA3 of 8 rats while they foraged for food in four distinct environments. Based on the baseline firing properties of previously reported cells recorded from tetrodes located unambiguously in the hilus or GCL (23 and 37 cells respectively), together with an additional 31 cells recorded in CA3c, we trained a random forest classifier to identify putative GCL, hilus, and CA3 cells from a larger data set (245 cells total). Consistent with our previous results, putative GCs (n=112) were rarely active (5% of cells per session), and the majority of these cells had single fields, while putative hilus neurons (n=35) tended to have multiple fields and >75% had fields in ≥ 3 environments. The firing of active cells in CA3 (n=98) and the GCL was similar (single field, single room), but a higher percentage (23%) of CA3 cells was active in a given session.

The overlap of firing rates between environments (defined as the product of normalized mean firing rates) was higher than a shuffled distribution for cells in the hilus, but not GCL, suggesting that different populations of putative GCs were active in each environment. To test remapping in the GCL and hilus populations, we next generated population vectors (PV) of co-recorded cells in the hilus or GCL. In both the hilus and GCL, the maximum correlation between pairs of environments (after shifting and/or rotating one PV) never exceeded the 99th percentile of a shuffled distribution. Together, these results suggest that cells in both the GCL and hilus can support DG pattern separation through two distinct mechanisms. Consistent with Marr's model of "expansion recoding," unique populations of sparsely firing GCs appear to be recruited in each environment. In contrast, hilus cells may encode distinct environments through changes in the spatially correlated firing of the entire active population (Leutgeb et al., 2007).

Title: CA1 place fields respect local surface texture boundaries

Authors: ***C.-H. WANG**[1], J. D. MONACO[2], G. RAO[1], S. S. DESHMUKH[3], J. J. KNIERIM[1]; [1]Krieger Mind Brain Inst., [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Emerging evidence shows that local cues exert considerable influence over place-cell firing. For example, “landmark-vector cells” develop place fields located at a similar distance and direction from objects placed on the apparatus (Deshmukh and Knierim, 2013). Systematic manipulations of local surface cues lead to corresponding place field rotation or remapping (Shapiro *et al.*, 1997; Brown and Skaggs, 2002; Knierim *et al.*, 2002). In these studies, place cells were recorded as rats explored an apparatus with different sections covered by different textured surfaces. Some of the place fields followed the local surface cues when the local and global cue sets were rotated in opposite directions. Although the remapping and rotation properties of place fields have been widely examined with manipulations of surface cues, few studies have focused on the properties of individual place fields at the transition boundaries between different surface cues and the distribution of place fields with respect to the boundaries. Given the salience of a sudden change of surface texture, we hypothesized that the transition boundaries could be salient cues that influence the precise firing locations of place cells.
In the present study, we demonstrate that CA1 place fields tended to terminate near texture boundaries when the rats foraged for food on a circular track. The track width was 10 cm and its outer diameter was 76 cm. Each quadrant of the circular track was covered by a different texture surface with distinct tactile and visual cues, and salient global visual cues were present at the perimeter of the circular, curtained environment, approximately 1.35 m from the track. We analyzed 2619 place fields from the CA1 region of 27 rats, from a database composed of both published and unpublished data. Examples of individual place fields were observed that fired

specifically at a texture boundary, in the middle of a texture patch, or that fired across two different texture patches. However, when the entire sample was analyzed, the place field boundaries (i.e., the onset and offset of the place field firing) were not uniformly distributed on the track (Kolmogorov-Smirnov test, $p < 0.0001$). Rather, the boundaries tended to coincide with the texture boundaries (chi-squared test, $p < 0.0001$; bootstrap, $p < 0.0001$). These results show that the CA1 spatial representation respects the boundaries between different textured surfaces. This phenomenon may enable segmentation/compartmentalization of experiences by natural environmental boundaries.

Title: Extreme control of CA1 spatial maps by coherently moving virtual reality landmarks

Authors: ***R. P. JAYAKUMAR**[1], M. S. MADHAV[2], F. SAVELLI[2], M. BREAULT[3], H. T. BLAIR[5], J. J. KNIERIM[2], N. J. COWAN[4];
[2]Zanvyl Krieger Mind/Brain Inst., [3]Biomed. Engin., [4]Mechanical Engin., [1]Johns Hopkins Univ., Baltimore, MD; [5]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Constructing a cognitive map such as that expressed by place cells in the hippocampus requires the integration of self-motion cues and landmark information that can stabilize the map with respect to the external world. Using a planetarium style virtual reality (VR) dome, we investigated the dynamics of the CA1 hippocampal place cell network by coherently manipulating distal landmarks, putting them in conflict with integrated self motion cues. In the VR dome, rats ran in a circular path experiencing unaltered inertial and proprioceptive feedback. The surrounding visual scene consisted of salient virtual landmarks that were either static or rotated coherently as a function of the rat's running speed. The rotation resulted in the continuous movement of the landmark constellation against the laboratory (absolute) reference

frame.
Previously (Madhav et al., 2015, SFN Abstracts), we showed anecdotally that the place cell map was locked to the landmarks at relative (to the landmarks) velocities ranging from close to zero (i.e., producing a treadmill-like experience) to three times the actual running speed of the animal. Here we quantified the influence of the moving landmarks on the place cell network using two independent, population-level approaches: a position decoder based on unsorted spikes, and spatial frequency estimation scheme based on Fourier analysis of firing rates. Using unsorted spikes when the landmarks were held stationary, we trained a position decoder (Kloosterman et al., 2013). The decoder was then applied to epochs where the landmarks were moving. When the landmark constellation was moving, the decoded position tracked the rat's position relative to the landmark constellation (not the static laboratory reference frame). The tracking error increased for higher landmark velocities, which may be attributed to an increasing conflict between self-motion cues and landmark cues, the degrading of the decoded position due to partial remapping of the place fields, or a combination of the two. To address this ambiguity, we developed a Fourier-based algorithm which estimates how the spatial frequency of the place cell population evolves during an experiment. This analysis is relatively insensitive to remapping. In all cases, the decoded spatial frequency was dramatically more compatible with a map controlled by the virtual landmarks than by the laboratory reference frame. These results show that visual landmarks can override self-motion cues even under extreme conditions of conflict between self-motion and landmark information.

Title: Lateral entorhinal cortex neurons are sensitive to circular movement direction relative to the center of an open-field arena

Authors: ***C. WANG**[1,2], H. LEE[1,2], S. DESHMUKH[3], G. RAO[1,2], D. YOGANARASIMHA[4], F. SAVELLI[1,2], J. J. KNIERIM[1,2];

[1]Johns Hopkins Univ., Baltimore, MD; [2]The Zanvyl Krieger Mind/Brain Inst., Baltimore, MD; [3]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India; [4]Natl. Brain Res. Ctr., Haryana, India

Abstract: The lateral entorhinal cortex (LEC) is hypothesized to provide the hippocampus with rich multisensory input that represents the items and events of an episodic memory. Compared to the medial entorhinal cortex (MEC), little is known about the behavioral correlates of LEC neuronal activity. LEC neurons convey much less spatial information to the hippocampus than the MEC. Instead, LEC neurons appear to encode more information about the objects present in an environment, including information about the remembered locations of previously present objects. In the presence of objects, a small number of LEC neurons appear to have spatially tuned "place fields" away from the objects. Thus, although a number of LEC neurons have activity that can be classified as spatial/object correlates, the influence of other behavioral variables remain open to investigation. We recorded LEC neurons from 15 rats as they foraged for food in a large, open-field arena (8 rats in a rectangular arena with objects and 7 rats in a square arena with no objects). Surprisingly, we found that approximately half (235/447) of LEC cells were significantly modulated by whether the rat was moving in a clockwise or counterclockwise direction relative to the center of the behavioral arena. Some cells fired almost exclusively when the rat was running in the clockwise direction, whereas simultaneously recorded cells fired almost exclusively when the rat was running in the counterclockwise direction. Although the underlying mechanism for this circular direction selectivity is unknown, one intriguing possibility suggested by this phenomenon is that LEC neurons are influenced by sensorimotor events happening during movement in the arena.

Title: A simple relational task produces a higher immediate early gene expression in the avian hippocampus

Authors: *M. J. ACERBO[1], J. RICK[2], K. PANFIL[2], A. KOSKI[2], M. STACHO[3], O. GÜNTÜRKÜN[3], O. LAZAREVA[2];

Abstract: Recently, we showed that hippocampal lesions in pigeons selectively impair relational behavior in a transitive inference task. In the current study, we have explored the involvement of the hippocampus in another traditional relational task, transposition. Unlike transitive inference, transposition does not require manipulating relational information; instead, animals are simply trained to learn the physical relation between the stimuli (e.g., larger or smaller) and use the same relation when presented with novel pairs of stimuli. We trained two groups of pigeons to complete a task either relationally or associatively. The pigeons learned to discriminate two pairs of circles of different sizes, S1-S2 and S3-S4 (where S1 was the smallest and S4 was the largest). For the relational group the smaller (or the larger) circle in each pair was rewarded. For the associative group the smaller circle in one pair and a larger circle in another pair were rewarded; these pigeons had to memorize each exact stimulus instead of relying on their relationship. Training was followed by a test with two novel pairs, S2-S8 and S2-S3. Next, we analyzed c-Fos and ZENK expression in the NCL and four hippocampal areas: dorsomedial ventral (DMv), an area similar to the mammalian CA1; dorsalmedial dorsal (DMd), an area similar to the mammalian CA3; and dorsolateral ventral (DLd) and dorsolateral dorsal (DLd), areas similar to the mammalian entorhinal cortex. We found greater number of cells expressing c-Fos in the relational group than in the associative group for all four areas, although only the DLd activity was significantly higher. Similarly, we found greater number of cells expressing ZENK for all four areas in the relational group than in the absolute group. However, statistical differences were restricted to the DLd area of the right hemisphere. These results indicate that avian hippocampus may be involved in relational tasks that are based on a physical relationship and that do not explicitly require encoding or manipulating relationships between different training stimuli. Furthermore, our results imply that simple relational tasks may share a common substrate with spatial learning.

Abstract: Understanding the neurobiological basis of cognition and behavior, and disruptions to these processes following injury and disease, requires a large-scale assessment of neural populations, and knowledge of their patterns of connectivity. We present an analysis platform for large-scale investigation of functional and neuroanatomical connectivity in rodents. Retrograde tracers were injected (for details see Wilber et al 2015 Frontiers in Neural Circuits) and in a subset of animals behavioral tests to drive immediate-early gene expression were administered. This approach allows users to perform whole-brain assessment of function and connection in a semi-automated quantitative manner (for details see Mesina et al 2016 Journal of Neuroscience Methods). Brains were cut in the coronal plane, and an image of the block face was acquired. Wide-field fluorescent scans of whole sections were acquired and analyzed using a Matlab toolkit, available for download at https://github.com/lilicamd/BrainSegmenterGUI. The platform utilized open-source and custom software to accommodate a largely automated analysis pipeline in which neuronal boundaries are automatically segmented, the positions of segmented neurons are co-registered with a corresponding image acquired during sectioning, and a 3-D representation of neural tracer (and other products) throughout the entire brain is generated (results available at https://github.com/lilicamd/MethodsSpace). Our focus on segmented units of interest (e.g., NeuN labeled neurons) and restricting measures to these units produces a flexible platform for a variety of whole brain analyses (measuring activation, connectivity, markers of disease, etc.). This open-source toolkit allows an investigator to visualize and quantify whole brain data in 3-D, and additionally provides a framework that can be rapidly integrated with user-specific analyses and methodologies.

Title: Directionality in distal CA1 is driven by sensory cues, while proximal CA1 is influenced by self-motion differences

Authors: *Z. NAVRATILOVA[1], L. T. HOANG[2], J. L. VALDES[3], M. TATSUNO[1], B. L. MCNAUGHTON[1];
[1]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Univ. of Arizona, Tucson, AZ; [3]Univ. of Chile, Santiago, Chile

Abstract: The primary correlate of hippocampal firing is location in space (O'Keefe and Dostrovsky 1971). Other factors can influence the firing rates of CA1 and CA3 'place cells' (e.g. Leutgeb et al. 2005), the strongest of which seems to be running direction during bi-directional traversals of narrow tracks (McNaughton et al. 1983). We recently showed that these directional differences are not present during the first traversals of the track, suggesting that they are not due to deficient path integration (the ability to sum up distances and directions traveled to calculate relative position), but instead are due to learning different associations to the traversals of each direction (such as sensory cues; Navratilova et al. 2012).
CA1 and CA3 place cells receive information about location and self-motion from neurons in the medial entorhinal cortex (MEC), and sensory information from the lateral entorhinal cortex (LEC). While CA3 cells each receive inputs from both entorhinal cortices, cells in the proximal (to CA3) half of CA1 receive inputs from MEC, and the distal half of CA1 is innervated by LEC axons. All CA1 cells also receive inputs from CA3, and all show location-specific firing, with distal CA1 cells expressing a larger number of place fields (Henriksen et al., 2010). Larger numbers of distal CA1 cells are recruited during a non-spatial memory task (Nakamura et al., 2013).
We hypothesized that distal CA1 cells are more influenced by sensory inputs, and thus more likely to develop directionality in an environment dominated by distal visual cues. We recorded from 12 tetrodes along the proximal-distal axis of CA1 while rats ran back and forth between two food dishes. One half of the track was rich in local sensory cues, and the other half had no local cues. Distant visual cues were visible. Cells from both proximal and distal CA1 showed differences in firing rates between running directions after several traverses of the track. However, the population of proximal CA1 cells showed a high correlation between traverses of

the track in opposite directions, regardless of the type of cue that was present, while the distal CA1 population showed a low correlation between opposite directions when only distant visual cues were present. As the rats ran the track repeatedly, they developed stereotyped behavior, including running faster when approaching a food dish, and slower when leaving one. This difference in running speed in opposite directions significantly influenced the firing rates of proximal (but not distal) CA1 cells. Thus, firing rate differences between opposite direction traverses were due to running speed differences in proximal CA1, and visual cue differences in distal CA1.

Title: Emergence of sequential multineuronal reactivation in rat parietal cortex in parallel with learning

Authors: *I. SKELIN[1,3], A. A. WILBER[3,2], C. J. MONTZ[3], S. KILIANSKI[3], B. MCNAUGHTON[3,2];
[1]Neurosci., [2]Univ. of Lethbridge, Lethbridge, AB, Canada; [3]Univ. of California Irvine, Irvine, CA

Abstract: Tuning to specific combinations of linear, and angular velocity is organized in a modular fashion in rat parietal cortex, as assessed by pooling multineuronal spiking activity (MUA) recorded on multiple single tetrodes. Based on this modularity, we sought to determine if patterns of module activation that are apparent during behavior undergo reactivation during post-experience sleep - a postulated mechanism of memory consolidation previously demonstrated on single neuron level (Wilson and McNaughton, 1994). We found evidence for modular reactivation using both cross-correlation of MUA patterns between tetrode pairs and explained variance, methods which are sensitive to correlated activity at the whole epoch level. To test the

hypothesis that sequential module activity patterns would be reactivated during post-experience sleep, we applied the *template matching* method (Euston et al., 2007). Templates were created by multiple trial averaging of either the total spiking activity from a single tetrode (module) or the envelope amplitude of Hilbert-transformed high-frequency (300-900 Hz) component of the local field potential (LFP), recorded from a single wire on the same tetrode. The time-windows for template construction were either 1 sec preceding ('approach') or 1 sec following the brain stimulation reward ('depart'). The Pearson correlation coefficient was calculated between the templates and the sliding window of time-compressed (5x) spiking or Hilbert envelope activity during sleep. The significance of matching was assessed by comparing the correlation coefficient obtained using behavioral to100 shuffled templates. High matching values are concentrated around the times of hippocampal sharp wave/ripples (+- 200 ms), suggesting that populations of modules reactivate with hippocampal populations. The ripple-triggered reactivation peaks tend to emerge and get higher following repeated behavioral training sessions, even when the number of trials decreases, and independent of the number of ripples during sleep. The templates constructed based on the Hilbert-transform envelope of high frequency power show similar dynamics, but appear more sensitive than templates based on multi-neuronal spiking activity. These results support the conclusion, that memory trace reactivation and hippocampal-cortical interactions can be observed at the level of modular activity, expressed either as multi-neuron spiking or high frequency LFP power fluctuations, and indicate that these processes can potentially be studied without resort to recording from many individual isolated units.

Title: Modular memory reactivation in the parietal cortex

Authors: *A. A. WILBER[1,2], I. SKELIN[2,3], C. J. MONTZ[2], S. KILIANSKI[2], B. MCNAUGHTON[2,4];
[1]Florida State Univ., Tallahassee, FL; [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [3]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Lethbridge, AB; [4]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Irvine, CA

Abstract: A fundamental framework for neural coding in the parietal cortex (PC) is egocentric (e.g., body-centered, route-centered) and a preponderance of evidence suggests neural coding within this framework by single cells in PC (e.g., Zipser and Andersen, 1988; McNaughton et al., 1994; Nitz, 2006; Whitlock et al., 2012; Wilber et al., 2014). However, studies describing the larger organizational structure of these single cells (e.g., large scale populations of cells) have been thus far confined to theoretical or computational approaches (e.g., McNaughton et al., 1995; Xing and Andersen, 2000; Byrne, Becker, and Burgess, 2007). Therefore, we looked for evidence of population level encoding in egocentric coordinates in the rat PC. To do this we assessed pooled multi-neuronal spiking activity (MUA) recorded on single tetrodes as a function of egocentric cue light location, linear, and angular velocity in rats that had been trained to either run 1) a cued random spatial sequence to 32 light locations evenly spaced around the perimeter of a circular platform or 2) a complex repeating element spatial sequence from memory. We found that the MUA recorded on a single tetrode were frequently significantly tuned to a specific self-motion state and often anticipated that movement. Next, we set out to test the hypothesis that these cortical modules would participate in memory reactivation during rest. As a first step, we looked for evidence of memory replay using two methods: explained variance (EV) and cross-correlations. First, we utilized EV performed on the MUA from each of up to 18 tetrodes to look for sessions where replay appeared to be strong. This method utilizes a partial correlation between the *task* & *post-task rest* session after controlling for correlations between the *pre-task rest & task*. Next, for data sets in which EV suggested replay was likely to occur across the PC modules, we assessed memory replay using cross-correlations between the population of module pairs (similar to Euston et al., 2007). For this analysis, PC module pairs with significant cross-correlations are identified. After normalizing, cross-correlations are then sorted, and plotted for *pre-task-rest*, *task* and *post-task-rest*. We found that, for data sets in which EV indicated that memory reactivation was likely to occur, cross-correlations suggested that co-activation between module pairs was more likely in *post-task-rest* for modules that were strongly co-active during behavior. Thus, we have shown modular coding of movement. Further, interactions between modules during *post-task-rest* suggest that inter-modular interactions play a role in normal learning and memory.

Title: Hippocampal and posterior parietal neural dynamics during two working-memory tasks.

Authors: *I. TAXIDIS, K. SAMADIAN, E. HOFFBERG, A. MYLAVARAPU, J. SADIK, N. R. SABOORI, M. BEDROSSIAN, P. GOLSHANI;

Abstract: Various studies suggest that both hippocampus and posterior parietal cortex (PPC) are activated during delayed-response, working-memory behavioral tasks. Spiking sequences have been observed in CA1 during the delay in a match-to-sample olfactory task [1] and a spatial alteration task [2] in head-fixed and freely-moving rats respectively. Similar sequences were found in the mouse PPC during a visually-cued virtual-navigation task [3]. These sequences may be critical for task performance, but their link to working-memory is not well understood. Are they associated with the actual memory of the stimulus, irrelevantly of the stimulus type, or could they encode preparatory activity for the ensuing post-delay response? How do these sequences respond when the delay is extended or reduced? To gain more insight into these questions, we have trained head-fixed mice to perform two olfactory working-memory tasks. A delayed odor-discrimination lick left/right (DOD) and a delayed non-match-to-sample link/no-lick task (DNMS). In DOD, stimulus-memory cannot be dissociated from preparatory activity for the response, whereas in DNMS, only stimulus-memory is relevant during the delay. Using *in vivo* two-photon microscopy in PPC, during the DOD task, we recorded from hundreds of neurons over multiple days, with varying delay periods. We observed task-modulated activity in several neurons that discriminated between left/right trials or trial stages, leading to spiking sequences covering the entire trial duration. These neurons typically retained their task modulation during variable delays. Interestingly, lesioning the PPC with bilateral aspirations did not affect the performance of well-trained animals in either task, suggesting that PPC sequences are not essential for working-memory in a non-navigational olfactory task. We are extending two-photon imaging to the dorsal CA1, during the DNMS task, to examine the involvement of the hippocampus. Understanding whether and how the posterior parietal cortex and hippocampus can generate sequential activity, and how this activity is linked to the memory load are critical steps for understanding the mechanisms underlying working memory.

Title: Movements in the vertical dimension organize the timing of spatially-specific firing in the hippocampus and posterior parietal cortex

Authors: ***L. E. SHELLEY**, D. A. NITZ;
UCSD, La Jolla, CA

Abstract: Neurons of both the hippocampus and posterior parietal cortex map the position of an animal in external frames of reference. Hippocampal neurons primarily map position within the space of the observable environment. In a complementary fashion, posterior parietal cortex neurons map position within the space of known routes irrespective of the position of those routes in the observable environment. Maps of route position given by the activity of posterior parietal cortex (PPC) neurons appear to derive initially from the tendency of a subset of these neurons to have activity correlates to specific locomotor behaviors such as left or right turns or simple forward locomotion. A mapping of route position is then achieved when robust and reliable modulation in the firing activity during performance of the preferred locomotor behavior occurs as a function of the location of that behavior along a full route.
Recently published experiments suggest that the form by which vertical space is mapped by hippocampal place cells and entorhinal cortex grid cells is fundamentally different and of lower resolution than that of horizontal space. However, the way that an animal moves through a position (e.g., the overall trajectory taken and/or the individual actions executed) can potently modulate spatially-specific firing in both hippocampus and PPC. As movement in the vertical dimension involves distinct types of action and trajectories, we addressed the possibility that posterior parietal cortex might encode specific actions associated with movement in the vertical dimension and that hippocampal neurons' place specific firing would be altered by such actions. Single neuron recordings in both regions were collected as animals made traversals of a long, 5-

looped, squared spiral track. The animal's route had vertical components in the form of stairways and ramps. Based on position tracking data, the beginnings and endings of individual stair-stepping movements were identified. Analyses of firing relative to the phase of these movements revealed that such actions impact the activity of both hippocampal and PPC neurons. Such firing included the tendency for a sub-population of hippocampal place cells to exhibit greater place-specific firing over specific phases of the hop to landing cycles associated with stairway climbing. Together, the findings identify a significant new form of action encoding in PPC and a new form of temporal organization in hippocampal neurons' place-specific firing. The latter finding suggests a temporal signature for movements in the vertical dimension that could be incorporated in the generation of episodic memories.

Title: Hippocampal and Posterior Parietal Cortex spatial encoding during pursuit.

Authors: *A. S. ALEXANDER[1], A. M. CONNER[2], J. C. TUNG[2], D. A. NITZ[2];
[1]UCSD, San Diego, CA; [2]Cognitive Sci., UCSD, La Jolla, CA

Abstract: ***Aims:*** Known forms of spatial representations, such as 'place cells' of the hippocampus (HPC) and 'route cells' of the posterior parietal cortex (PPC) are utilized for navigation and memory. Neurons that exhibit these spatial firing properties are commonly examined during free foraging or route running along tracks. These tasks have elucidated much about the encoding of spatial relationships. However, animals are capable of more complex navigational feats than these paradigms probe. In the wild, rats will travel in packs and hunt small prey. These behaviors involve pursuit, a form of flexible navigation wherein the goal is to track a target in real time. Navigation of this type requires quick decision making to coordinate the musculature, but also often requires the animal to track it's movements within the broader environment to return to a home nest. It is currently unknown how the aforementioned brain regions are recruited during pursuit. ***Methods:*** We developed a novel pursuit paradigm wherein

rats must catch a target moving in pseudorandom trajectories within an environment for reward. At fixed environmental locations, the moving target performed a stereotyped trajectory that the animal learned and subsequently executed shortcut trajectories, a form of spatial insight. **Results/Conclusions:** We report that PPC neurons generate representations of the stereotyped trajectory, despite the path being embedded within an unpredictable navigational environment. Furthermore, HPC place cells were modulated during pursuit, suggesting that the animal's goals and behavioral context may shape spatial encoding.

Title: Dorsal subiculum encodes functionally analogous path locations

Authors: ***J. M. OLSON**, K. TONGPRASEARTH, E. L. TAO, A. WOOTEN, H. C. LO, D. A. NITZ;
Cognitive Sci., Univ. of California San Diego, LA Jolla, CA

Abstract: Hippocampal neurons often have place-specific firing, but the details of how and when firing fields form and change differs across subregions. These differences in firing field patterns may provide clues to the different functional roles of each subregion. Hippocampus's two main output subregions, CA1 and subiculum, have very different efferent connectivity to surrounding cortices, suggesting they are parts of different functional circuits. Prior work in open field recordings has suggested that CA1 and subiculum may be largely similar, with subiculum neurons tending to have larger firing fields and generalizing more often across environments than CA1. Often in hippocampus, however, the shape of paths the animal takes through an environment impacts the place-specific firing. In the current work, we studied and compared CA1 and subiculum neurons while animals ran on a track with 6 distinct paths - four towards reward locations and two returning to the starting location. The four reward-oriented paths were equal in length, starting at the same segment and consisting of four straight runs interleaved with three 90-degree turns. Two non-overlapping paths of two turns each provided the animal with

options to return to the starting point of the four rewarded routes. All corresponding track segments across the four reward paths are equal length, as are the corresponding track segments of the return paths. This structure results in paths and segments that are spatially separated but functionally analogous in their progression from a choice point towards a goal point. Critically, such sections were parts of different action sequences in addition to being in different positions in the environment. While previous work has shown that CA1 place fields sometimes generalize across spatially local and action-sequence-related locations, preliminary results for CA1 show low numbers of firing fields that are typically not in analogous track locations. However, subiculum neurons often show firing fields in functionally analogous spaces, even in locations in space and routes that involve running in opposing orientations. The findings to date suggest that CA1 and subiculum outputs reflect a difference in information and therefore function to their separate efferents. Consistent with previous reports, more generalization occurs in subiculum, extending to include distinct spatial and behavioral locations that are functionally similar. These results hint to subiculum as a region that could be key to drawing out similarities between experiences and building more abstract spatial relations than typically described in other hippocampal subregions.

Title: Phase precession in subicular axis cells modulates with field size within individual neurons

Authors: ***K. TONGPRASEARTH**, J. M. OLSON, E. L. TAO, D. A. NITZ;
Cognitive Sci., Univ. of California San Diego, LA Jolla, CA

Abstract: Phase precession is a well-established organizational phenomenon in place field firing. As an animal moves through a single firing field of a neuron, individual action potentials coincide with earlier phases of the theta band in the local field potential. This phenomenon is

found widely across spatial representations in the hippocampus and related cortices, including CA1, CA3, entorhinal cortex, and subiculum. Across the length of a field, the neural activity precesses through 360 phase degrees, or one cycle, of theta. In recent work, we have recorded from dorsal subiculum while rats navigate a multi-path maze designed for its multiple track segments and travel orientations. The task consisted of four equal length paths of straight runs interleaved with three 90-degree turns that led to different reward sites. Two non-overlapping two-turn return paths then provided the animal routes back to the starting point of the four three-turn routes. Similar to many hippocampal subregions, subicular neurons exhibited altered spatial representations during path-running. Our results from a subpopulation of subiculum neurons (~10%) revealed a novel form of spatial tuning, the encoding of the animal's current axis of travel. These "axis cells" exhibited firing fields in two travel orientations, approximately 180 degrees apart. Here we investigated whether this novel cell type exhibits phase precession. While previous work have reported that phase precession is robust in principal neurons of dorsal subiculum, the same was not observed in head direction cells, the most prominent orientation-specific neurons. Preliminary results provided evidence for robust phase precession, indicating that axis-tuned neurons are likely to be integrated in the temporally organized structure common across the hippocampus and entorhinal cortex. Additionally, a unique feature of our task is the varied length of spatial segments. As a result, field sizes associated with high neural activity in axis cells greatly varied according to the track length of those particular orientations, with lengths ranging from 20-130 cm. As found elsewhere in hippocampus, preliminary results suggested phase precessions through only one cycle of theta for each field of axis cells despite the greatly different firing field sizes, demonstrating a change in phase precession rate within single neurons. This result indicates that these representations are fixed to the distance of each track segment in the two directions and so each segment’s length is built into the subicular representation.

Title: Concordant representation of spatial decisions and uncertain environments in hippocampus and visual cortex

Authors: *A. B. SALEEM, J. FOURNIER, K. D. HARRIS, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: Most decisions are made based on uncertain information. Multiple models have been proposed for how neuronal populations might represent such decisions and encode uncertainty. One model suggests uncertainty reduces mean rates (Ma et al., 2006). Alternative models include an increased spread of population activity (Zemel et al., 1998), or increased coherent errors (Burak et al, 2009). To test the predictions of these models, we measured population activity in primary visual cortex (V1) and hippocampus (CA1) during spatial decisions in conditions of uncertainty.

We trained four mice to perform a decision task in virtual reality, where we could control sensory uncertainty. The task involved traversing a corridor and licking in a reward zone to obtain a water reward. We modulated uncertainty by setting the visual contrast of cues to low (18% contrast), medium (60%), or high (72%) values. Task performance increased with visual contrast, from 69% correct at low contrast to 85% at high contrast.

Once mice learned the task, we recorded from neural populations in V1 and CA1 simultaneously using multielectrode probes. As expected, features in the environment were encoded by both V1 and CA1 neurons, and we could predict the animal's position from the activity of simultaneously recorded cells from either area using an independent Bayes decoder.

The position estimates decoded from V1 and CA1 were highly correlated with each other. A fraction of these correlations were signal correlations: i.e. they were explained by the fact that activity in both areas depended on position in the corridor. However, we also observed significant noise correlations: if the CA1 population underestimated or overestimated position, the V1 population typically made a similar error.

Sensory uncertainty affected the representation of the environment in V1 and CA1 in distinct ways. In V1, increasing uncertainty reduced mean firing rates, while in CA1 mean firing rates remained unchanged. Instead, population analysis revealed that under high uncertainty CA1 neurons made coherent errors, as expected for an attractor network. The coherent errors made by the hippocampal population were also correlated with behavioural errors made by the animal. Indeed, when the mouse licked outside the rewarded zone, CA1 neurons erroneously placed it in the reward zone.

We conclude that while both V1 and CA1 encode the virtual environment and make correlated errors, the representation of uncertainty is distinct in the two regions: V1 reduces its mean firing rate and CA1 neurons make coherent errors.

Title: Integration of self-motion and visual signals in mouse CA1

Authors: *J. FOURNIER, A. B. SALEEM, K. D. HARRIS, M. CARANDINI;
UCL, London, United Kingdom

Abstract: CA1 place cells fire in specific locations in the environment, providing an animal with a continuous update of its position. Their firing reflects a combination of sensory and self-motion signals (Gothard et al., 1996; Jeffery et al, 1997; Redish et al., 2000). However, it is not clear how the combination of these two signals contributes to the representation of space by populations of CA1 neurons.

We investigated this question in a virtual environment, where visual and self-motion signals can be reliably manipulated. We trained mice running on a wheel to perform a navigation task in a virtual corridor. Mice learned to lick in specific positions of the corridor to obtain a water reward. We changed the gain of the wheel (i.e. by how much it displaced the virtual world) randomly by +/- 20% on a fraction of trials. While the mouse performed the task, we recorded from populations of CA1 neurons with silicon probes. These probes typically yielded recordings from populations of >50 well-isolated neurons.

Many putative pyramidal neurons (cells with complex spike bursts) exhibited typical properties of place cells, as described in freely-moving animals. They showed place fields specific to positions in the virtual corridor (Harvey et al, 2009; Chen et al, 2009) and place cell firing relative to theta phase revealed clear phase precession (O'Keefe & Recce, 1993). While place fields tiled the entire corridor, they appeared clustered, as if the corridor was encoded in segments instead of metric positions (Gupta et al., 2012).

To quantify the relative contribution of visual and self-motion signals on the encoding of position in CA1, we used a Bayesian decoder to predict the position of the animal from the neuronal ensemble in the different gain conditions. When we altered the gain of the wheel, the position decoded from the CA1 population was intermediate between the prediction based on

visual cues and the one based on self-motion cues. This effect was consistent with the animals' behavior: the distribution of licks was also intermediate between the predictions of the rewarded location based on vision and self-motion.
We conclude that the population of CA1 place cells encode both visual and self-motion signals in virtual reality, consistent with observations in real environments. We are currently exploring the nature of the interaction between these two streams of information on position encoding by CA1 neurons.

Title: Prefrontal cortex reservoir network learns to create novel efficient navigation sequences by concatenating place-cell snippets replayed in hippocampus

Authors: *N. CAZIN[1,2], M. LLOFRIU ALONSO[3], P. SCLEIDOROVICH CHIODI[3], T. PELC[4], A. WEITZENFELD[3], J.-M. FELLOUS[4], P. F. DOMINEY[1,2];

Abstract: Rats navigate efficiently between baited reward sites in an open field. From trial to trial, rats explore both inefficient path segments as well as segments that contribute to the final path. During inter-trial pauses, place fields that have been recently traversed reactivate in short sequences ("snippets") in the hippocampus. We hypothesize that this replay exposes prefrontal cortical circuits to subsequences of the final sequence that should be generated. We test the hypothesis that by using efficient segments that include a reward, the reservoir can learn to reconstruct the efficient final trajectory. We model PFC as a recurrent reservoir network of leaky integrator neurons, with fixed recurrent inhibitory and excitatory connections, and modifiable readout connections. Readout neurons feed-back into the reservoir, allowing for autonomous sequence reproduction and generation. Hippocampal place cells are distributed in a 16x16 grid over the area. Trajectories linking the 5 wells are used to generate place cell snippets, allowing us to perform learning experiments. We separately study snippet concatenation, selection and

recombination in a series of simulations. For snippets that have place fields with sufficient spatial overlap, the PFC reservoir is capable of concatenating them in order to generate the target sequence, even if it has never been seen in the training data. When snippets are generated from two sequences of different lengths, with more overlap between subsequences, the system selects and generates the shorter sequence. We then generated snippets from multiple sequences that were not the target sequence, but that contained components of the target sequence. Snippets associated to a reward had a higher probability of being replayed than others snippets. Thus, trajectory components being a part of a rewarded path were favored, and the PFC reservoir discovered the efficient sequence. The simulations were compared to rat data and we found good but not complete agreements. While being driven with the target sequence, the model produced predictions of the next place cell firing pattern that were spatially coherent with an efficient sequence but failed at generating an efficient sequence when driven only with the previous prediction at each simulation step. These results indicate that (1) recombination capabilities of the cortical reservoir contribute to target sequence identification, and that (2) it is likely that additional cues (e.g. visual perception of the arena) also contribute to the generation of the target sequence.

Title: Contralateral inactivation of the dorsal hippocampus and prefrontal cortex using dreadds impairs spatial learning

Authors: *D. M. MAHARJAN[1], E. H. GLANTZ[1], Y. DAI[1], S. P. JADHAV[1,2];
[1]Psychology, Brandeis Univ., Waltham, MA; [2]Neuroscience, Psychology and Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Coordinated activity between the hippocampus and the medial prefrontal cortex (mPFC) is critical for learning and memory-guided behavior. The hippocampus and prefrontal cortex support memory formation and retrieval, working memory, planning, and decision making. Several functional disconnection studies have previously reported spatial memory impairments using contralateral inactivation of the mPFC and the intermediate or ventral hippocampus (*Floresco et. al*, *1997; Wang et. al, 2006; Wang et. al, 2008*; *Churchwell et al. 2010*). Contralateral inactivation disrupts hippocampal-prefrontal interactions by functionally disconnecting ipsilateral projections between the regions. Theta oscillations and sharp-wave ripples (SWRs) have been have been implicated as the physiological mechanisms underlying hippocampal-prefrontal interactions, and we have shown that these network patterns mediate communication between these regions during learning of a W-track spatial alternation task (*Siapas et. al, 2005*; *Gordon*, *2011*; *Jadhav, et al., 2016*). This communication may be supported by minor projections between dorsal hippocampus and prefrontal areas, and due to the dense interconnectivity throughout the longitudinal axis of the hippocampus (*Cenquizca and Swanson, 2007; Witter and Amaral, 2004*). Here, we tested if contralateral inactivation of the mPFC and the dorsal hippocampus leads to impairment in learning of the W-track task. We used a chemogenetic approach to contralaterally inactivate the mPFC and the dorsal CA1 regions of the hippocampus in adult Long Evans rats during learning of a W-track spatial alternation task. Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) were transduced with the use of viral vectors to specifically target the prelimbic, infralimbic and anterior cingulate cortices of the mPFC in the right hemisphere of the rodent brain, and the dorsal CA1 layer of the hippocampus in the left hemisphere of the brain. Clozapine-*N*-oxide (CNO) injections were used to inactivate these regions during learning. We found that the animals with DREADDs inactivation were impaired in the outbound, spatial working memory component of the task as compared to control animals. Our results thus provide behavioral evidence that functional disconnection of mPFC and dorsal hippocampus via contralateral inactivation impairs the ability of animals to learn a spatial working memory dependent task.

Title: The role of the hippocampus and medial prefrontal cortex in path integration, spatial alternation, and nonspatial alternation

Authors: *M. SAPIURKA[1,2], L. R. SQUIRE[3,2,4,5], R. E. CLARK[3,2];
[1]LA Jolla, CA; [2]VA Med. Ctr. San Diego, San Diego, CA; [3]Psychiatry, [4]Neurosciences, [5]Psychology, UCSD, La Jolla, CA

Abstract: Working memory refers to the limited amount of information that can be held in mind with active maintenance, and is thought to be independent of the hippocampus and the adjacent structures of the medial temporal lobe (MTL). Working memory capacity is limited by the complexity of the information being maintained. While working memory can support the recall of 7 digits, its capacity for more complex stimuli is far more limited (i.e. 3-4 objects and 1 face). A recent study (Kim, Sapiurka et al, 2013) found that patients with damage to the MTL were intact at a spatial navigation task, path integration, presumably by using their intact working memory. In contrast, rodents with lesions of the hippocampus were impaired at path integration, even when trials took fewer than 3 seconds to complete, were less than 1 m in length, and involved no turns. One explanation for these results is that, while human working memory capacity is sufficient to support path integration performance, rodents may be unable to construct a working memory of a complex spatial environment. Accordingly, rats need to rely on long-term memory to successfully path integrate. To explore this possibility, we first tested rats with lesions of the medial prefrontal cortex (mPFC) on path integration and on spatial alternation, a test of spatial working memory. Lesions of mPFC have been associated with impaired working memory. If path integration requires long-term memory, there might be no effect of mPFC lesions on task performance. Indeed, despite impaired performance on spatial alternation, rats with mPFC lesions performed as well as controls at path integration. For comparison, we also tested rats with hippocampal lesions on spatial alternation. Hippocampal lesions robustly impaired performance on spatial alternation. To further test the effects of mPFC and hippocampal lesions on working memory, we developed a nonspatial working memory task, odor alternation, in which animals alternated choices between two differently scented objects. Rats with hippocampal lesions performed as well as controls on odor alternation, while rats with mPFC lesions performed no better than chance. We suggest that rats with hippocampal lesions are impaired on spatial memory tasks because of their limited working memory and impaired long-term memory not because of a broad inability to navigate or to process spatial information.

Title: Inactivation of medial prefrontal cortex, dorsal, or ventral hippocampus during a temporal sequence task in a radial arm water maze

Authors: *S. LEE[1,2], J. R. PFLOMM[2], E. J. MARKUS[2];
[2]Dept. of Psychological Sci., [1]Univ. of Connecticut, Storrs, CT

Abstract: The hippocampus and medial prefrontal cortex have been linked to memory formation, specifically working and episodic memories. These types of memories both have a temporal component. To further examine temporal processing we developed a temporal sequence order task in an 8-arm radial water maze. Rats experienced multiple maze sessions in the same room. Each session had a different fixed correct goal arm; however the room and maze were kept identical. Therefore to identify the correct goal for a given session one would need to remember the number of previous sessions already experienced that day.
We have previously shown that rats can learn up to seven locations in this task, and these seem to be learned as a sequence with more errors in the middle sessions than in the beginning and end sessions.
The current experiment used Muscimol to temporarily inactivate the dorsal/ventral hippocampus or medial prefrontal cortex in a within-animal repeated design. Animal testing concluded with infusions of fluorescent muscimol to visualize the spread of inactivation.
Male F-344 rats (N=9), approximately six months old, were trained in an eight-arm radial water maze with a removable escape platform. Rats were taught the first arm in the sequence, and additional arms were added when rats mastered the previous arm(s). After initial exposure to the maze and task, swim latencies stabilized to five seconds for a rat to select their first arm choice. Rats successfully selected the correct goal location in less than one-minute.
Prior to surgery, rats were trained on a three-arm sequence. Post surgery after their performance stabilized, the animals were tested under muscimol and control conditions. Initial results indicate that medial prefrontal cortex inactivation impaired performance for even the first session. Hippocampal inactivation had much less of an impact on performance. The complete finding and implications will be presented and discussed within the context of temporal processing.

Title: Influence of the social environment on the behavior of rat pairs exploring a novel open field

Authors: *L. HORBAL, S. AHMED, S. LEE, E. J. MARKUS;
Dept. of Psychological Sciences, Behavioral Neurosci. Div., Univ. of Connecticut, Storrs, CT

Abstract: Exploration of a new environment is an essential component of animal behavior, providing potentially crucial information regarding sources of food, shelter, and a mates. The manner in which rats explore a novel environment has been examined previously using the open field task. Recent work by Weiss and colleagues indicates that rats may explore familiar arenas differently in the presence of another rat (Weiss et al., Animal Cognition, 2015 18(1), 39-51). They reported rats acting as either the “leader” or “follower”, where the leader primarily explores, while the follower is focused on the behavior of the leader. We sought to further examine differences in behavior between single rats and dyads during the exploration of an environment novel to the animals. Nine month-old male F344 rats (Harlan, IN), on a 12hr light/dark cycle with free access to food and water. Animal were paired for 10 days prior to and throughout testing. The open field exploration was assessed using a Plexiglas enclosure (70.5cm L X 70.5cm W) with a white plastic floor of the same area. During experimental trials, either one or two rats were placed in the southeast corner of the open field, and allowed to explore for fifteen minutes. The positions of the subjects within the open field were recorded using SMART-TW video multiple subjects tracking software (Panlab, Spain). The software allowed for tracking of multiple subjects simultaneously, each one physically marked with a different color. The head and back of each rat was tracked separately using two different colors.
Animals were placed in the novel environment either individually or in pairs. The pairs were either cage-mates or “strangers”. Exploration pattern on the first (novel) and second (familiar) days was compared, as was the interactions between the rat pairs.

Title: Cortico-hippocampal neural activity during self-movement: navigating from heading to place

Authors: *W. K. PAGE, C. J. DUFFY;
Dept Neurol, Ctr. Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: Navigation relies on the real-time integration of self-movement cues to update the internal representation of the observer's location in the environment. Environmental vision provides a variety of self-movement cues, most prominently, the radial patterns of visual motion in optic flow that reflect heading direction and environmental layout. Neurons in medial superior temporal cortex (MST) are responsive to optic flow, combining those responses with visual signals derived from the relative movement of earth-fixed objects and vestibular signals about self-movement. In contrast, hippocampal neurons are selectively activated when the animal's is in a particular room location, with the net effect of creating a hippocampal map of extrapersonal space. We hypothesize that MST's self-movement responses are integrated to generate a hippocampal representation of extrapersonal spatial location. To test this hypothesis, we trained monkeys in an active steering to location task and recorded neural activity in MST and hippocampus. The monkey's chair was mounted on a room-sized, motorized, 2-axis translational sled. The monkey had free-viewing of the room and of a small video display which simulated a top-down view of the room. The video display could indicate the monkey's current room position and the current goal location. The monkey used a 2D joystick to steer sled movement, attain the target goal location, and earn liquid reward. Neural signals were recorded during and between self-movement excursions. MST cortical and hippocampal single neurons, and intracranial evoked potentials, were recorded during stroboscopic and continual room illumination. We find that the stroboscopic illumination yields ERPs reflecting self-movement. Continual illumination shows MST neuronal responses to self-movement whereas hippocampal neurons show room location dependent activity. These findings suggest that MSTd neurons are well-suited to providing self-movement signals supporting hippocampal place activity.

Title: Strategy-specific patterns of Arc expression in the hippocampus and retrosplenial cortex during T-maze learning

Authors: *R. CZAJKOWSKI[1], B. ZGLINICKI[2], E. REJMAK[1], W. KONOPKA[2];
[1]Mol. and Cell. Neurobio., [2]Neurobio. Ctr., Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Spatial memory depends on several interconnected brain regions with spatially tuned neurons. Hippocampus harbors place cells that form the spatial map of the environment. Retrosplenial cortex (RSC) contains neurons that process information about the direction (head direction cells). The precise function of RSC in the spatial memory network is still a matter of debate. T-maze is one of the most commonly used behavioral tasks that allow testing rodent spatial memory and navigation. In the first phase of each training trial the animal is forced to make a turn into selected arm and collect a reward. In the second phase, both arms are open and only the previously unvisited arm is rewarded. We modified the T Maze design in order to increase the dependency on allothetic, extramaze cues. Walls were made of transparent plexiglass and a large projection screen was placed in front of the maze. Animals were trained to follow two sequences (right-left or left-right) based on two images projected onto the screen (context A or B, respectively). Almost all animals (13 out of 14) learned to perform both versions of the task within 16 sessions (8 trials per session). During the test phase, the context was replaced between forced and choice phase. In half of the animals (7 out of 13) this resulted in revisiting the arm, consistently with the changed spatial cues. 48 hours later the animals were subjected to one regular trial in each of the contexts with 18 minutes interval between trials. 2 minutes after second trial animals were sacrificed and brains were processed for in situ hybridization (catFISH) with a probe for immediate early gene Arc. The number of Arc-positive nuclei (activated only in trial 2) and double positive cells (nucleus and cytoplasm, activated in both trials) was counted for RSC and hippocampal regions: dentate gyrus, CA1 and CA3. The overall number of Arc positive nuclei was significantly higher in the animals that did not follow spatial cues in both agranular RSC (6.82% vs 3.25%, $p<0.05$) and in granular RSC (4.43% vs 1.86%, $p<0.05$). There were no differences observed in dentate gyrus, CA1 or CA3. No differences in the level of overlap between cytoplasm and nuclei labeling was observed in any of the regions, except for CA3 where higher overlap between context representations was observed

for animals expressing the non-spatial strategy ($p<0.05$). Since Arc is commonly associated with learning – dependent plasticity, these results suggest that the non-spatial animals were acquiring the spatial strategy (high level of Arc in RSC) and the spatial representations for both contexts were still indistinguishable in the non-spatial animals (high overlap of Ctx A and B).

Title: Cholecystokinin from the entorhinal cortex switches high-frequency-induced long-term potentiation in the hippocampus

Authors: *J. SU[1], W. YE[2], X. CHEN[1], H. FENG[1], P. JANDRICHOVSKY[1], J. HE[1]; [1]City Univ. of Hong Kong, Hong Kong SAR, China; [2]Guangzhou Inst. of Biomedicine and Health, Chinese Acad. of Sci., Guangzhou, China

Abstract: Our earlier studies showed that activation of cholecystokinin (CCK) neurons that originated from the entorhinal cortex induce long-term potentiation and neuroplasticity in the auditory cortex. Lesions in the entorhinal cortex or the hippocampus will lead to memory deficits which have received intensive studies, including temporal, spatial, episodic memory, as well as associative fear conditioning. After AAV-DIO-ChR2-eYFP injected into the entorhinal cortex of the CCK-Cre mouse, we discovered that entorhinal CCK neurons project to hippocampus

regions. We hypothesized that CCK is involved in the high-frequency stimulation induced long-term potentiation (LTP). High-frequency electrical stimulation (in Theta Burst format) in Schaffer collateral induced CA3-CA1 LTP on the wild-type mouse and CCK B-receptor knockout (CCK-BR KO) mouse, but not on the CCK peptide knockout mouse (CCK-KO). It was interesting to note that the hippocampus has many CCK A-receptors (ref. Allen Brain Atlas), which might be the reason of why CCK-BR-KO still has High-frequency stimulation induced LTP. The CCK-KO mouse exhibited severe fear memory and spatial memory deficit. On the CCK-Cre mouse with injection of AAV-DIO-ChR2-eYFP in the entorhinal cortex, we induced CA3-CA1 LTP with Low-frequency electrical stimulation on Schaffer collateral after High-frequency laser stimulation of the projection terminals originated from the entorhinal cortex. We explain that High-frequency stimulation of the CCK terminals induced CCK release in hippocampus, and LF stimulation could induce LTP in the presence of CCK.

Title: *In vivo* identification of brain structures implicated in spatial learning and memory, and its modulation by emotional drive in mice

Authors: *S. ALMEIDA-CORREA[1], B. T. BEDENK[2], A. GENEWSKY[1], S. A. BURA[1], J. DINE[1], M. CZISCH[1], C. T. WOTJAK[1];
[1]Stress Neurobio. and Neurogenetics, [2]Max Planck Inst. of Psychiatry, Muenchen, Germany

Abstract: Cognition might be impaired during negative affect. Specially, hippocampus-dependent memories, such as spatial learning, can be dramatically disrupted by emotional drive. Most information concerning this matter is based on *ex vivo* analyses. Given the impact of these impairments at the individual's life, it is important to understand the interplay between emotion and cognition *in vivo*. With that in mind we aim to investigate the role of emotionality on cognitive performance in the water cross maze (WCM), to identify the brain structures involved in these processes and to demonstrate their mutual interaction. Specifically, (i) we performed *in vivo* identification of brain structures involved in hippocampus-dependent (place based) versus

hippocampus-independent (response based) spatial learning, through MEMRI analyses after WCM training; (ii) we will compare these *in vivo* (MEMRI) data and *ex vivo* (IEG) analyses of neural activity for learning, to complement the dissection of neuronal populations implicated in the different spatial learning strategies; (iii) validate the causal involvement of (a) the brain structures identified in spatial learning, with particular emphasis on consequences of the modulation of activity (though DREADDs) in brain structures implicated in stress and anxiety (i.e. amygdala) and memory (i.e. hippocampus); (b) of neuronal circuits in emotional control of spatial learning (pathway analysis), through optogenetics, in specific targets, previously identified by MEMRI. We believe that these investigations will contribute to the understanding of the impact of emotionality on cognition, therefore elucidating some basic aspects of psychiatry disorders in which these detrimental effects of persistent arousal are present.

Title: Modulation of primary motor cortex inhibition during motor imagery

Authors: *F. LEBON[1], C. STINEAR[2], C. PAPAXANTHIS[1];
[1]INSERM U1093, DIJON, France; [2]Med., Univ. of Auckland, Auckland, New Zealand

Abstract: Motor imagery is a specific cognitive state during which the corticomotor system is specifically involved. However, one paradox remains unsolved: how the facilitation of the corticomotor pathway during motor imagery does not produce descending motor output? One hypothesis is that inhibition is recruited during motor imagery to prevent descending motor output (Jeannerod, 1994). An alternative explanation is that during motor imagery the level of activation is insufficient to produce a descending motor command (Guillot et al., 2012).
We used transcranial magnetic stimulation (TMS) to probe the modulation of inhibitory circuits within the primary motor cortex at rest and during imagined movement of the index finger of the right hand (electromyographic electrodes positioned on the First Dorsal Interosseus muscle). Single-pulse TMS was delivered over the left hemisphere to assess corticomotor excitability. Paired-pulse TMS with 2 ms and 100 ms inter-stimulus intervals was used to assess short-interval intracortical inhibition (SICI) and long-interval intracortical inhibition (LICI), respectively. Finally, we stimulated the median nerve 23 ms prior to single and paired-pulse

TMS to test the effect of low-threshold peripheral nerve stimulation on cortical processes by measuring short-interval afferent inhibition (SAI).
As expected, motor imagery increased corticomotor excitability and reduced SICI (Lebon et al., 2012; Stinear et al., 2004). We also found that motor imagery decreased LICI, demonstrating that this cognitive process acts on both fast and slow inhibitory neural mechanisms within the primary motor cortex. Then, we tested the same mechanisms with stimulation of the median nerve to elicit afferent inputs. We replicated previous results showing the presence of SAI at rest: the conditioning peripheral nerve stimulation decreased single-pulse MEPs (motor-evoked potentials) and reduced SICI and LICI (Udupa et al., 2009 and 2014). Interestingly, motor imagery reduced the inhibitory effects of SAI in comparison to rest: greater single-pulse MEPs and greater SICI and LICI. This would mean that the activation of sensory brain areas observed during motor imagery (Hetu et al., 2012) may block the effect of afferent inputs onto motor cortex.
While the increase of corticomotor excitability during motor imagery may originate from the reduction of intracortical inhibitory mechanisms (SICI and LICI), the concomitant activation of associated motor brain areas, such as the sensory cortex, may reduce this activity to prevent descending motor output, and therefore actual execution.

Title: Body schema boundaries are formed by sensorimotor body-environment distinction.

Authors: ***M. DOBRICKI**[1], B. J. MOHLER[2];
[1]Dept. of Psychology, Univ. of Wuerzburg, Wuerzburg, Germany; [2]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany

Abstract: The basic self-perception of being a body that is delimited and in this sense distinct from the environment should be defined by the boundaries of the body schema. The body schema was and is extensively investigated in humans, e.g., in studies on neurological disorders,

as well as in animals, e.g., in studies on somatosensory receptive fields. Yet, it was so far not investigated how the boundaries of the body schema are formed. We have investigated if these subjective body boundaries result from the distinction of body and environment sensations regarding their predictability by the motor representation of active bodily self-motion. In a first study, we enabled healthy humans to control with their physical body a life-sized virtual body that was mirroring their movements in extrapersonal space. In a second study, we asked human subjects to control either such a mirror-avatar or one that was additionally unpredictably shaking. We found that the remote motor control of the mirror-avatar caused the body schema boundaries to decline while inhibiting the distinction of auto-kinesthetic sensations that are, and visual motion sensations that are not, directly predicted by the motor representation of active bodily self-motion. This sensorimotor body-environment distinction was instead intensified by the remote motor control of the shaking-avatar, which fortified the body schema boundaries. Our findings suggest that the distinction of sensations that are, and those that are not, directly predicted by motor representation based on their motor predictability is forming the human body schema boundaries. This sensorimotor body-environment distinction corresponds to the previously suggested self-world distinction that is regarded as fundamental for motor control to arise from sensorimotor integration and for body self-perception in general. Such a sensorimotor distinction and the body schema boundaries that it forms may accordingly affect the sense of agency and various other body self-perception components such as the sense of bodily self-identification and self-location.

Title: Virtual embodiment enhances brain motor resonance mechanisms

Authors: ***M. SLATER**[1,2], M. GONZALEZ-FRANCO[3], J. ARROYO-PALACIOS[3], R. KATZ[4], A. RODRIGUEZ-FORNELLS[1];
[1]Icrea-University of Barcelona, Barcelona, Spain; [2]Computer Sci., Univ. Col. London, London, United Kingdom; [3]Univ. of Barcelona, Barcelona, Spain; [4]Univ. of Utrecht, Utrecht, Netherlands

Abstract: Introduction: Using immersive virtual reality (IVR) it is possible to visually substitute a person's body by a life-sized virtual body (VB), seen from first person perspective (1PP), and which moves synchronously and in conformity with a person's real movements, as seen through a head-tracked head-mounted display (HMD), and real-time motion capture. Such a setup has been used to investigate body ownership and illusory agency, where participants attribute actions of the VB to themselves. We carried out an experiment to explore aspects of brain activity (surface EEG signals) when a virtual arm moves. The objective was to understand the relationship between real, and virtual arm movements. Given that previous research has shown that the mirror neuron mechanisms are more active from 1PP our hypothesis was that VB ownership might increase those effects.
Method: The experiment had 4 conditions: Motor execution in VR (ME1PP): participants performed the motor action with each arm in turn, while the virtual arm moved synchronously, with the VB seen from 1PP. Motor observation in 1PP (MO1PP): participants saw their VB from 1PP, and observed the motor action while not moving themselves. Motor observation in 3PP (MO3PP): participants saw the VB from third person perspective (3PP) and observed the motor action while not moving themselves. Real arm observation (RME): participants performed the motor execution looking at their real body without VR. In each case the left and right arm moved 80 times. There was a 64-multichannel EEG recording (amplifier g.Tec Medical Engineering). There were 18 right-handed healthy male participants who completed all 4 conditions.
Results: The lateralized readiness potential (LRP) was studied as it is a sensitive marker of motor execution and it has been previously associated with the activation of the mirror neuron system. A significant increase in the amplitude of the LRP was found for both motor execution conditions (RME and ME1PP). Importantly, no differences were observed between these conditions indicating that the LRP was equivalent in the real virtual environment during action execution (notice that in both cases participants were moving their arms). Although the amplitude of the LRP during the observation conditions is reduced compared to the real execution conditions, the MO1PP has an earlier activation (onset latency) than the MO3PP condition, being more aligned with the temporal dynamics observed in the case of the real motor execution.
Conclusion: This suggests that strong body ownership while observing the virtual arm moving may contribute towards motor resonance mechanisms.

Title: The right temporoparietal junction encodes efforts of others during action observation

Authors: ***N. MIZUGUCHI**[1,2,3], H. NAKATA[4], K. KANOSUE[3];
[1]Keio Univ., Yokohama-Shi, Japan; [2]The Japan Society for the Promotion of Sci., Chiyoda-ku, Japan; [3]Fac. of Sport Sci., Waseda Univ., Tokorozawa, Japan; [4]Fac. of Human Life and Envrn., Nara Women's Univ., Nara, Japan

Abstract: Smooth social interactions require a deep understanding of others' intentions and feelings. In the present study, to investigate brain regions that respond to inference of others' effort level, we recorded brain activity during action observation of different effort levels using functional magnetic resonance imaging (fMRI). We used a dumbbell curl movement to depict a movement requiring effort. To dissociate the factors of effort level of the actor and weight of the dumbbell, we used four combinations of dumbbell weight and actor physique: a thin actor or a built actor lifting a heavy or light dumbbell. During observation of dumbbell curls, the bilateral front-parietal action observation network (AON) was activated. This included the premotor cortices, parietal cortices, visual areas 5/superior temporal cortices (STS), amygdalae, hippocampi, right dorsolateral and ventrolateral frontal cortices. When we evaluated brain regions associated with the actor's effort level, activity in the right temporoparietal junction (TPJ) and STS was observed. However, activity in the front-parietal AON was independent of the actor's effort during action observation. This finding suggests that the right TPJ and STS play an important role in the inference of others' effort levels during the observation of others' movements.

Title: Spectral fingerprint of heartbeat-related brain responses in the human somatosensory cortex revealed by ECoG

Authors: *M. J. KERN, F. MANZOURI, A. SCHULZE-BONHAGE, T. BALL;
Epilepsy Ctr., Univ. Med. Ctr. Freiburg, Freiburg, Germany

Abstract: Introduction: The cortical processing of cardiac action-related activity is an important viscero-afferent process in the human brain. Consequently, the investigation of heartbeat-related brain responses, especially in the context of heartbeat perception, has become a prominent topic in neuroscience research. Just recently, for the first time a focally localized cortical heartbeat-evoked potential (HEP) within the human primary sensory cortex and its precise time course were described in ECoG (Kern et al., 2013). Although the HEP is well described in the time domain, there is a lack of data on its fingerprint in the frequency domain. Hence, the aim of this study was to characterize heartbeat-related brain responses by ECoG, especially in the frequency domain.
Methods: For the analysis of heart cycle-related ECoG changes, we used heartbeats from recordings of epilepsy patients during natural behavior. A large number of heartbeats (up to ~7000 per patient) were used, without additional burden on the patients, allowing a heart-rate-dependent analysis. For the time frequency analysis, we used a multi tapered time resolved fast Fourier transformation.
Results: First, we replicated our results from 2013 and detected HEPs in the primary sensory cortex in several additional patients. Second, we observed a negative correlation of heart rate and HEP amplitude, while the time course of the HEP remained unaffected. Third, our new findings revealed a prominent heartbeat-related changes in the alpha (8-13Hz), beta (15-35Hz), and gamma (>50Hz) frequency bands within the primary sensory cortex. The spatiotemporal pattern of the heartbeat-related spectral magnitude changes was in good accordance with the pattern of HEPs and its magnitudes were also negatively correlated to the heart rate.
Conclusions: Our findings indicate the existence of heartbeat-related neuronal signals in the alpha, beta, and gamma frequency domain, and with a topography further supporting the hypothesis of cardiac-related information processing via a somatosensory pathway. These signals existed although the patients were not specifically instructed to either try to perceive their heartbeats or to ignore it. Thus, the processing of cardiac-related information seems to unconsciously proceed in natural, non-experimental conditions and manifests itself in distinct cortical responses both in the time and frequency domains.

Title: Mind-wandering in sensory cortices

Authors: ***S.-M. HUNG**, P.-J. HSIEH;
Neurosci. and Behavioural Disorders Programme, Duke-Nus Med. Sch., Singapore, Singapore

Abstract: Mind-wandering occupies a significant amount of our waking time and has been shown to be detrimental to task performance. However, the nature of mind-wandering and its relationship to sensory cortices remain elusive. Here we utilized fMRI and online thought sampling to examine the neural correlates of mind-wandering. Specifically, the thought sampling procedure probed participants to report mind-wandering events and their corresponding modalities (e.g. visual/auditory) while they underwent a fixation task during scanning. The 9-second period prior to each probe was extracted and labeled as mind-wandering or non-mind-wandering events, depending on how focused they were on the fixation task. Whole brain analysis comparing mind-wandering versus non-mind-wandering events showed stronger mean BOLD (blood-oxygen-level dependent) activation in regions involved in the default mode network, including posterior and anterior cingulate cortices. Critically, when we compared events in which participants reported having visual-only or auditory-only contents, visual cortex (i.e. Cuneus) and auditory cortex (i.e. Transverse temporal gyrus) were more activated, respectively. Furthermore, early visual cortex (i.e. v1) exhibited distinct pattern activity and stronger mean BOLD activation when comparing events with visual contents to non-mind-wandering events. Our results suggest a strong link between mind-wandering and sensory cortices as mind-wandering of specific sensory contents recruits its corresponding sensory cortices.

Title: Hypnotic states induce high-frequency power changes (70-140 Hz) in the default mode network

Authors: *J. CORLIER[1,2], C. BERNARD[3], C. FLAMAND-ROZE[3], V. BOUILLERET[3], V. NAVARRO[1,2,4], I. CELESTIN-LHOPITEAU[3,5], M. LE VAN QUYEN[1,2];

Abstract: Hypnotic suggestion is being increasingly used clinically, especially because of its efficacy in stress, anxiety and pain management [1]. Recent works suggest that hypnosis produces alterations in the default mode network (DMN), probably related to the changes in self-referential processing [2]. In this study, our aim was to investigate the fine-scale temporal dynamics of local-field potentials within the DMN during hypnosis. Taking advantage of invasive intracerebral recordings of epileptic patients undergoing a diagnostic evaluation in a presurgical context, we recorded in total from 10 patients and 690 fronto-temporal cortical sites, while the patients were undergoing a hypnotic induction by an experienced hypnotherapist. Focusing on the high-gamma power (HGP, 70-140 Hz that was previously shown to reflect changes in DMN-activity, [3]) and following the subdivision of the DMN into distinct functional-anatomic components proposed by [4], our results show: 1) a reduction of HGP in medial frontal components of the DMN, possibly reflecting a reduction in self-referential cognitive activity, 2) increases in HGP in the medial temporal DMN-component, presumably reflecting increased retrieval of autobiographic memories or imaginary scenarios; 3) increase of HGP at fronto-parietal locations of the attentional network indicating a progressive absorption during the hypnotic induction and also 4) HGP changes in the amygdala suggesting changes in emotional processing. In sum, our findings indicate that hypnosis has a modulatory effect on regions processing explicit cognitive control, memory recall, emotional and attentional processing. Selective targeting of these changes may be used to improve outcome in psychotherapy, pain control or in learning and memory function [5].References: [1] Patterson &

Title: Individual differences in unconscious processing capacity

Authors: *N. ROOT[1], A. RASHEED[2], V. RAMACHANDRAN[2];
[1]Univ. of California San Diego, LA Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: Experimenters have used a variety of masking techniques to demonstrate the presence or absence of unconscious processing. There is a growing body of evidence that the degree to which a stimulus is processed without conscious awareness depends on the choice of masking technique. Could there also be individual differences in the degree to which a stimulus is processed unconsciously? We replicate three unconscious semantic priming studies that used different masking techniques - Continuous Flash Suppression (CFS), object substitution masking, and the attentional blink - administered in counterbalanced order to the same group of subjects. We found a main effect of masking technique; for example, there was evidence for unconscious priming under object substitution, but not under CFS. The typical interpretation of this result would be that unconscious semantic priming does not occur under CFS. However, this null effect of the prime is the mean of a distribution; i.e., data are averaged across subject at some point in the analysis. We instead looked at the within-subject correlation of effect size across different choices of masking technique choice. The amount of unconscious priming a subject experienced in each suppression technique was significantly correlated. In other words, it is possible that the distribution of unconscious priming effects in an experiment yielding a null effect of unconscious priming is not entirely a result of random noise, but instead a combination of random noise and individual differences in amount of unconscious processing or susceptibility to various types of masking.

Title: The fade in consciousness in anesthesia is associated with loss of deterministic responses to transcranial magnetic stimulation

Authors: *M. DARRACQ[1], M. BOLY[2], O. GOSSERIES[2], M.-A. BRUNO[3], V. BONHOMME[3], J.-F. BRICHANT[4], M. ROSANOVA[5], S. LAUREYS[3], G. TONONI[2], M. MASSIMINI[5], R. D. SANDERS[2];

Abstract: Phase Locking Factor (PLF, also known as inter-trial coherence) analysis of Transcranial Magnetic Stimulation electroencephalography (TMS-EEG) provides an index of deterministic phase-locked cortical activity. We hypothesized that relative to wake, average PLF calculated across the scalp would fade under anesthesia with ketamine and propofol. However, ketamine and propofol have distinct anesthetic profiles. While both induce unresponsiveness, in this setting propofol is associated with unconsciousness while ketamine is associated with dreaming (disconnected consciousness). Hence we further hypothesized that if consciousness is a graded phenomenon, the fade in PLF would be greater for propofol than ketamine. We calculated the change in PLF following TMS, directed at the superior parietal gyrus, compared to baseline (assuming a Rayleigh distribution of baseline values between -400 to -50ms before TMS pulse [$p<0.05$]) over 60 EEG channels. We averaged the function of PLF over time for all channels per subject (propofol n = 8; ketamine n = 6) per condition and computed the area under the curve (PLF-AUC, integral). Group level contrasts were conducted using paired t-tests for wake versus propofol, and wake versus ketamine. Data are presented as mean ± standard deviation. The paired t-test contrasts show that propofol (wake 101 ± 50, propofol 11 ± 8, $p=0.0007$) and ketamine (wake 72 ± 39, ketamine 39 ± 15, $p = 0.0337$) decreased PLF-AUC relative to wake. Next we contrasted the drug effects through analysis of the proportional change in PLF-AUC induced by the drug from wakefulness (to eliminate heterogeneity in wakeful values) using an unpaired T-test. While both ketamine and propofol decreased PLF-AUC, the propofol effect was more profound (90±7% vs. 49±27%, $p = 0.0127$). Anesthetics decrease average scalp PLF-AUC in a graded manner consistent with their graded effect of consciousness. Such a metric could have clinical utility in detection of anesthesia awareness. Furthermore the graded changes observed are consistent with the idea that consciousness fades, rather than shatters, under anesthesia. Preliminary tests suggest that PLF-AUC under ketamine and propofol is an index robust enough to measure changes using a reduced group of electrodes, implying the possibility of studying the spatial heterogeneity of the fade in PLF across these states.

Title: Loss of cross frequency coupling and hierarchical cortical connectivity in propofol-induced unresponsiveness.

Authors: *R. D. SANDERS[1], M. DARRACQ[1], O. GOSSERIES[2], M. BRUNO[2], V. BONHOMME[2], J. BRICHANT[2], M. ROSANOVA[3], R. MORAN[4], M. I. BANKS[1], G. TONONI[1], M. MASSIMINI[3], S. LAUREYS[2], M. BOLY[1];
[1]Univ. of Wisconsin, Madison, Madison, WI; [2]Coma Sci. Group, Liege, Belgium; [3]Univ. of Milan, Milan, Italy; [4]Virginia Tech. Carillion, Richmond, VA

Abstract: We hypothesized that the fade in consciousness that occurs under anesthesia involves impaired cross-frequency coupling and connectivity between hierarchical levels of cortex. This was tested using dynamic causal modelling (DCM) of occipital Transcranial Magnetic Stimulation electroencephalogram (TMS-EEG) data to model direct activation of a cortical network involved in perception and imagery and the subsequent integration of information between cortical areas. Eight subjects underwent occipital TMS-EEG recording during wakefulness followed by propofol titrated until loss of responsiveness to verbal command. TMS-EEG data were finite impulse response filtered at 0.5-40Hz, epoched, referenced to an averaged electrode, followed by sensor space, time frequency analysis. Merged data then underwent beamformer source reconstruction followed by DCM of the induced response from 1 to 400ms. Bayesian model selection (BMS) was used to optimize models for the analysis. DCM of the induced response employed an equivalent current dipole electromagnetic model. BMS supported full modulation of all connections between lower order inferior occipital gyrus (IOG) and higher order parietal (superior parietal lobule, SPL) and frontal sources (dorsolateral prefrontal cortex) and non-linear and linear cross frequency coupling. Statistical thresholds were set at Family Wise Error rate $p<0.05$. Sensor- and source-based time frequency analyses showed that propofol reduced evoked power following TMS at different frequencies in different regions. DCM, with full factorial analysis and F contrast across all connections, indicated that propofol-induced

unresponsiveness was associated with altered gamma and alpha-gamma cross frequency coupling. The change in gamma coupling involved an increase in ascending connectivity from IOG to SPL but decreased coupling across all descending connections. In contrast, the decreased alpha-gamma coupling involved ascending connections. Subsequent T contrasts for decreases in ascending and descending connectivity confirmed that descending connectivity was impaired in the gamma range while alpha-gamma ascending connectivity was impaired. Propofol-induced unresponsiveness was associated with spatial variation in evoked power, altered cross frequency coupling and disturbed bidirectional connectivity between hierarchical cortical areas. These data support theoretical advances suggesting consciousness fades during anesthesia due to altered integration of information between hierarchical levels of cortex.

Title: Default mode network activity analysis during self-contemplating image formation

Authors: *D. GUPTA[1], Q. MENG[1], E. HONG[2], F.-S. CHOA[1];
[1]Computer Sci. and Electrical Engin., Univ. of Maryland Baltimore County, Halethorpe, MD;
[2]Univ. of Maryland Sch. of Med. and Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: The wakeful resting condition is characterized by a default mode of brain function involving high levels of activity within a functionally connected network of brain regions. Studies indicate that this Default Mode Network (DMN) is the brain's baseline of information processing. Its activation represents how our brains consolidate experience and prepare to react to the outside environment, separate from the activity of conscious thought. Hence, DMN helps us make sense of our surrounding environment. Other work implicates that the associated cortical regions for contemplation and mind wandering, is essential for our consciousness and they bear thoughts not directly related to immediate external sensory inputs. In this work, we study and analyze the DMN using Electroencephalography (EEG), which provides higher temporal resolution as compared with other techniques such as PET and fMRI. This allows us to study the dynamics of different bands of brain-waves in DMN operations at the millisecond scale. In our study, subjects were asked to sit down quietly on a chair with eyes closed and think

about some parts of their own body, such as left and right hands, left and right ears, lips and nose etc. The moment when the image was formed in the subject's mind, he or she will mark the time. Next, the recorded brain electrical activity maps, 300ms prior to the time marked instant, were analyzed for each of the 4 wave bands namely, Delta, Theta, Alpha and Beta waves. We found that for most EEG datasets during this 300ms, Delta wave's activity lied mostly at the frontal lobe or the visual cortex and its movement across these brain regions were slow. On the other hand, theta wave's activity rotated along the edge of cortex in a clockwise and counterclockwise fashion. Furthermore, Beta wave acted as inquiry types of oscillations between any two regions of the cortex. Lastly, Alpha wave's activity looked like a mix of the Theta and Beta wave's activities along similarity with that of the Theta wave's activity. From these observations, we conclude that Beta and high Alpha are playing a role in information inquiry within the brain. Whereas, Theta and Alpha waves are more likely to play the role of developing and binding of imagination in the DMN operations.

Title: Graph theoretical analysis of functional connectivity network during breath-counting mindfulness meditation

Authors: ***S. HIWA**[1], M. IIZUKA[2], T. HIROYASU[1];
[1]Fac. of Life and Med. Sci., Doshisha Univ., Kyotanabe-Shi, Kyoto, Japan; [2]Grad. Sch. of Business, Doshisha Univ., Kyoto, Japan

Abstract: Objective: Mindfulness meditation is a way of paying attention to one's experience in an accepting and nonjudgmental way. Practitioners try to observe their current experiences such as emotion, thoughts and sensations inside and around them. It is widely used as means of relaxation and stress reduction. The meditation requires our nonjudgmental observing, but its concept and instructions are often difficult for beginners. In this research, we investigated whether meditation beginners could derive any positive effect even by a simple way of focusing their breathing and counting them.
Methods: Three healthy male adults (average age: 22.33 ± 0.58 years, right-handed) with no experience of meditation were asked to mediate for 5 min in the functional magnetic resonance imaging (fMRI) scanner, by breath counting meditation. Participants performed the meditation

task after 5-min resting period, and closed their eyes consistently in the scanner. ROI-to-ROI functional connectivity was calculated using the functional connectivity toolbox (CONN), based on automatic anatomical labeling (AAL) atlas. Functional connectivity networks during resting and meditation states were analyzed based on graph theoretical measures of network centrality. Results: Analysis of an eigenvector centrality measure revealed that the centrality of five brain regions, superior occipital gyrus, left putamen, left pallidum, right superior temporal gyrus and middle temporal gyrus were differed between resting and meditation states. Superior occipital gyrus and superior temporal gyrus are associated with visual and auditory processing respectively, but their eigenvector centralities were decreased in meditation state compared with resting state. This might suggest that the participants could focus on their breathing, keeping the mind from wandering. Since putamen and palladium are part of basal ganglia and associated with voluntary motor control, the change of centrality of these regions suggested that they affected regulation of the rhythm of breathing. Middle temporal gyrus is related to mind-wandering, so that the meditation might reduce its centrality.
Conclusion: Graph theoretical analysis extracted the change of functional connectivity network from the resting state to the meditation state. Five brain regions, superior occipital gyrus, left putamen, left pallidum, right superior temporal gyrus and middle temporal gyrus were potentially crucial to distinguish between the resting and the meditation states. This result suggested the possibility that even a novice meditator could derive the benefits of meditation by a simple practice of counting the breath.

Title: Functional connectivity in the salience network associated with trait mindfulness

Authors: *E. M. BILEVICIUS[1], S. D. SMITH[3], J. KORNELSEN[2,4];
[1]Physiol. and Pathophysiology, [2]Radiology, Univ. of Manitoba, Winnipeg, MB, Canada; [3]Psychology, Univ. of Winnipeg, Winnipeg, MB, Canada; [4]St. Boniface Hosp. Res., Winnipeg, MB, Canada

Abstract: Resting state networks are comprised of brain structures with activity that is highly correlated over a period of time. Researchers have identified a number of resting state networks in the brain and the salience network (SN) is one such network. It is important for the integration of sensory information and has keys nodes in the insula and anterior cingulate cortex (ACC). The SN's role in sensory integration makes its activity relevant to a number of phenomena including mindfulness. Neuroimaging investigations have looked at the structural and task-based functional changes that accompany mindfulness, which is defined as purposeful attention to moment-to-moment experiences with an accepting and nonjudgmental stance. However, relatively few studies have observed the neural substrates associated with trait mindfulness, an individual's intrinsic or fundamental level of mindfulness. In the current experiment, we examined whether differences in trait mindfulness were related to functional connectivity in the SN. Thirty-two undergraduate students completed the Mindfulness Awareness and Attention Scale (MAAS) on a separate testing session and underwent a 7-minute resting state functional magnetic resonance imaging scan. An independent components analysis was conducted to identify and create functional connectivity maps of the SN. Participants' scores on the MAAS were entered as a covariate to determine how mindfulness influenced functional connectivity within the brain's SN. High MAAS scores were associated with increased functional connectivity in the bilateral anterior and posterior insula and bilateral ACC as well as decreased function connectivity in the precuneus. These findings suggest high trait mindfulness enhances functional connectivity in key nodes of the SN while at the same time decreasing connectivity in a key node of the default mode network (DMN). This is especially interesting as the DMN is associated with mind wandering. These results follow the underlying principles of mindfulness, suggesting this relatively simple mindset is beneficially associated with alterations in the neural pattern of resting state functional connectivity.

Title: Neural correlates of self-criticism and self-praise in healthy participants and their relation to mindfulness and depression

Authors: ***J. LUTZ**[1], U. HERWIG[2], A. BRÜHL[2];
[1]Psychology, Ctr. For Mindfulness and Compassion, CHA, Harvard, Somerville, MA; [2]Dept. of

Psychiatry, Psychotherapy and Psychosomatics, Psychiatric Hospital, Univ. of Zurich, Switzerland, Zurich, Switzerland

Abstract: Self-criticism is a vulnerability factor for depression. The processing of self-criticism encompasses activation in self-related cortical midline regions, emotion-generating regions, such as the amygdala, along with prefrontal regulatory activations in healthy subjects. In contrast, neural and behavioural correlates of self-praise and their relation to depression is less well understood. At the same time, mindfulness, the non-judgemental awareness of experience in the moment, potentially influences the perception and regulation of such self-related emotions. Twenty-three healthy participants (11 women, 12 men, M_{age} = 44.4, *SD* = 11.4) were presented with previously chosen, and thus individually tailored stimuli of self-praise, self-criticism, negative but not self-related trait adjectives and neutral adjectives in a block-designed fMRI experiment. Compared to neutral stimuli, individualized self-criticism and self-praise activated similar frontal and emotion processing areas. Correlation analyses further revealed that people with high mindfulness scores showed decreased DLPFC activity, both during self-criticism and self-praise. Activations during self-criticism but not during self-praise were related to symptoms of depression. Our results suggest that most activation patterns previously reported for self-criticism are present during self-praise and therefore seem to be valence-unspecific. Further, individuals with higher trait mindfulness seems to recruit fewer regulatory resources when facing self-related emotions. Finally, we confirm the clinical relevance of self-criticism for depression, while positive self-appraisals might be more related to measures of resilience.

Title: A brief mindful instruction de-automatizes approach-oriented impulses towards attractive foods: Behavioral and ERP evidence.

Authors: C. BAQUEDANO[1,2,3], V. LOPEZ[1], C. FABAR[1], *D. COSMELLI[1], A. LUTZ[2,3]; [1]Escuela de Psicologia, Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Lyon Neurosci. Res. Center, INSERM U1028, CNRS UMR5292, Lyon, France; [3]Lyon 1 Univ., Lyon, France

Abstract: Being aware that mental events are mere representations and not necessarily an accurate depiction of reality, is one of the key feature of mindfulness meditation. In Western psychology this process has been called decentering, de-reification or cognitive diffusion. Decentering can be opposed to experiential fusion, the process of being lost or totally immersed into the contents of one's mind. Excessive experiential fusion is a hallmark in the prediction of psychological distress, and of several psychiatric disorders such as depression or addictive disorders .

Here we investigated whether a "decentered attitude" compared to an "immersed attitude", as induced by brief instructions, differentially modulate automatic approach-avoidance tendencies when processing visual stimuli. Specifically, we focused on how these instructions modulated impulses towards attractive foods.

In a paradigm adapted from Papies et al 2012, 50 healthy participants saw first neutral and attractive food pictures with either a mindful or immerse attitudes. Then participants performed an Approach-Avoidance Task (AAT) based on these images[7]. Dependent measures include behavioral and salivary volume measures, electroencephalography (EEG, 64 channels), self-report questionnaires, and qualitative interviews.

Replicating Papies et al. 2012, we found reduced automatic bias toward attractive food only in visual stimuli that followed the mindful instruction but not the immersed instruction, as measured by performances in the ATT. We also found that the saliva volume was reduced during the mindful condition compared to the immersed one and that the two instructions differentially impacted N1 early (80ms-120ms) evoked related potentials (ERPs) during AAT.

Overall, these findings suggest that a decentered attitude de-automatizes the approaching bias towards attractive stimuli found during experiential fusion and that this is given by a modulation in an early stage of image processing during the Approach-Avoidance conflict. These findings provide novel information on the mechanisms by which mindfulness-based interventions for food disorders or addiction could strengthen the participants' cognitive capacity to down-regulate craving.

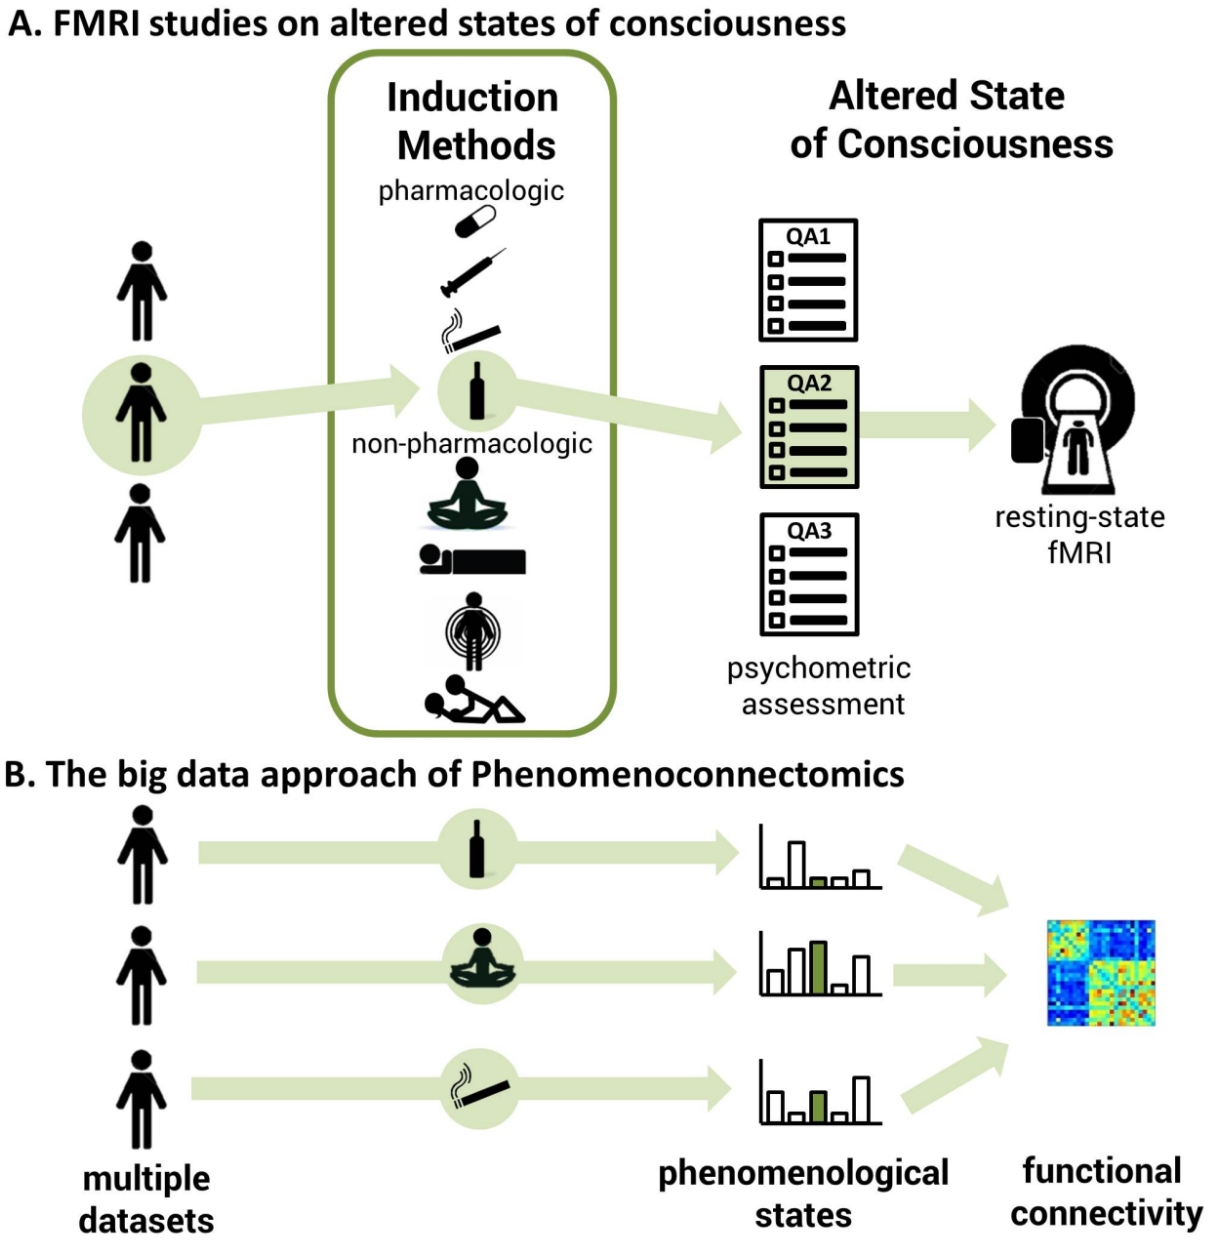
Title: Phenomenoconnectomics

Authors: *T. SCHMIDT;
Inst. of Cognitive Sci., Univ. Osnabrück, Osnabrück, Germany

Abstract: *Phenomenoconnectomics* is a new empirical approach to relate phenomena of subjective experiences to modulations of brain connectivity. Analogous to other Big Data approaches it relies on the joint analysis of data from multiple neuroimaging studies.
Inducing altered states of consciousness (ASCs) within neuroscientific experiments aims to characterize brain mechanisms underlying changes in perception and thinking. Multiple recent fMRI-studies reported changes in functional brain connectivity when psychoactive substances such as LSD were administered. Besides pharmacological treatments, numerous other induction methods for ASCs are available that can be utilized in human research (e.g. meditation- or breathing-techniques). The careful assessment of the subject's phenomenological state with standardized psychometric tools allows the study of similarities in ASCs induced using different techniques. However, individual neuroimaging studies on ASCs are limited to small numbers of subjects. They therefore suffer from low statistical power and often do not allow to map the variability in subjective experiences to underlying brain processes.
Phenomenoconnectomics aims to overcome these limitations by the joint analysis of data from multiple ASC studies. The analysis of changes in functional connectivity in relation to ASC phenomena (e.g. Hallucinations) will allow descriptions such as: "When subjects experience X, the brain network Y exhibits the connectivity pattern Z, independent of how X was induced." Here, I will present the newly developed Altered States of Consciousness Database (ASDB), as the technical framework for *Phenomenoconnectomics*, by providing: (1) an overview on experimentally applicable induction methods for ASCs in humans, (2) a pool of psychometric assessment tools for subjective experiences, (3) meta-analyses on psychometric data for different induction methods of ASCs (years 1960-2016), (4) the computational framework for a Big Data approach to identify changes in functional connectivity patterns related to experiences of ASCs.



A. Multiple recent resting-state fMRI studies explored effects on brain connectivity, when altered states of consciousness (ASC) were induced. Several studies were reported using pharmacological as well as non-pharmacological induction methods (e.g. Trance, Hypnosis). The possibility to identify brain networks that correlate with specific ASC phenomena (e.g. hallucinations, ego disolution, fear etc.) within individual studies are limited, due to induction method specific effects. **B.** The approach of **Phenomenoconnectomics** combines multiple ASC neuroimaging datasets for joint meta-analyses. It allows to dissociate particular phenomena that appear accross differently induced ASCs. The standardized assessment of such phenomena with psychometric tools (questionnaires) allows to relate them to changes in brain connectivity.

Insurance Service Ilsan Hosp., Goyang-si, Korea, Republic of

Abstract: Background: The incidence of delirium is high in ICU as 20~40%, and it is a risk factor to increase the duration of a hospital stay, morbidity, and mortality. However delirium tends to have been overlooked compared to other medical and surgical conditions, because it is thought to be a vitally ‘real’ emergency state or it is difficult to notice the delirium if not in specialized care. The purpose of this study is to exam the effect on clinical outcomes of the delirium notification system. Methods/Design: Since September 12, 2014, our team has performed the “Delirium and Distress Management Project: IDDM Project” to the ICU patients. In this project the psychiatrist evaluated the patients' delirium, anxiety, and pain daily. Since December 1, 2014 the psychiatrists have noticed the delirium state by two methods. One is to hang the sign on the bedside of the patient and the other is to have the warning sign in the electronic medical chart appear. The preliminary analysis of the data was January to March 2014,before operating notice systems were in use, and January to March 2015 after operating notice systems were in use. Result: The severity of medical illness score was higher in 2015 (mean=14.9, SD=10.0) than 2014 (mean 12.5, SD=7.9). Under controlling it as confounding factor, the incidence of delirium, hospital day, and mortality were not different between the two periods. The pain score was showed a statistically significant decrease after the notice than before the notice (2014: mean 2.68, SD 2.35, 2015: mean 2.33, SD 0.80). The anxiety score was also diminished in 2015 (mean 11.29, SD 5.55) compared to 2014 (mean 12.32, SD

5.60).Conclusion The result showed improvement of the clinical outcome of pain and anxiety. Considering the pain and anxiety are the significant factor for affecting delirium, the proper intervention of them might help control the delirium. Our team has been analyzing bigger data for illumination on this subject, and expect more insight on this issue.

Title: Patients with medial orbitofrontal lesions show reduced spatial memory

Authors: ***L. DAHMANI**[1], Y. YANG[1], L. K. FELLOWS[2], V. D. BOHBOT[3];
[1]McGill Univ., Verdun, QC, Canada; [2]Montreal Neurolog. Institute, McGIll Univ., Montreal, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Aim: In a previous study, we found that spatial memory was associated with increased fMRI BOLD activity and grey matter in the medial orbitofrontal cortex (mOFC). To further determine the critical contribution of this region in spatial memory, we investigated spatial memory in patients with mOFC lesions.
Methods: We tested 20 control participants and 16 patients with brain damage to the frontal cortex: 8 patients with mOFC (mOFC+ group) and 8 patients with frontal lesions that did not overlap with the mOFC (mOFC- group). Participants were administered the 4-on-8 virtual maze. In the 4-on-8 virtual maze, participants have to learn the location of 4 target objects among 8 arms. Then, a probe trial is administered in which landmarks are taken away. The probe gives an indication of how much participants relied on landmarks to find the objects and gives an index of spatial memory, as landmark use is a hallmark of the spatial memory strategy. Finally, we administered the Rey Auditory Verbal Learning Test (RAVLT) and the Test of Nonverbal Intelligence-3 (TONI-3) to investigate verbal memory and IQ. We compared the three groups on their navigation strategies as well as their performance on the navigation task and neuropsychological tests.

Results: The mOFC+ group performed better than the control group on the probe trial of the 4-on-8 virtual maze, indicating that they relied less on landmarks. Verbal reports following testing revealed that the mOFC+ group noticed fewer landmarks in the environment than the other two groups. The mOFC- group, on the other hand, showed deficits in learning, regardless of navigation strategies. The mOFC- group also performed worse than the control group on the RAVLT and had lower IQ scores than the other two groups.
Conclusion: We had previously found that spatial memory was associated with increased fMRI BOLD activity and grey matter in the mOFC. In the current study, we confirm the critical contribution of this area as patients with lesions to the mOFC show reduced spatial memory without showing global cognitive deficits. On the other hand, the learning deficits exhibited by the mOFC- group may be due to global cognitive deficits.

Title: Perceptual generalization and category induction are compromised in Alzheimer's disease and semantic dementia

Authors: ***J. S. PHILLIPS**, C. T. MCMILLAN, M. GROSSMAN;
Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Learning of semantic concepts depends on the ability to generalize across details of learning episodes. Low-level generalization requires abstraction from specific episodic details to recognize semantically related but perceptually novel instances of a category. Higher-level generalization involves recognition of supraordinate category relationships between subcategories. We used a visual category learning task to examine perceptual generalization of learned features and the ability to form a new supraordinate category representation. Participants were older adults with normal cognition (n=11), semantic dementia (SD; 6), Alzheimer's disease (AD; 9), or mild cognitive impairment (MCI; n=8), a prodromal phase of AD. Materials were images of fictitious animals that varied on 7 features (e.g., head shape, horns). We hypothesized patients would be impaired relative to controls in all aspects of learning. SD patients were expected to perform worst due to selective anterior temporal lobe atrophy, with lesser deficits for

AD patients, and least impairment in MCI. In Phase 1, participants viewed items from 2 distinct categories ("X" and "Y") one at a time. They matched each item to a model image for the correct category and received immediate feedback. In Phase 2, participants had to categorize perceptually novel exemplars of X and Y categories. Additionally, they had to reject items of a new, third category ("Neither"). Perceptual generalization was assessed as the difference in X and Y accuracy between Phases 1 and 2. Accuracy was highest for controls, followed by MCI, SD, and AD patients. However, controls and MCI patients had decreased accuracy for perceptually novel items, suggesting that initial rejection of perceptual novelty was part of normal generalization. In Phase 3, participants were told that X and Y items should be considered members of a single category, and they should discriminate the joint X/Y category from the Neither category. Category induction was assessed by participants' d-prime scores. Controls discriminated best between Neither and supraordinate X/Y categories, followed by MCI, SD, and AD patients. Results confirmed that perceptual generalization and new category induction are relatively preserved in MCI, but are compromised in SD and AD.

Title: Entorhinal cortical atrophy in asymptomatic APOE4 carriers at risk for Alzheimer's disease

Authors: ***K. KONISHI**[1], R. JOOBER[1], J. POIRIER[1], K. MACDONALD[1], M. CHAKRAVARTY[2], R. PATEL[2], J. BREITNER[1], V. D. BOHBOT[1];
[1]Psychiatry, [2]Biomed. Engin., Douglas Mental Hlth. Univ. Institute, McGill Univ., Verdun, QC, Canada

Abstract: Early detection of Alzheimer's disease (AD) has been challenging as current biomarkers, such as neuroimaging, and measures of amyloid and TAU, are invasive and costly. Strong predictors of future AD diagnosis include lower volume of the hippocampus and

entorhinal cortex. In addition, the ε4 allele of the Apolipoprotein E gene (APOE) gene is the strongest known genetic risk factor for AD. These studies suggest that studying functions that are critically mediated by the hippocampus and entorhinal cortex, such as spatial memory, in APOE-ε4 allele carriers, may be key to the identification of individuals at risk of AD, prior to the manifestation of cognitive impairments. Using a virtual navigation task developed in-house, specifically designed to assess spatial vs non-spatial compensatory strategies, the current study is the first to differentiate APOE-ε4 allele carriers with atrophy in the hippocampus, entorhinal cortex and fimbria from APOE-ε4 allele carriers with grey matter comparable to non-APOE-ε4 allele carriers.

Title: Task difficulty effects on object-location binding memory performance according to gender difference

Authors: ***J. PARK**[1,1], T. KIM[1], Y. M. PARK[1], S. I. KIM[1], I. Y. KIM[1], J. K. KANG[2], J.-J. KIM[3], D. P. JANG[1];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Dept. of Neurol., Asan Meidical Center, Univ. of Ulsan, Seoul, Korea, Republic of; [3]Yonsei Univ. Gangnam Severance Hosp., Seoul, Korea, Republic of

Abstract: Research on sex differences in spatial cognition has reported that there are distinct tests for male-favoring or female-favoring performance. There were sex differences in object-location binding memory performances according to stimulation type and measurement parameters. To investigate the inconsistent results obtained regarding sex differences in object-location memory, we used the fractal objects version of the 'What was where?' task developed by Pertzov et al. to measure object measurement and location memory performance in object-location memory under conditions that reduced the use of verbal strategies. In particular, object-location memory performance was measured by 'swap error'. The 'swap error' is defined as when participants relocate target objects around the locations of other presented objects rather

than at random locations. This 'swap error' is not a simple failure of object identity or object location, but rather indicates failure to bind the object identity and object location in memory. Therefore, this measurement is more sensitive for object-location binding memory performance. The purpose of this study is to investigate sex differences in object-location memory by controlling task difficulty and using more sensitive measurements, including object memory, location memory and object-location binding memory. Females outperformed males on 'swap error' measurement, where an object-location binding memory index was calculated based on the number of times the participants confused an object's location with that of another object. One of our most interesting findings is that the swap error of males increased at a higher rate in difficult sessions compared to females. When only the four-object trials from Session 34 and Session 45 were compared, in which the level of difficulty was presumed to be similar but with varying mental load, the 'swap error' of males was significantly increased in Session 45 compared to females. In conclusion, there may be gender differences in object-location binding memory and the binding memory performance of males could be influenced more by mental or cognitive load than that of females.

Title: Modulation of spatial and response strategies by phase of the menstrual cycle in women tested in a virtual navigation task

Authors: *V. D. BOHBOT[1], D. HUSSAIN[2], S. HANAFI[3], K. KONISHI[3], W. G. BRAKE[2]; [1]Douglas Mental Hlth. Univ. Institute, Dept. of Psychiatry, McGill Uni, Verdun, QC, Canada; [2]Psychology, Concordia Univ., Montreal, QC, Canada; [3]Psychiatry, Douglas Mental Hlth. Univ. Institute, McGill Univ., Verdun, QC, Canada

Abstract: Different memory systems are employed to navigate an environment. It has been consistently shown in rodents that estrogen impacts multiple memory system bias such that low estradiol (E2) is associated with increased use of a striatal-mediated response strategy whereas high E2 increases use of a hippocampal-dependent spatial memory. Low E2 also enhances

performance on a response-based task whereas high E2 levels improve learning on a spatial task. The purpose of the present cross-sectional study was to investigate navigational strategies in young, healthy, naturally cycling women. Participants were split into either an early follicular (i.e., when E2 levels are low), ovulatory (i.e., when E2 levels are high) or mid/late luteal (i.e., end of the cycle, when E2 levels decrease and progesterone levels rise) phase group, using self-reported date of the menstrual cycle. Serum hormone level measurements (E2, progesterone, testosterone) were used to confirm cycle phase assignment. Participants were administered a verbal memory task as well as a virtual navigation task that can be solved by using either a response or spatial strategy. Women tested in the ovulatory phase, under high E2 conditions, performed better on a verbal memory task than women tested during the other phases of the cycle. Interestingly, women tested in the mid/late luteal phase, when progesterone is high, predominantly used a spatial strategy, whereas the opposite pattern was observed in the early follicular and ovulatory groups. Our data suggest that the specific memory system engaged differs depending on the phase of the menstrual cycle and may be mediated by both E2 and progesterone, rather than E2 alone.

Title: Virtual environment human navigation task for assessing spatial cognition and navigation

Authors: ***C. STEVENSON**[1,2,3], A. ELHOSSEINY[4,5], A. DINIZ-FILHO[5], G. CAUWENBERGHS[1,2], F. MEDEIROS[5], E. MACAGNO[3,6];
[1]Bioengineering, [2]Inst. for Neural Computation, [3]California Inst. for Telecommunications and Information Technol. (CalIT2), [4]Computer Sci. and Engin., [5]Ophthalmology, [6]Div. of Biol. Sci., UC San Diego, San Diego, CA

Abstract: In order to perform the wayfinding necessary for efficient navigation, individuals must observe their environments, remember positions and properties of multiple features, and integrate them into a usable representation of the world. Various conditions can detrimentally affect the ability to perform such tasks, including loss of visual acuity or cognitive impairment. It is important to understand how these conditions affect spatial cognition and how we can design spaces to improve individuals functions, particularly as they age.
To study this we have developed the Virtual Environment Human Navigation Task (VE-HuNT). This is an experimental paradigm which uses virtual reality to construct a simulated 3D immersive environment and related experimental tasks to assess various aspects of spatial cognition. VE-HuNT is run on the 4kave, a more cost-effective derivative of the immersive CAVE VR systems, providing a realistic, yet controlled virtual environment within which to perform experiments. VE-HuNT allows researchers to implement a variety of cognitive tasks within a virtual room (or rooms), while monitoring subject progress in real time.
We used VE-HuNT to assess the effects that environmental cues had on individuals abilities to navigate and how subjects learned. Seated subjects used a steering wheel and pedal to move through three virtual rooms, each with a different complement of spatial cues. In each room, the subject was shown a target on the floor somewhere in the room and instructed to move to it. The target was then hidden from view and the task repeated, finding the same location from different start points. We recorded temporal and positional information and used the path data to analyze the abilities and strategies subjects employed to complete the tasks. Traditional metrics of visual and cognitive function were also collected.
From this data we were able to assess the impact that environmental conditions had on path learning, strategies in navigation, and how these were affected by sensory deficits. It was shown that subjects learned the location of the target in each room. Whether or not cues were spatially precise and their relative positions to each other had an effect on the time subjects took to find the target. This effect became more pronounced in subjects with significant visual loss, due to advanced glaucoma. Subjects were also found to use various strategies for finding their location within the room, including visually scanning the room before moving and/or moving to a particular location in the room before proceeding to the target.

Title: Using virtual reality environments to assess context segmentation and spatial memory performance using a 2d and virtual reality test environment.

Authors: *K. M. HORECKA[1,2], M. R. DULAS[3], C. WIDDOWSON[3], N. J. COHEN[3];
[1]Univ. of Illinois at Urbana-Champaign Col. of Liberal Arts and Sci., Urbana, IL; [2]Neurosci., [3]Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Virtual Reality (VR) has been identified as a useful tool in neuropsychological evaluation thanks to its increased control and measurement capabilities over other methods (Schultheis et al, 2002). More recently, evidence shows that along many measures, VR provides similar ecological validity to real environments (Kuliga et al, 2014). One area of research which is particularly amenable to VR paradigms is learning and memory. Previous work has suggested that context-boundaries impact the binding of sequential information, resulting in within-context information being remembered as closer together than across-context information, even when equidistant, i.e. the segmentation effect (DuBrow & Davachi, 2013). The present study explored segmentation effects in spatial memory; a VR spatial navigation task with four contexts (colored rooms) and 4 objects per context was constructed to evaluate how memory for item pair locations within a context differ from pairs which cross contexts. During study, participants were instructed to explore the VR environment (beginning from pseudo-random positions and orientations) and learn locations of all items before being tested on both 2D map and in the VR environment. Measurements of participant position, orientation, and memory for item locations were assessed across four trials. Results showed significant increases in performance (speed, efficiency of movement/orientation, and memory accuracy) across successive training/test trial, as well as a significant difference in memory for the distance between within-context and across-context item pairs, with across-context pairs being remembered as further apart and within-context pairs closer together despite these pairs being equidistant). Additionally, participants showed larger segmentation effects in the 2D testing paradigm than VR. Finally, across all trials, segmentation effects remained relatively stable in VR test, while 2D test showed a significant linear decrease in across-context distances across the trials. These results show that virtual reality can be used successfully in exploring spatial memory and segmentation stability across multiple trials, as well as provide tantalizing new measures which increased spatiotemporal resolution of behavior beyond other existing methods.

Title: Theta oscillations in the human medial temporal lobe during ambulatory movement

Authors: ***Z. M. AGHAJAN**[1,2], P. SCHUETTE[1,2], T. FIELDS[3], M. TRAN[4,5], N. HASULAK[7], T. TCHENG[7], D. ELIASHIV[3], J. STERN[3], I. FRIED[4,5,8], N. SUTHANA[1,2,4,5,6];
[1]Dept. of Psychiatry and Biobehavioral Sci., [2]Semel Inst. for Neurosci. and Human Behavior, [3]Neurol., [4]Neurosurg., [5]David Geffen Sch. of Med., [6]Psychology, UCLA, Los Angeles, CA; [7]NeuroPace, Inc, Mountain View, CA; [8]Functional Neurosurg. Unit, Tel-Aviv Med. Ctr. and Sackler Sch. of Med., Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: Theta oscillations are implicated to play a critical role in learning and memory by coordinating the spiking activity of neuronal ensembles, via mechanisms such as spike timing dependent plasticity. This rhythm has been heavily studied in rodents, where it is continuously present during movement at frequencies within 6-12Hz. In humans, however, a functionally similar theta is thought to occur at lower frequency ranges (3-7Hz) and in shorter bouts. This lower frequency theta rhythm is observed during a variety of behaviors, including virtual navigation (1), but has never been tested during real world ambulatory movement.To examine the oscillatory properties within the human medial temporal lobe (MTL) during movement, we measured hippocampal and entorhinal intracranial EEG (iEEG) from 3 patients with pharmacoresistant epilepsy (two sighted and one congenitally blind) who are chronically implanted with the FDA approved NeuroPace RNS® Neurostimulator. Subjects performed a task in which they walked, following linear and circular paths at various speeds. Positional data was tracked at 60Hz using the Optitrack system with sub-millimeter motion tracking; and iEEG was recorded at 250Hz and stored in the RNS Neurostimulator with an analogue filter equivalent to a 1st order Butterworth with 3db attenuation at the cutoff frequencies (4-90Hz). Electrode localization was performed through co-registration of a high-resolution post-operative CT and high-resolution pre-operative MRI. To characterize significant oscillations within different

frequency ranges, we used the BOSC detection algorithm (2). Episodes with significant oscillations between 3-20Hz (occurring for at least 3 cycles and above 95% chance level) were detected and the percentage of time during which they were present was computed for low and high movement speeds (divided based on the median speed). We found that in all 3 subjects, there was a significant increase in this measure in the theta range typically associated with rodent movement (6.5-9.5Hz, $P<0.05$, $N=72$) during fast movements compared to slow movements. In the sighted patients, these episodes were transient and present ~30% of the time, while this percentage was ~65% in the visually-impaired subject. Our results suggest that higher frequency theta indeed exists in humans during movement. The precise link between this pattern and its behavioral correlates will be an exciting area for future study given this novel methodology for simultaneous motion capture and iEEG recording during ambulatory human behavior.

Abstract: Restoration of memory function using electrical stimulation to modulate activity in the human medial temporal lobe has recently become a focus of considerable interest and stimulating targets such as the fornix[1] and the entorhinal area[2] have shown promise for memory improvement. However, these studies were conducted by applying high amplitude currents via large electrode contacts, which provide limited regional specificity. In this study, we applied low-current 150 μA electrical stimulation in a theta-burst pattern (4 100 Hz pulses at 5 Hz) through 100 μM micro-electrodes to the entorhinal area while participants completed a face recognition memory task.

Patients with pharmacoresistant epilepsy who met clinical criteria were implanted with depth-electrodes in the hippocampus and the entorhinal area for seizure localization. Patients learned an average of 49±7 novel portraits of people on a computer screen during an encoding phase where the number of learned images was based on subject-specific neuropsychological memory scores. Following a distractor task, the same images from the encoding phase (targets) and similar-looking portraits of different people (lures) were presented during a retrieval phase. In the retrieval phase, patients were asked to identify whether the image was NEW or OLD via button press. Trials were classified as *recollected* if the subject correctly identified the target ***and*** correctly rejected the corresponding lure. The right entorhinal area (REA) or the left entorhinal area (LEA) was stimulated during learning preceding half of the trials in a randomized fashion. Memory performance during stimulation and non-stimulation trials was then calculated in 9 patients (N = 9; REA, N = 5; LEA, N = 5) and 16 sessions (n = 16; REA, n = 8; LEA, n= 8). We used the Generalized Estimating Equations (GEE) to model the effects of stimulation and the side of the brain stimulated (REA or LEA) on the number of portraits recollected. Across all trials, the interaction between stimulation condition and the site of stimulation was statistically significant (GEE, $p=0.002$). There was a statistically significant effect of stimulation of the REA on number of pictures recollected (GEE, $p<0.0001$). However, these differences between stimulation and non-stimulation trials were not significant in the LEA for the number of pictures recollected (GEE, $p=0.491$). Taken together, our results show that theta-burst microstimulation of the REA during learning enhances subsequent recollection of novel portraits.

Title: Stimulation of entorhinal white matter enhances declarative memory encoding

Authors: *P. J. SCHUETTE[1,2], M. TRAN[3], A. TITIZ[3], N. TCHEMODANOV[3], E. A. MANKIN[3], Z. M. AGHAJAN[2], D. ELIASHIV[4], J. STERN[4], S. A. WEISS[4], D. KIRSCH[2], B. KNOWLTON[5], I. FRIED[3,6], N. A. SUTHANA[2,3,5];

Unit, Tel-Aviv Med. Ctr. and Sackler Sch. of Med., Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: The medial temporal lobe (MTL), which includes the hippocampus and adjacent entorhinal, perirhinal, and parahippocampal cortices, plays a critical role in the formation of declarative memories (*1*). Intracranial electrical stimulation has shown potential promise for improving hippocampal-dependent memory (*2*), yet little is known about how targeting different areas within the MTL could affect behavior. In this study we sought to determine the specific sites for which such stimulation can improve memory. Based on the functional circuitry of the hippocampal region, we hypothesized that stimulation of the entorhinal white matter during learning would generally improve subsequent memory while adjacent gray matter MTL stimulation during learning would, in fact, impair subsequent memory. Twenty-three patients (*M* age ± *SD*: 34.26 ± 12.34 yrs, 9 female) with pharmacoresistant epilepsy who had been implanted with depth electrodes for clinical evaluation participated in five different declarative memory tasks. High-resolution magnetic resonance imaging (MRI, (*3*)) and automated image segmentation methods (*4*) were used to localize 40 distinct intracranial stimulating electrodes within the MTLs of our participants to entorhinal white matter or adjacent MTL gray matter regions. A performance index was calculated as the percentage difference score for stimulated compared to non-stimulated trials, averaged across all memory tasks for a given electrode region. A positive performance index indicated that memory for stimulated trials was better than non-stimulated trials, while a negative performance index indicated that memory for non-stimulated trials was better than stimulated trials. Our results show that memory performance with white matter stimulation was significantly better than that with gray matter stimulation (N_{gray} = 16; N_{white} = 24; gray *Mdn*, [25th, 75th]: -5.80, [-21.48, 4.06]; white *Mdn*, [25th, 75th]: 20.05, [2.74,

50.72]; $p = .007$, $Z = 2.72$). Additionally, white matter stimulation significantly improved memory ($p = .01$, $Z = 2.58$), while gray matter stimulation showed no statistically significant memory effect ($p = .19$, $Z = -1.31$). The results suggest that stimulation of the entorhinal white matter, presumably the perforant path input to the hippocampus, can enhance declarative memory encoding, while stimulation of neurons in nearby gray matter is ineffective in improving MTL memory function.

Title: Grid cell activity in the human entorhinal cortex scales with the size of virtual environments

Authors: *Z. NADASDY[1,2,3], P. NGUYEN[4], Á. TÖRÖK[5], D. BRIGGS[6,8], J. SHEN[10], P. MODUR[6,9], R. J. BUCHANAN[7,9];

Abstract: The activity of grid cells in the entorhinal cortex of the rodent, primate and human provide a spatial coordinate system that can inform an individual of its location. Grid geometry

in rodents is generally preserved across settings, but has displayed a limited degree of adaptation to certain environmental features. It is possible that the environment's influence on grid geometry varies across species and with evolution. Human subjects implanted with entorhinal cortical electrodes performing virtual navigation tasks enabled us to investigate this in humans, where the environment-grid relationship has not been studied. Here, we report that human entorhinal cortical neurons exhibit changes in grid period, grid geometry, and grid orientation in close association with changes in environment size, shape, and visual cues. Our results demonstrate that the human entorhinal cortex is endowed with an extensive adaptive capacity to incorporate context-dependent factors into its neuronal representations of space.

Title: Weaving in and out of sight: RSC and OPA integrate the current field of view with the remembered 360-degree panorama.

Authors: *C. E. ROBERTSON[1], A. MYNICK[2], K. HERMANN[3], D. KRAVITZ[4], N. KANWISHER[3];
[1]Harvard Society of Fellows, Cambridge, MA; [2]Wellesley Col., Wellesley, MA; [3]MIT, Cambridge, MA; [4]George Washington Univ., Washington, DC

Abstract: How are discrete and fleeting views of a panoramic environment knit into a unified representation in the brain? Here, we probed the psychological and neural mechanisms supporting panoramic visual memory (behavior and fMRI).
Participants were introduced to novel 360° panoramic environments: photospheres of real world locations, either dynamically revealed across a panoramic display or actively explored using a virtual reality headset from a naturalistic, egocentric perspective.
Viewing experience was controlled so that participants viewed either: 1) a contiguous, coherent panoramic scene (two overlapping quarters), 2) a discontiguous panoramic scene (two non-overlapping quarters of the same panorama), or 3) a contiguous, incoherent panoramic scene (a spliced panorama that smoothly morphed between two panoramic scenes).
Exp. 1 (behavior, n=20): We first demonstrate the conditions under which two discrete views from opposite poles of a 360° panoramic environment are associated in memory: non-

overlapping views of a visual environment are linked in memory only if the visual information standing between them is experienced, not by mere spatiotemporal co-occurrence ($p < 0.001$) or transitive association with a third, unrelated view ($p < 0.01$).
Exp. 2 (fMRI, n=12): These findings parallel neural changes: discrete views of a panoramic environment increase in representational similarity in two specific regions of the scene network, the RSC and OPA, as a function of visual memory for the spatial information that unites them (both $p < 0.003$). PPA did not evidence this effect, but did show robust scene- and view-selective responses ($p > 0.93$). These results demonstrate neural representations of the scene within the current field of view are imbued with our memory for the broader panoramic environment.
Exp. 3 (behavior, n=20): Finally, memory for a broad, panoramic environment causes discrete views from within this environment to prime each other in perception. On each trial, participants were shown an image from one of the studied panoramas and asked to remember its spatial position (left/right side of the panorama). The image was primed by either another image from the same panorama (Valid Prime) or a black square (Neutral Prime). We observed significant perceptual priming between scene views from the same panorama (Valid - Neural), as a function of visual memory for their linking spatial information ($p < 0.006$).
Our findings demonstrate that individual perceptual experiences trigger visual memory for the panoramic environment far beyond the current field of view - both in the brain and in perception - helping to support our sense of a seamless panoramic visual expanse.

Title: Translational episodic and episodic-like memory models: paired associate learning vs. what-where-which

Authors: *R. F. LANGSTON, J. DUNCAN, E. MIDDLETON;
Div. of Neurosci. (Mailbox 6), Dundee, United Kingdom

Abstract: Episodic memory testing methods are inconsistent between humans and animals, between clinicians and psychologists, and between age groups being tested. We aim to determine the effects of the theoretical and procedural differences between episodic memory tests commonly used in humans and rodents and create novel standardised protocols that can be used

in both populations, in health and disease and throughout the lifespan. We designed two tests, one based on the clinically used dementia diagnostic Paired Associate Learning (PAL) and the other based on the rodent behavioural test of episodic-like memory, associative what-where-which(WWW) memory. The human test is traditionally screen based and the rodent test is traditionally done with 3D stimuli but we adapted both to a procedurally identical screen version. Participants' reaction times and number of errors in selecting stimuli were recorded. Initial experiments on 83 healthy student volunteers revealed a striking difference in memory performance between the clinically used paired associate learning test and the experimentally used episodic-like memory test. We then went on to study the factors which may govern this difference in difficulty. The presence (WWW) or absence (PAL) of an additional contextual component to the stimulus scene, stimulus presentation (either sequential or concurrent) and memory strategy (recollection or recognition) were identified as the main differences between the two tasks. 60 student volunteers then carried out eight different memory tests with the above variables incorporated in all their possible combinations. The presence of a contextual component (as in WWW) had a significant effect on performance with subjects accumulating more errors in the WWW than the PAL task in their original forms. Forcing the use of a recall strategy (as in PAL) rather than allowing recognition memory to be used (as in WWW) had no effect on performance in either task. The way in which stimuli were presented had a significant effect on performance. Sequentially presented stimuli (as in PAL) resulted in a greater number of errors than concurrent presentation (as in WWW). Participants also provided a confidence score after each response and completed tests at 2 different difficulty levels. Confidence score showed an inverse correlation with difficulty level but not with any other performance measures. Overall the results indicate that the WWW rodent episodic-like memory task is more difficult than the human PAL task, however scores on each did show a positive correlation indicating that they are somewhat comparable.

Title: Reconstructing spatial location and forward planning during navigation

Authors: *J. W. ANTONY, C. BALDASSANO, M. ALY, K. A. NORMAN, N. B. TURK-BROWNE;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: The spatial location of an animal can be reconstructed from the activity of neurons in the hippocampus and other brain regions. Similar regions have been implicated in human spatial processing, but relatively little work has been aimed at reading out exact spatial location. Here we use inverted encoding models applied to high-resolution fMRI data to reconstruct spatial location during both actual and planned navigation. We trained a model with 91 spatial channels that tiled a circular arena in a virtual reality environment while participants searched for a hidden platform. Although circular, the arena contained two visual landmarks on opposing walls that participants could use to orient themselves. Platform locations changed every second trial, forcing participants to search for the platform in an exploratory manner on odd-numbered ("unknown") trials, but allowing them to use memory for the platform location from the previous trial on even-numbered ("known") trials. Critically, this paradigm forced participants to fully explore the environment across trials, generating sufficient data to train the model. We trained voxel-wise weights for each channel using each participant's location data from most of the unknown trials and then performed cross-validation by using these weights to estimate participant location on the held-out trials. We found that spatial location could be reconstructed with above-chance accuracy in early visual cortex and the superior parietal lobule. Next, we asked whether and how participants represent the platform location during planning by applying the trained model to the known trials. We restricted analysis to timepoints during which they were located at the starting point of the environment, before starting to move. Because the location and view were constant across trials during these timepoints, above-chance reconstruction necessarily indicates that a region contains a memory representation of the platform location. In this analysis, we found reliable information about platform location in the left hippocampus. Further analyses examined other features of the task, such as heading direction/orientation and distance to the platform, and sought to quantify receptive field sizes for location and orientation.

Title: Procedural learning with and without feedback are impaired by inhibition of the dorsolateral prefrontal cortex (DLPFC)

Authors: *L. WILKINSON, P. KOSHY, E. EWUL, E. M. WASSERMANN, S. SCHINTU; Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Motor sequence learning is slowed by inhibitory TMS of the primary motor area (M1) contralateral to the performing hand, while motor function remains unchanged. This could be from interference with the reinforcement learning network of cortical and basal ganglia areas or with a network specific for motor learning. The right DLPFC is implicated in procedural learning on the non-motor Weather Prediction Task (WPT) and has its own basal ganglia link. If it supports procedural learning in general or provides access to such a network, inhibitory TMS there should also interfere with motor learning. Enhanced feedback with monetary reward and punishment speeds learning and should increase reliance on the reinforcement learning network. We delivered real continuous theta-burst TMS (cTBS; n= 15) or sham over right DLPFC (n= 15) or sham (n= 20) to two groups before they performed a motor sequence learning (serial reaction time) task in two different sessions, where they learned either with or without monetary reward/punishment, based on response accuracy and reaction time (RT). Subjects trained on two intermixed sequences: one more (85%, probable sequence), one less (15%, improbable sequence), likely to determine cue order. We measured learning as the difference in RT on probable and improbable sequence trials. In each session, subjects were tested for sequence recall 60 minutes after stimulation. Real cTBS impaired initial learning and sequence recall when the task was learned with and without feedback. Moreover, real cTBS abolished the usual improvement in learning seen with monetary reward/punishment. In an earlier study, we did not see this with cTBS delivered to M1. We conclude that the right DLPFC provides TMS access to a network involved in procedural learning under reinforcement conditions.

Title: Resting state connectivity in parietal regions supports visuo-motor skill learning

Authors: *A. L. MANUEL[1], A. G. GUGGISBERG[2], F. TURRI[2], A. SCHNIDER[2];
[1]Dept. of Clin. Neuroscience,Laboratory of Cognitive Neurorehabilitation, [2]Clin. Neurosci., Geneva Univ. Hosp., Geneve, Switzerland

Abstract: Procedural learning, including learning of a visuo-motor skill, is subject to fast training-induced plasticity and to offline consolidation. Improvements are typically seen during the training itself, but also following learning as the skill continues to evolve offline during sleep. The present study investigates how brain connectivity relates to plastic changes during visuo-motor skill learning and to offline consolidation. Twenty healthy participants were assigned to one of two groups: The experimental group performed a computerized mirror-tracing task, in which right-left movements with the mouse were reversed on the screen. The control group performed a similar task but with concordant direction of cursor movements. Comparison of the two groups allows dissociating visuo-motor skill learning from simple motor performance. Participants trained for 15 minutes on Day 1. High-density EEG (156 electrodes) was recorded at rest for both groups before and immediately after training. Subjects were again tested for offline consolidation 24h later. The mirror-tracing group, but not the control group, showed greater tracing accuracy and faster completion time across trials in the training session. The mirror-tracing group, but not the control group, showed offline improvement from Day 1 (last 4 trials) to Day 2 (first 4 trials) in tracing accuracy (31% improvement) and completion time (27% improvement). Connectivity analyses showed increased coherence in the superior right parietal cortex in the alpha-beta range (8-20 Hz) from before to after training on Day 1 for the experimental group and decreased coherence in the same area and bands in the control group. These findings demonstrate the presence of offline consolidation of a visuo-motor skill, but not of simple motor performance. This effect is predicted by performance on Day 1 and associated with augmented connectivity in the right superior parietal cortex during training.

Title: Neurobehavioral validation of an individualized behavioral indicator for the presence of incidental explicit awareness in sequential motor learning

Authors: *R. LAWSON, L. A. WHEATON, J. JOHNSON;
Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: Prior studies have demonstrated that the presence of explicit awareness in motor learning is associated with neural changes, impacts consolidation, and can have detrimental effects on motor performance. However, the majority of these studies utilize an intentional paradigm to study the impact of explicit awareness. Due to the challenging nature of identifying when a subject has incidentally developed awareness, it is currently unknown how this method of developing awareness impacts motor learning and subsequent performance. The aim of this study is to provide neurobehavioral validation of a previously identified indicator for the presence of incidentally developed explicit awareness. Twenty, naïve subjects were exposed to a visuomotor task which contained a seven-key repeating sequence unknown to subjects. Subject response latency and accuracy were recorded and compared to the previously established behavioral threshold for prediction of the presence of awareness. EEG measurements were made concurrently to identify network changes occurring during the task. Changes in coherence were utilized as a neural verification of the network shift expected when a subject shifts motor behavior from an externally guided movement to an internally driven execution of the discovered sequence. Establishing a behavioral indicator of such incidentally developed explicit awareness provides a tool in which to further examine the impact of such awareness in motor learning.

Lab., Aberdeen, MD; [8]Dept. of Psychological and Brain Sci., [7]Univ. of California, Santa Barbara, Santa Barbara, CA; [9]Dept. of Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD

Abstract: Human skill learning is a complex phenomenon requiring coherent communication across distributed networks of cortical and sub-cortical brain regions [1]. The fine-scale temporal coordination of these regions is critically dependent on white matter tracts that form direct anatomical links, allowing effective transmission of information across the brain [2]. We hypothesized that individual variation in white matter tracts subserving inter-cortical circuits activated by skill learning would be correlated with individual differences in the rate at which subjects learned a set of new motor sequences. Subjects were trained on a Discrete Sequence Production task, wherein they practiced a sequence of key presses following a series of visual cues. Subjects practiced both in-scanner and at home for a total of six weeks. For each subject, diffusion-weighted scans were collected at four time points, one prior to training and then three more at following two-week intervals. Deterministic tractrography was performed separately for each scan to generate connectivity matrices representing white matter streamlines linking cortical and sub-cortical brain regions. Due to their critical role in this particular type of learning [3], we focused our examination on broad swaths of motor and visual regions that form functional modules during task execution. We found that increased white matter connectivity linking early visual regions strongly predicts inter-subject differences in rate of learning: greater connectivity being associated with better learning. Moreover, we found that the strength of multi-edge paths between motor and visual modules was also correlated with learning rate, supporting the role of polysynaptic connections in successful skill acquisition. Our results demonstrate that the combination of diffusion imaging and tractography-based connectivity can provide predictive information about individual differences in learning, particularly when combined with network analysis methods.

Title: Neural correlates of focus of attention during golf putting

Authors: *L. SUZUKI, S. K. MEEHAN;
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Verbal instructions have the potential to influence strategies used during motor skill acquisition and improve learning. For instance, the instructions can be worded to promote either an external focus with emphasis on elements of the environment such as the movement of a golf club or an internal focus of attention, that emphasizes elements of the body such as the position of the hands. The superiority of the external focus of instructions has been demonstrated for a variety of tasks but the brain correlates associated with each type of instructions remain unknown. Therefore we measured brain activity with functional near infrared spectroscopy (fNIRS) while participants practiced golf putting under instructions stressing different foci of attention. Participants were pseudo-randomly assigned to the internal focus or the external focus practice group based upon initial putting performance at a distance of 300 cm from the hole. Participants assigned to the internal focus group were then given three instructions that stressed kinematics of the arm/hand. Participants assigned to the external focus group were given three similar instructions that stressed the resulting movement of the putter. Both groups subsequently performed six practice blocks of thirty putts at varying distances. Golf putting performance was quantified using a modified scoring system that awarded decreasing points for putts that stopped further from the hole. fNIRS was recorded throughout the session using optodes positioned over the bilateral frontal and sensorimotor cortices. Contrary to previous research our preliminary results show that the internal focus group demonstrated greater improvement in golf putting performance from the pre to posttest. The fNIRS results revealed that improved putting performance for the internal group was associated with greater motor but less dorsolateral prefrontal cortex activity during swing execution following practice. In the external focus group the pattern of activation was reversed with more activation in the dorsolateral prefrontal cortex. Dorsolateral prefrontal cortex has been associated with the declarative memory system. The increased dorsolateral prefrontal cortex activity in the external focus group may reflect a greater reliance upon explicit strategies at the expense of skill proceduralization for this task.

Title: Reactivation of declarative memory is essential for the enhancement of the sequential motor skill

Authors: *S. K. SUGAWARA[1,2,3], Y. H. HAMANO[1,4,3], N. SADATO[1,4];
[1]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan; [2]Waseda Univ., Tokyo, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]SOKENDAI (The Grad. Univ. for Advanced Studies), Hayama, Japan

Abstract: Motor sequential skill is consolidated by sleep. The hippocampus seems to condition the sleep consolidation through interaction with the striatum during training (Albouy et al. 2013). The striatum is related to the chunk formation of the sequence (Penhune and Steele, 2012), whereas the hippocampus is believed to associate temporally discontiguous but structured information during the early phase of motor sequence learning (Albouy et al. 2008; Schendan et al. 2003). It is unknown how the interaction between two structures conditions the sleep consolidation. Considering that the interaction is competitive during the training period (Albouy et al. 2008), we hypothesized that the imbalance between them will affect the sleep consolidation.One hundred five healthy righthanded volunteers participated in this fMRI study with sequential finger tapping learning task for two consecutive days. In reactivation group (n = 58), participants exercised one sequential finger-tapping skill as fast and as accurate as possible (maximum mode) alternating with constant mode with 2 Hz controlled by visual cue, the latter of which requires the retrieval of the learned skill with exact sequential order. In control group (n = 47), participants only performed the maximum mode. 24 hours after the training, all participants retested the learned skill. Considering association of consecutive finger movements during constant mode as reactivation of declarative memory, we expected that its reactivation during training leads to imbalance between hippocampus and striatum, which in turn may preoccupy the skill enhancement.At the end of first day, performance of the reactivation group was significantly greater than that of the control group. Meanwhile, the sleep consolidation was significant in the control group but not in the reactivation group. In addition, at the end of first day, the task-related activity in the declarative memory system including hippocampus and posterior cingulate cortex was significantly greater in the reactivation group compared with the control group. On the other hand, the offline increment of task-related activation was

significantly more prominent in the declarative memory system of the control group than those of the reactivation group. These results show that the activation in the declarative memory system is associated with the skill enhancement during training in the reactivation group, as well as during sleep in the control group. We concluded that the reactivation of declarative memory component of the sequential motor skill is critical for both instantaneous skill enhancement during training and the conditioning for sleep consolidation.

Title: Age impacts motor performance but not motor learning in both expected and unexpected events

Authors: *C.-L. YEN, R. K. SHIELDS;
Physical Therapy and Rehabil. Sci., Univ. of Iowa, Iowa City, IA

Abstract: Age may be a moderating factor which influences motor performance and motor learning due to changes in the central nervous system. Despite the fact that motor performance declines in old age, old adults may be able to learn new motor skills by practice, possibly through physiological and behavioral adaptations. Previous studies have shown that aging does not deteriorate the ability to acquire a new motor skill in expected events, such as visual motor and ballistic tasks. However, there have been no studies investigating whether age influences the ability to learn to respond to unexpected events. **Purpose:** The purpose of this study was to determine whether age would influence the ability to learn to respond within the transcortical reflex timeframe following unexpected events at different speeds and resistance levels. We hypothesized that old adults would attenuate the capacity to learn to respond in the transcortical reflex timeframe because older adults show reduced non-dominant cortical excitability. **Methods:** Thirty old (60-80 y/o) and 38 young healthy adults tracked a target set at 3 speeds (Slow-72, Medium-126, Fast-180 degree/second) and 3 resistance levels (Low-10%, Medium-17.5%, High-25% maximal voluntary isometric contraction) using the left wrist before and after motor training over 1 week (Day1Pre, Day1Post, Day3, Day7). Unexpected stretches were imposed to the wrist extensor muscles by releasing the resistance of the device. We calculated

the error to measure learning. Repeated measures ANOVAs were used to compare differences across 4 time points, 2 groups, and conditions with 3 speeds or resistance levels. **Results:** Although old adults showed increased errors in all trials, both old and young adults showed a 2-3 degree reduction in error over both perturbed and unperturbed conditions in the transcortical reflex timeframe from Day1pre to Day7. No difference was shown between Day1post, Day3 and Day7. Moreover, both groups showed the highest errors in the Fast condition. However, practice caused a similar improvement in conditions with each speed. Compared to young adults, old adults demonstrated a similar amount of improvement in all 3 speeds and 3 resistance levels over both perturbed and unperturbed events. **Conclusions:** This study showed clear evidence that despite higher errors in old adults; old adults did not lose the capacity to learn in both expected and unexpected events with all speeds and resistance levels. These findings assist in designing novel rehabilitation interventions for people with aging or neurological diseases.

Title: Acquisition of conditioned avoidance while breathing enhanced CO2 (4%) in humans: sex differences and behavioral inhibition

Authors: *D. P. MILLER[1,2], P. F. MARTINO[1], J. R. MILLER[1], M. T. ALLEN[2,3], J. SHEYNIN[4,5], C. E. MYERS[6,7], R. J. SERVATIUS[2,8];
[1]Neurosci., Carthage Col., Kenosha, WI; [2]Stress and Motivated Behavior Inst., Syracuse, NY; [3]Psychology, Univ. of Northern Colorado, Greeley, CO; [4]Veterans Affairs Ann Arbor Healthcare Syst., Ann Arbor, MI; [5]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI; [6]Pharmacology, Physiol. & Neurosci., Rutgers-New Jersey Med. Sch., Newark, NJ; [7]Dept. of Veteran's Affairs, VA New Jersey Hlth. Care Syst., East Orange, NJ; [8]Rutgers Biomed. Hlth. Sci., Newark, NJ

Abstract: Behaviorally inhibited temperament and female sex have been demonstrated to be vulnerabilities for the development of anxiety disorders. We have suggested that the critical nature of avoidance in diagnosing anxiety requires the study of avoidance acquisition and vulnerabilities, which has been effectively examined in non-humans (e.g., Servatius et al, *Beh Brain Res*, 192, 2008). In humans, Sheynin et al (e.g., *Frn Beh Neurosci*, 8:323, 2014) utilized a

computer-based task to demonstrate sex and temperament differences in avoidance acquisition. We used this task to examined avoidance acquisition while participants breathed enhanced CO2 (4%), which activates stress response. We hypothesized that activating stress response would alter learning and physiological responding in vulnerable individuals. Participants were undergraduates between the ages of 18-22. Behavioral inhibition characteristics were categorized based on responses on the Adult Measure of Behavioral Inhibition. Participants were fitted with a Hans Rudolph face mask apparatus and allowed to breath air for 15 minutes to allow heart rate to return to baseline levels. Avoidance acquisition was accomplished using a computer-based spaceship video game (courtesy of Sheynin and Myers). During avoidance acquisition, all participants inhaled 4% CO2 enhanced air during the first 12 trials of training. The following 12 trials were extinction trials, during which all participants inhaled air through the face mask system. Overall, we demonstrated that individuals successfully acquired conditioned avoidance in the computer-based spaceship video game while inhaling 4% CO2 enhanced air. Females appeared to show some deficits in extinction compared to males. Further, males made more moves, more shots, and scored more points than females. Behaviorally inhibited individuals and females showed decreased locomotion. Our results appear to be in agreement with previous research using the spaceship video game where participants directly inhaled normal air (e.g., Sheynin et al., 2014). Our procedure is effective in examining cognitive processes while inducing stress in participants.

Title: The cognitive basis of human avoidance behavior

Authors: *J. SHEYNIN[1,2], S. BAIDYA[3], I. LIBERZON[1,2];
[1]Veterans Affairs Ann Arbor Healthcare Syst., Ann Arbor, MI; [2]Dept. of Psychiatry, [3]Col. of Literature, Science, and the Arts, Univ. of Michigan, Ann Arbor, MI

Abstract: While avoidance behavior can be an adaptive behavior that protects one from harm, excessive avoidance might be maladaptive and be linked to the development of

psychopathology. Indeed, excessive avoidance behavior is a key symptom in all anxiety disorders and posttraumatic stress disorder (PTSD). In both human and non-human animal research, avoidance is often studied in the context of fear conditioning, where the subject is required to perform a specific response (e.g., pressing a keyboard/lever) to prevent an aversive event (e.g., electric shock). On such paradigms, it has been a challenge to dissociate the two commonly theorized drivers of avoidance behavior, namely, fear and cognitive expectancy. Here, we used a recently developed computer-based task that uses a mild aversive event, to focus on the cognitive aspect of avoidance behavior. On this task, the participant controls a spaceship avatar and seeks to get a high score (later translated into monetary award) by shooting an "enemy" spaceship that moves on the screen. During the task, different "warning stimuli" that predict an aversive event (points loss) in some cases, appear on the screen. The participant learns that hiding the spaceship in designated "safe areas" protects from the aversive event but also prevents the opportunity to gain reward (points). Such avoidance response was studied in three distinct phases: (1) acquisition, where participants learned the avoidance response, (2) generalization, where participants demonstrated avoidance response to stimuli that share some similarities with the previously conditioned warning stimuli, and (3) operant extinction, where stimuli are not associated with the aversive events anymore, and participants gradually decreased their avoidance responding. Results show that healthy adults successfully learned the avoidance response on this task, validating this task for studies of learned avoidance. Interestingly, participants with anxiety vulnerabilities demonstrated greater avoidance responding, suggesting that excessive avoidance might put one at a higher risk to develop psychopathologies. Lastly, self-reported expectancy of the aversive events was associated with the degree of the avoidance behavior. Implication of these findings to psychotherapy, as well as future follow-up directions will be discussed.

Title: Exercise effects on classical eyeblink conditioning in humans

Authors: *T. ALLEN;
Sch. Psych Sci., Univ. Northern Colorado, Greeley, CO

Abstract: The benefits of exercise for neural function are well known. A study in male rats has found that exercise improves eyeblink conditioning (Green et al., 2011). There were no exercise effects on pseudo-conditioning with unpaired presentations of the tone CS and the air puff US. The current study was conducted to determine if exercise enhances eyeblink conditioning in humans. In this preliminary study, we used self-report of normal exercise habits to group our participants as high or low exercise. We hypothesized that participants self-reporting higher levels of weekly exercise would exhibit enhanced acquisition of conditioned eyeblink, but that there would be no differences in response to unpaired CS and US trials. Sixty seven undergraduates (14 males and 53 females, mean age = 19.6 years) voluntarily participated for research credit. All participants completed a questionnaire about their exercise habits. Participants were grouped as low exercise (one hour or less per week) or high exercise (3 or more hours per week). Thirty participants in the acquisition condition received 6 blocks of ten trials each of which consisted of 8 paired trials with a 500 ms tone CS which overlapped and co-terminated with a 50 ms, 5 psi corneal air puff US along with a US alone trial and a CS alone trial. Thirty seven participants in the pseudo-conditioning control condition received 60 pseudo-randomly presented CS alone and US alone trials. Pseudo-conditioning resulted in no significant increase in eyeblinks to the tone. There was a decrease in UR amplitude across US alone trials in the pseudo-conditioning in both high and low exercise individuals. Low exercise participants exhibited enhanced CR acquisition as compared to high exercise participants. There were no differences between high and low exercise groups in UR amplitude on US alone test trials across six blocks of acquisition training. Surprisingly, we found the opposite effects for exercise in human eyeblink conditioning as was previously reported in male rats. Methodological differences between the prior rat study and the current human study including gender and eyeblink evoking stimuli may account for inconsistent results across species. Possible neural mechanisms in the hippocampus and cerebellum as well as stress and anxiety effects involving exercise and eyeblink conditioning will be discussed.

Title: Method to evaluate human learning rate of movement control

Authors: *A. VIGGIANO[1], G. RAGOGNETTI[2], L. LORUSSO[1], A. MARCELLI[2];
[1]Med. and Surgergy, Univ. of Salerno, Baronissi, Italy; [2]Dept. of Information and Electrical Engin. and Applied Mathematics, Univ. of Salerno, Fisciano, Italy

Abstract: One intriguing approach to understand the mechanism for human learning is to formulate a mathematical model of the operant conditioning. The learning principle of such models is the update of the synaptic weights of some of the neurons of the network when a reinforcement signal occurs. The rule for such update requires establishing the amount of changes in the synaptic weights. This consists often of a parameter "α"chosen in such a way to obtain a "good" performance of the model. The aim of the present research was to estimate a possible "physiological" value for the parameter α in humans. To this end, a group of volunteers were asked to learn to control the movement of a robotic head to point it toward a light source through a computer keyboard. The participants received a graphical feedback on the monitor correlated to the light intensity and the position of the robotic head and a success or failure signal following the movements that they chose. The feedback consisted of three vertical bars representing respectively the light intensity at two photosensors placed on the two sides of the robot head (first and second bar) and the position of the head (third bar); each bar had three possible levels. Looking at the graphical feedback, the participants had to chose to press one out of three keys; each key moved the robotic head on one out of three positions (center, left, right). After the movement was chosen, a positive signal (a green frame and a bell sound) was given if the head pointed toward the light source; otherwise a negative signal was given (a red frame and a buzz sound). The position of the light source changed randomly after the positive (or negative) feedback was given. The participants, however, did not see the robotic head and were blind about the real meaning of the information appearing on the screen and the movements consequent to the key press. The results demonstrated that peoples correctly learned to point the robotic head toward the light and that their learning curve was compatible with an α value smaller than 0.006; a correlation has been observed between the learning rate and the variability of subjects' responses. Furthermore, learning curves obtained with different levels of complexity of the task were also evaluated. The results support a theoretical exponential relationship between the α value and the inverse of the dimension of the training ensemble of stimuli. Finally, the variability of the experimental data between subjects was smaller for more complex tasks, suggesting that other personal factors, like previous experiences, contribute with a greater extent in simpler tasks; this factors should be taken into account to define the "simplicity" of a task.

Title: Causal evidence of the involvement of the DLPFC in implicit statistical learning

Authors: *D. NEMETH[1,2], G. G. AMBRUS[3], K. JANACSEK[2], A. TRIMBORN[3], G. KOVACS[3];
[1]Inst. of Psychology, Eotvos Lorand Univ., Budapest, Hungary; [2]Hungarian Acad. of Sci., Budapest, Hungary; [3]Friedrich Schiller Univ., Jena, Germany

Abstract: Human learning depends on multiple cognitive systems related to dissociable brain structures. These systems interact not only in cooperative but sometimes competitive ways in optimizing performance. Previous studies showed that manipulations reducing the engagement of frontal lobe-mediated explicit, attentional processes can lead to improved performance in striatum-related procedural learning. The aim of the present study was to investigate the role of the prefrontal cortex (PFC) in implicit statistical learning and its consolidation and to explore the competitive relationship between implicit statistical learning and frontal lobe functions. Healthy, young adults (n=20) were trained on a probabilistic sequence learning task. 1 Hz transcranial magnetic stimulation (TMS) or sham stimulation of both the left and right dorsolateral PFC (DLPFC) was applied right before the learning session and 4x during the learning session in order to disrupt frontal lobe functions. To assess the lasting effects of TMS on learning and consolidation, statistical learning performance (expressed as the faster reaction times for sequences with high as compared to low probabilities) was tested ten minutes, two hours, and 24 hours later. We found significantly lower level of learning in the bilateral DLPFC as compared to the sham stimulation group ten minutes after learning. However the DLPFC stimulation group showed better performance compared to the sham group after the 24-hour consolidation period. Our results support a dynamic antagonist relationship between the brain networks of automatic and controlled processes.

Title: Robustness of functional and structural brain plasticity in motor sequence learning

Authors: *C. THOMAS[1], A. STEEL[1], A. TREFLER[1], E. AGUILA[1], N. SADEGHI[2], C. PIERPAOLI[2], C. I. BAKER[1];
[1]Lab. of Brain and Cognition, NIMH, Bethesda, MD; [2]NICHD, Bethesda, MD

Abstract: Previous MRI studies have reported changes in human brain function and structure over short-term (hours) and long-term (weeks) training using different tasks. However, given the limited resolution of MRI compared with the likely substrate, and the potential for confounding factors, the robustness of these prior results is unclear. Here, in a group of 21 healthy adults, we employed a carefully controlled lateralized motor sequence-learning paradigm and collected resting-state fMRI (rsFMRI) and structural MRI (sMRI) data to investigate the topography and time-course of training-dependent functional and structural changes in the brain. The task involved learning a specific sequence of eight speeded button presses. Each participant was scanned before and after short-term (90 minutes) or long-term (1 hour/day for one week) training. To test for the specificity of changes to motor learning, active (i.e. videogame training) and passive control scans (i.e. rest) were conducted, and to test the reproducibility of any apparent changes, multiple scans were collected in each session. Finally, to relate the changes to behavior, we tested whether the functional/structural changes correlate with improvements in task performance. Analyses of the rsFMRI and sMRI data revealed significant diurnal changes in both functional and structural metrics such as global connectedness and cortical thickness, respectively. After controlling for these diurnal changes, there was still evidence for changes in some structural and functional measures for training compared to control conditions. However, these effects were widespread, and not always consistent between control scans or replication scans. Additionally, areas of functional and structural change were not limited to the expected motor areas and were found in both hemispheres despite lateralization of the training. We conclude that compared to the effect size of confounds like diurnal changes, the functional and structural changes induced by training do not appear robust.

Title: Practice promotes skill through automatization: evidence from an arbitrary visuomotor association task

Authors: A. D. FORRENCE, R. M. HARDWICK, J. W. KRAKAUER, *A. M. HAITH; Neurol., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The ability to respond accurately at short latency is a critical component of motor skill (Hardwick et al. 2015; SfN 2015, 806.29). Such rapid responding must typically be acquired through practice. Many skills depend on learning arbitrary associations between stimuli and actions. For example, musical sight-reading requires timely execution of a movement in response to a note on a page—an arbitrary symbolic stimulus. Here we consider whether such short-latency response skills might depend upon automatization through practice.

We tested this hypothesis using an arbitrary visuomotor association task in which four unfamiliar symbols each corresponded to pressing a specific key on a keyboard. Participants responded to a succession of symbol presentations, in a random order, as rapidly as possible (Serial Reaction Time condition; SRT). Feedback after each trial informed participants whether they had pressed the correct key and, if not, which key should have been pressed, enabling to learn the required mapping very rapidly. Participants then practiced this task for multiple days, aiming to improve their time to complete a set number of trials.

To more precisely measure participants' level of skill in this task, we employed a timed response (TR) paradigm to assess their ability to respond at a range of preparation times and thereby infer their speed-accuracy tradeoff. We measured subjects' level of skill this way at the outset of learning and following practice, and found that practice led to substantial improvements in the speed-accuracy tradeoff.

Following practice, we assessed the automaticity of the association between an arbitrary stimulus and its response by transposing the association between two stimulus-finger pairs. Participants practiced this revised mapping under SRT conditions, then performed the TR task so that we could evaluate their ability to express this mapping given varying amounts of time to prepare their response. Performance under the revised mapping in the SRT condition was comparable to that on the first day under the original mapping. However, in the TR condition, although participants could correctly express the revised mapping when allowed long preparation times, they reverted to the originally practiced map when forced to move at short preparation times.

Thus, stressing the reaction time revealed an automatic mode of responding that persisted despite participants successfully learning to comply with the revised requirements of the task. We suggest that a critical component of motor skill is the presence of an automatic mode of response that operates at short latencies.

Title: Motor cortical substrates of declarative influence over the procedural system: A short-latency afferent inhibition study

Authors: *S. K. MEEHAN[1], L. Y. SUZUKI[1], J. L. MIRDAMADI[2];
[1]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI; [2]Kinesiology, Indiana University-Bloomington, Bloomington, IN

Abstract: The declarative and procedural memory systems contribute unique elements to motor performance. The different contributions of each system can place them in competition such that the declarative system may impose constraints on the procedural system to match an explicit strategy. We have used short-latency afferent inhibition (SAI) to show that attention demands selectively influence neuronal populations in motor cortex. Activity in the same neuronal population has recently been linked to cerebellar mediated model-based learning. Therefore, we sought to assess the interaction between attention demands and cerebellar excitability in this particular population of neurons using SAI. SAI was elicited with electrical median nerve stimulation at the right wrist that preceded a single monophasic transcranial magnetic stimulus over the left motor cortical representation of the first dorsal interosseous. Motor evoked potentials were elicited using either posterior-anterior (PA) or anterior-to-posterior (AP) monophasic magnetic stimuli. PA magnetic stimuli predominantly recruit early indirect waves while AP magnetic stimulation predominantly recruit a distinct set of oligosynaptic pathways mediating later indirect waves. To assess the effect of attention load the magnetic stimuli for both current directions were delivered while participants engaged in a high or low load visual detection task. To investigate the interaction between attention load and cerebellar excitability participants completed the same combinations of current direction and attention load before and after intermittent theta burst stimulation (iTBS) over the posterior lobe of the cerebellum.

Preliminary results are consistent with our previous work. Attention load had no effect upon SAI elicited using the PA stimulation prior to cerebellar iTBS. Conversely, SAI was reduced under high compared to low attention load for AP stimulation prior to cerebellar iTBS. Additionally, cerebellar iTBS had no effect upon SAI elicited using PA stimulation. Excitation of the cerebellum did reduce the magnitude of SAI elicited using AP stimulation under low attention loads. However, the effect of cerebellar stimulation upon SAI elicited using AP stimulation was attenuated under high attention loads. The results of the current study suggest that attention and cerebellar influences converge on the neuronal populations mediating late indirect waves. The convergence of attention and cerebellar influences on this neuronal population may represent a substrate by which the declarative system shapes motor performance through the control of sensory input to motor cortex.

Abstract: In young adults, an acute bout of high intensity physical exercise, as compared to a resting condition, led to more improvement in motor performance 24 h after exercise, indicating that acute exercise boost motor learning (Roig et al., 2012). On a neurophysiological level studies revealed that EEG alpha (8-12 Hz) and beta (13-30 Hz) power were increased after short bouts of exercise, probably reflecting an enhanced state of physical relaxation or arousal (for a review see Crabbe & Dishman, 2004). However, so far no study used EEG correlates to investigated whether and how acute exercise also benefit motor learning. Further, cardiovascular fitness has been shown to be associated with motor performance (Hübner et al., under review). We aimed to investigate whether acute exercise also affects motor learning and EEG power during motor performance in high-fit older adults. Thirty high-fit older adults (65-74 years of age) are assigned to an experimental group (n = 15, acute exercise: 20 min moderate cycling at

65 % of peak Watt level performed during spiroergometry) and a control group (n = 15, resting condition: listening to an audio book). Groups are matched with respect to their cardiovascular fitness level (assessed with spiroergometry on a bicycle ergometer). Motor learning is assessed with a visuomotor precision grip tracking task. Participants have to track a sine wave pattern with their right dominant hand at baseline (immediately before acute exercise: 8 trials of 15 sec (i.e., 1 block)) and for practice (immediately, 30 min and 24 h after exercise: 4 blocks each). Tracking variability is operationalized as the root mean square error (RMSE) at baseline and of the last practice block. The EEG was recorded during baseline test, immediately and 30 min after practice. Alpha and beta task-related power (TRPow) are analyzed for central and frontal electrodes. Data collection and analysis are still in progress. We expect that motor performance of the experimental group is better 24 h after intervention as compared to the control group, indicating improved motor consolidation processes. With respect to the EEG we expect the experimental group to reveal stronger alpha and beta TRPow decreases immediately and 30 min after exercise in central and frontal electrodes, reflecting enhanced recruiting of cortical resources during motor learning. Title: Dynamic change of the parieto-premotor network during early motor sequence learning: an fMRI study

Authors: *Y. H. HAMANO[1,2,3], S. K. SUGAWARA[4,5,3], N. SADATO[1,2];
[1]Natl. Inst. For Physiological Sci., Okazaki, Aichi, Japan; [2]SOKENDAI (The Grad. Univ. for Advanced Studies), Hayama, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan; [4]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan; [5]Waseda Univ., Tokyo, Japan

Abstract: Motor sequence learning is known to be mediated by primary motor cortex, putamen, and cerebellum (Dayan & Cohen, 2011; Penhune & Steele, 2012; Loshe et al., 2014). Less evident is the learning related neural network change, particularly during early phase of the learning (~ 1 hour; Penhune & Steel, 2012). Here, we investigate how the neural network alters with early motor sequence learning by using eigenvector centrality mapping (ECM; Lohmann et al., 2010). Regarding each brain voxel as node and their functional connectivity as edge, ECM attributes a centrality value to each voxel such that the voxel receives a large value if it is more strongly correlated with other voxels which are central within the network. Thus ECM maps the importance of each voxel within the whole brain network with seed- and task-free fashion (Lohmann et al., 2010). A total of 58 normal volunteers participated in the functional MRI study with sequential finger tapping task by their non-dominant left hand. We adopted the block design which includes task epoch of constant speed mode with 2 Hz controlled by visual cue alternating with rest epoch. We first modeled out the task-related activity to extract residuals. Then, we sorted the residual time series data of each task and rest epochs separately, and concatenated these data to estimate whole-brain ECM. By evaluating the increase of centrality during task-state and during resting state separately, we observe learning related network changes which is state-dependent. As learning progressed, the centrality during task state was significantly increased in bilateral posterior parietal cortex. As the intraparietal sulcus regions are critical in visuo-motor integration, and as the task is the visually cued sequential finger tapping, the enhanced centrality in the posterior parietal cortex may represent the learning of cue-tap synchronization. Meanwhile, the centrality during rest-state was significantly increased in bilateral dorsal premotor areas and anterior parietal cortex. As no task was performed, these areas are supposed to be critical nodes for the network representing the spatial and temporal features of the skill *per se.* Our present findings are consistent with the notion that the parieto-premotor network codes the learned sequential finger tapping skill (Kornysheva & Diedrichsen, 2014). The anterior network holds the memory of the sequence *per se*, whereas the posterior network is related to visuo-motor coordination. We conclude that, in addition to the M1, cerebellum, and the striatum, the cortical network including premotor area and parietal cortex holds the memory of the learned sequential skill even in the early learning stage.

Title: Investigating motor adaptation in essential tremor and the influence of VIM thalamic deep brain stimulation

Authors: *J. A. GUERIN[1,2], S. LEE[1,2], M. AHN[1,2], S. R. JONES[1,2], W. F. ASAAD[1,2,3,4,5]; [1]Neurosci., [2]Brown Inst. for Brain Sci., [3]Neurosurgery, Alpert Med. Sch., Brown Univ., Providence, RI; [4]Neurosurg., [5]Norman Prince Neurosciences Inst., Rhode Island Hosp., Providence, RI

Abstract: Essential Tremor (ET), the most common adult movement disorder, has been historically considered a monosymptomatic disorder and is characterized by a debilitating, involuntary action tremor (4–12 Hz). ET is thought to arise from abnormal cerebellar function, and some evidence suggests that ET patients may have additional motor deficits. For medication-refractory ET, deep brain stimulation (DBS) of the cerebellar thalamus, the ventral intermediate nucleus (VIM), can be an effective treatment. While DBS is principally effective in reducing tremor magnitude, further investigation into its effects on non-tremor symptoms is needed. We sought to investigate (1) whether patients with ET exhibit motor learning deficits and (2) the extent to which DBS influences motor learning.

ET patients and age-matched controls performed a modified center-out joystick task in which they moved a cursor on screen to one of eight randomly appearing targets. During blocks of standard trials, joystick and cursor trajectories were mapped naturally. In some blocks of trials, the mapping between the joystick movement and cursor trajectory was rotated counterclockwise by 45 degrees, requiring an adjustment in movement to successfully get the cursor to the target. In other blocks, cursor trajectories were rotated randomly across trials either by 45 degrees counterclockwise or by 45 degrees clockwise. Intermittent probe trials were also included in which the cursor movement was mapped to the ideal trajectory irrespective of the subject's real joystick movement, thus providing no visual feedback about movement error.

To assess motor learning, we investigated motor adaptation, deadaptation, and savings. We measured path length on each trial by isolating gross movement from tremor frequency activity by low-pass filtering cursor trajectories and calculating the cumulative vector distance between consecutive joystick points. Path lengths were compared between (1) non-DBS ET patients and age-matched controls and (2) DBS 'ON' and DBS 'OFF' states in postoperative ET patients. Our preliminary data suggest that ET patients demonstrate deficits in adaptation relative to healthy controls and that deficits may be exacerbated in DBS 'ON' states. In addition, ET patients undergoing awake surgery for DBS electrode implantation performed this task while we simultaneously recorded spikes and local field potentials from VIM and surface potentials from sensorimotor cortex using electrocorticography. Together, these data may provide further evidence of additional motor symptoms in ET and potential deficits introduced with DBS.

Title: Longitudinal representational similarity analysis of extensive motor sequence learning

Authors: ***S. T. GRAFTON**[1], L. J. VOLZ[2], A. A. SCHLEGEL[2,3], N. F. WYMBS[3];
[1]Psychological & Brain Sci., [2]Sage Ctr. for the Study of Mind, UCSB, Santa Barbara, CA;
[3]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Introduction: We previously used repetition suppression functional magnetic resonance imaging (fMRI) to show that representations for newly acquired motor sequences appear over time-scales that vary significantly from region to region. Here, we extend these results by using representational similarity analysis (RSA) on the same longitudinally acquired fMRI data to identify regions where neural representations of sequence specific movements are consistently strengthened over 6 weeks. We hypothesized that multivariate sequence representations in several key motor regions including M1 and premotor cortex will show evolving representational patterns reflecting the depth of training. Specifically, we predicted that long-term, training would lead to increasing multivoxel dissimilarity measures for two extensively trained sequences as well as increasing dissimilarity with other sequences that were not trained extensively.
Methods: 20 healthy subjects practiced 6 motor sequences daily, over 6 weeks at different levels of exposure (extensive, moderate, minimum). Each sequence consisted of 10 button presses performed with the right hand (2 presses per finger). Subjects also underwent a total of 4 fMRI sessions, one before training and then, every two weeks during training. In every fMRI session each motor sequence was performed 50 times resulting in a total of 300 trials. BOLD data recorded during sequence performance in an event-related design was analyzed in the framework of a GLM and resulting beta images were used to calculate dissimilarity matrices in a set of regions of the motor system.

Results: Dissimilarity matrices were computed comparing the relation of neural activation elicited by the sequences trained at different intensities, derived from the 4 fMRI-sessions. Dissimilarity patterns changed between sessions for several motor regions. Increasing dissimilarity was observed between the two extensively trained sequences with each other as well as when they were compared with the minimally trained sequences in the left PMv, SMA, right PMd and parietal cortical areas.
Conclusions: We observed a distinct longitudinal pattern of change in multivariate sequence representations over time, indicating the regionally represented informational content associated with a specific sequence evolves systematically different over time. Our findings indicate the formation of highly sequence-specific representations in PMv and SMA, which still evolve after extensive training and may therefore drive sequence learning on an ultra-slow timescale as proposed by recent multi-process models of motor learning.

Title: Cognitive-motor dual-task training influences consolidation and transfer of learning during a novel visuomotor weight-bearing task

Authors: *K. R. COLE, R. K. SHIELDS;
Physical Therapy and Rehabil. Sci., The Univ. of Iowa, Iowa City, IA

Abstract: Dual-task training, or training a motor task while performing a simultaneous cognitive task, may improve automaticity of movement. Dual-task training may be essential for functional mobility (e.g. walking and talking). **Purpose**: We determined the effects of dual-task training on motor skill acquisition and retention of a visuomotor weight-bearing task. We also determined the generalizability of this learning to a new task. **Methods**: Forty healthy adults (18-36 years old) performed a visuomotor task, tracking a sinusoid on a screen while performing a single limb squat. Every 1.0s, an upright or inverted ‘T’ of four different colors flashed on the screen for 0.5s. Two control groups (20 subjects) performed solely the motor task, while ten were instructed to also sum one ‘T’ color/orientation (DT1), and another ten subjects to sum two ‘T’ color-orientations (DT2). Day1 consisted of 20 training trials at a medium speed and resistance.

Subsequently, each performed the motor task under a 3x3 matrix of resistances as percent of body weight (5, 10, 15%) and velocity (.2, .4, .6 Hz) of the target. Two days later, subjects performed five training trials under their original condition, followed by the 9 novel conditions of the cross-condition. One-way ANOVA (significance of 0.05) was used to determine differences between groups for error (target - user position). **Results**: All groups demonstrated a significant learning effect after training ($p=0.05$); albeit the number of trials to achieve proficiency was greater in the DT2 group compared to controls and DT1 ($p=0.014$). Limited carryover of the learned behavior was present for DT during slow velocity ($p<.0001$), while no difference in error was evident at the fast velocity, supporting carryover. 48hrs later, all groups performed similarly on the first trial ($p=0.45$), though after 5 trials, those in the control group achieved 25% less error compared to the DT2 group ($p=0.01$). **Conclusion**: Young adults performing dual-task training require additional training to achieve a similar proficiency when compared to training without the dual-task strategy. Dual-tasking does not influence motor task consolidation; however, it does continue to affect further training. Interestingly, performing a difficult cognitive task allows transfer of motor skill to faster speeds, though not slower speeds. This may be due to increased reliance on automaticity (decreased attention to the motor task) during faster conditions, rather than attending to both cognitive and motor tasks at slower speeds. Future work will examine dual-task training effects on those with movement impairments due to age and neuromuscular compromise.

Title: Effector specificity in procedural category learning

Authors: K. JENTINK[1], A. I. WILSON[1], H. MECHTENBERG[1], Z. LIU[2], *C. A. SEGER[1,2]; [1]Psychology, Colorado State Univ., Fort Collins, CO; [2]South China Normal Univ., Guangzhou, China

Abstract: There is debate about the role of motor systems in category learning. One theory is that subjects learn direct mappings from stimuli to motor responses, and therefore learning should be specific to particular motor effectors. This theory is supported by studies finding that disrupting the stimulus - motor response relationship by altering the motor response can interfere with category learning. Alternatively, subjects may learn an intermediate category representation, learning to map each stimulus to a category label, and separately learning to map the category label to a motor response. If an intermediate category representation is learned, it should be accessible to any motor effector and disruption of the category-response mapping should not affect categorization. Our study sought to identify the neural systems recruited during category learning with consistent versus inconsistent category-response mappings using functional magnetic resonance imaging (fMRI). Thirty participants learned an information-integration category task outside the scanner, half with consistent mappings, and half with inconsistent mappings that changed on a trial by trial basis. All subjects were then scanned while performing the task under the same conditions. Participants in both consistent and inconsistent mapping conditions had similar accuracy during scanning, indicating that all were able to learn. A direct comparison showed a striking overlap between consistent and inconsistent mapping groups: both conditions recruited regions frequently associated with category learning, including the basal ganglia, intraparietal sulcus, and premotor and motor cortexes. A direct comparison found greater activity for the inconsistent mapping in the intraparietal sulcus, medial occipital regions, and globus pallidus. Our results support theories of category learning that include an intermediate category representation, rather than learning being limited to specific stimulus-motor response mappings. Both behavior and neural systems were very similar across conditions. Our results further point to a role of the intraparietal sulcus and medial occipital regions in determining and implementing the current category - motor response mapping.

Title: Age-related differences in the consolidation of implicit statistical memory across human life span: Evidence from a probabilistic sequence learning task

Authors: *K. JANACSEK[1,3], D. JUHÁSZ[4], D. NEMETH[3,2];
[1]MTA TKI, [2]Hungarian Acad. of Sci., Budapest, Hungary; [3]Eotvos Lorand Univ., Budapest, Hungary; [4]Univ. of Szeged, Szeged, Hungary

Abstract: Statistical learning is a fundamental mechanism of the brain which extracts and represents regularities of our environment. It underlies predictive behavior and decision making in many day-to-day activities. Therefore it is crucial to understand how we form associations based on statistical regularities, and how the acquired information consolidates and stabilizes over time. The ontogenetic changes of these processes, however, are still poorly understood. Here we aimed to characterize age-related differences in the consolidation of statistical memories between 7 and 85 years of age. Three-hundred participants were recruited and clustered into nine age groups. The Alternating Serial Reaction Time (ASRT) task was used to assess implicit statistical learning. Participants were retested 24 hours after the learning phase. Although all groups showed retention of the acquired statistical regularities after the 24-hour consolidation period, we found greater inter-individual variability in the extent of retention in childhood between 7 and 13 years of age and in the elderly population (60-85 years of age). These results remained stable even after controlling for age-related differences in overall accuracy and reaction time. Our findings suggest that the fronto-striatal circuits mediating statistical memory formation and consolidation undergo marked changes in childhood and in late adulthood, while seem to be well-established in adolescence and adulthood.

Title: The impact of reward and punishment on the neural correlates of sequence learning

Authors: *A. D. STEEL[1,2], E. H. SILSON[1], C. J. STAGG[2], C. I. BAKER[1];
[1]NIH, Bethesda, MD; [2]Fmrib, Univ. of Oxford, Oxford, United Kingdom

Abstract: While several studies have examined the impact of feedback on skill learning, the multitude of different approaches and paradigms used make synthesizing general principles problematic. Here, we employed closely matched paradigms across two different tasks to assess the impact of feedback to sequence learning and retention, both behaviorally and neurally. Participants (n=72) performed either the serial reaction time task (SRTT, n=36) or force tracking task (FTT, n=36) with positive-, negative-, or pseudo-feedback during fMRI, with 20 mins resting-state data collected pre- and post-learning. In the SRTT, participants responded to a stimulus presented in 1 of 4 locations by pressing a corresponding button. In the FTT, participants modulated their grip force to move a cursor on the screen and track a moving target. In both tasks, unbeknownst to the subject, the stimulus followed a fixed sequence during certain blocks of trials. The difference in performance between fixed and random blocks indexed learning. Participants received feedback based on their performance. For the SRT, feedback was based on speed and accuracy; for FTT, feedback was based on distance from the target. The reward (REW) group was given monetary reward if subjects improved compared to the previous block. The punishment (PUN) group had money taken away if they were worse than the previous block. Control (CON) participants were told simply that they would be given compensation based on their performance. Behaviorally, PUN aided performance during SRTT, but impaired performance during FTT. Feedback did not alter retention at any time point. In the resting-state data, task-responsive voxels were clustered into networks based on their functional connectivity (FC). The FC of these networks was compared pre- and post- training. Different FC profiles predicted retention at 1-hour and at 24-hours post-learning: increased post-learning FC between basal ganglia (BG) and motor cortex was predicted by retention after 1-hour, while 24-hour retention was correlated with the average BG FC to all networks after learning. Neither task nor feedback significantly influenced these relationships. In sum, short-term retention is related to specific cortical-BG connections, whereas intermediate- and long-term retention is related wide-spread integration via BG. These results support the hypothesis that the BG play a critical role in memory formation independent of feedback given during learning. Together with our behavioral result, these findings suggest that the effects of feedback are transient and call into question the previous findings that reward aids the retention of motor skills

Title: Somatotopic cerebellar abnormalities in developmental amnesia due to bilateral hippocampal damage and in verbal/orofacial dyspraxia associated with bilateral caudate atrophy.

Authors: *G. P. ARGYROPOULOS[1], K. S. SALEEM[2], M. MISHKIN[2], F. VARGHA-KHADEM[1,3];
[1]Cognitive Neurosci. and Neuropsychiatry Section, UCL Inst. of Child Hlth., London, United Kingdom; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Health, Natl. Inst. of Hlth., Bethesda, MD; [3]Great Ormond Street Hosp. for Children NHS Fndn. Trust, London, United Kingdom

Abstract: Introduction
We previously described two distinct neurodevelopmental disorders, one labelled 'developmental amnesia' (DA), resulting from hippocampal atrophy due to neonatal hypoxia-ischaemia[1], and the other, a 'verbal and orofacial dyspraxia' (VOD), associated with atrophy of the caudate nucleus due to a point mutation in the gene *FOXP2*[2,3]. As both the hippocampus and the caudate nucleus connect with the cerebellum[4,5], we sought to determine the precise location of cerebellar structural abnormalities in these two disorders.
Methods
We used cerebellar VBM to compare gray matter volumes in the MRIs of 8 DA patients and 7 VOD cases with those of 13 healthy controls (Cs).
Results
Patients with DA had *larger* gray matter volumes than did both the VOD cases and Cs in mostly right HVIIb-HVIII (Fig. 1a-c), whereas the VOD cases had *smaller* gray matter volume than did both the DA patients and the Cs in a partly overlapping cerebellar region (Fig. 1a, c-d). Also, compared to the Cs, the VOD cases had *smaller* gray matter volumes in I-VI bilaterally and in mostly right HVIIa Crus I (Fig. 1d), as well as *smaller* gray matter volume in the dentate bilaterally compared to both other groups (Fig. 1e).
Conclusion
We propose that the differential locus of the cerebellar abnormalities and their behavioural consequences in DA and VOD reflect the basic underlying cerebellar somatotopy.

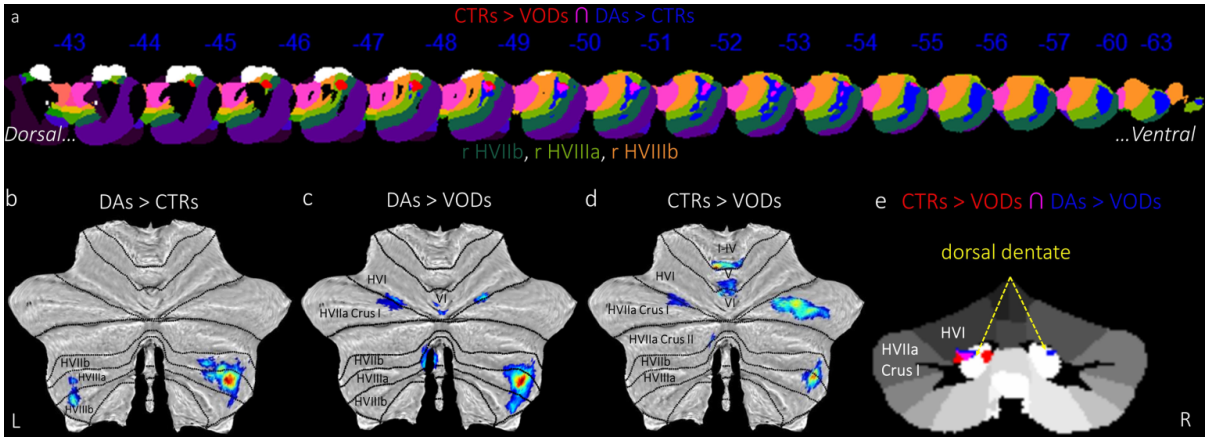

Fig.1. Cerebellar structural abnormalities in DA and VOD. Clusters survive corrections for non-stationary smoothness and FWE ($p < .05$); a: right serial axial slices; b-d: flatmaps; e: coronal slice, dentate.

Title: Brain reorganization and performance correlates of a rapid switch in handedness induced by drawing training in a left-handed blind individual

Authors: *L. T. LIKOVA, K. MINEFF, S. NICHOLAS;
Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: The neural correlates of hand preference are still debatable, and there are only a few studies on the mechanisms of enforced change of handedness from left to right in early childhood (e.g., Grabowska et al., 2012). The question of retraining handedness in late adulthood well outside the accepted critical period for brain plasticity, has not been previously studied. To address this question we used a unique training on a complex task in a 50 y.o. habitually left-handed man, who became totally blind 10 years ago. In a week of 2 hr/day of Cognitive-Kinesthetic Drawing Training (Likova, 2012), the participant learned to draw freely faces and objects from non-visual memory with his non-dominant (right) hand. He had never been able to draw well even with his dominant (left) hand while still sighted, and was highly surprised by this outcome. An additional session focused on training to draw the already memorized images with his dominant (left) hand. Functional MRI was run before and after the training on a sequence of five tasks (20s each): tactile exploration of raised-line drawings of faces and objects (left hand only); tactile drawing from memory (right and left hand); and a scribble motor/memory control (right and left hand). As expected, drawing with the dominant (left) hand produced bilateral activation with contralateral (right) predominance, as did drawing with the non-dominant (right) hand before training, but with left predominance. After training, however, rapid functional reorganization was observed for the non-dominant (right) hand, leading to a strong unilateral activation in the left (contralateral) hemisphere with a massive suppression in all motor control related, somatosensory and respective superior parietal areas the right (ipsilateral) hemisphere, correlated with the dramatic enhancements in drawing performance. This study is the first to show that the non-preferred hand is not always controlled by both hemispheres as has been thought. Only a week of CK training was able to overturn 50 years of dominance of the right hemisphere in a complex memory-driven motor task. The data suggest a critical role for functional mechanisms such as inter-hemispheric competition as opposed to structural predetermination in hand dominance. Consistent with previous findings (Likova, 2012, 2013, 2014, 2015), they also demonstrate the power of the Cognitive-Kinesthetic Drawing Training to cause rapid and effective brain reorganization. The results will be further discussed in the context of the long-standing debate about the sources of hemispheric asymmetry in the cortical organization of motor function.

Title: Explicitly trained sequences display vulnerability to performance pressure due to monetary incentives while implicitly trained sequences do not

Authors: *T. G. LEE;
Univ. of Michigan, Ann Arbor, MI

Abstract: Although increased motivation usually enhances performance, impaired performance can sometimes be seen in situations involving large rewards and high motivational states. Over thirty years of psychological research has provided scientific evidence of the anecdotally salient phenomenon of this "choking under pressure". However, the cognitive mechanisms underlying choking remain unclear. One proposed theory of choking asserts that reduced performance is due to an increase in explicit monitoring of a procedural skill. Here we tested whether explicit skill knowledge is a necessary prerequisite for choking under pressure.

Participants were trained across eight different blocks on four separate 8-item motor sequences in the discrete sequence production (DSP) task. Crucially, for two of the sequences the identity of the upcoming sequence was explicitly cued with a colored square just prior to each trial and participants were told to attempt to learn these sequences. The other two (implicitly trained) sequences were given an ambiguous gray square just prior to each trial and participants were told that these sequences were randomized. The sequence order was actually randomized on one third of the trials cued with the gray cue in order to effectively mask awareness of the implicitly trained sequences.

Following training, participants were asked to perform the same task for reward bonuses with time limits set on an individual-by-individual basis based on movement times at the end of training. Each trial was associated with a $5, $10, or $20 incentive by a reward cue displayed just prior to the start of the trial. Participants were able to modulate their performance (as measured by accuracy) on explicitly trained sequences based on the reward values displayed, but displayed stereotypical choking behavior as indexed by reduced performance at the highest incentive level. However, accuracy on implicitly trained sequences was unaffected by incentive value and participants did not display impaired performance for the highest level of reward. These results suggest that skill metacognition can both positively and negatively impact performance in a feed-forward manner and that knowledge of expected ability in a motor skill can contribute to choking under pressure. Future work with fMRI scanning during the training and performance of explicitly cued sequences with varying levels of incentives will elucidate the neural mechanism by which this skill knowledge impacts the motor skill.

Title: Investigating the effect of motor state during paired associative stimulation on cortical excitability and motor skill performance

Authors: W. A. GRAY, A. C. KNOTT, P. E. O'SHEA, E. C. OETTER, K. WILDE, *M. R. BORICH;
Emory Univ., Atlanta, GA

Abstract: Introduction: Repeated pairing of electrical stimulation of a peripheral nerve with transcranial magnetic stimulation (TMS) over the primary motor cortex (M1) "hotspot" for a target muscle can induce short-term neuroplastic adaptations in the human brain. Currently, it is unclear if motor state of the targeted muscle during this form of paired associative stimulation (PAS) influences the induction of long-term potentiation (LTP)-like plasticity. Additionally, the effect of PAS on both motor skill acquisition and learning is not well characterized. Here, we investigated the effect of motor state during PAS on measures of cortical excitability, motor skill acquisition and motor skill retention. **Methods:** Twelve young, neurologically-intact healthy participants completed three separate visits separated by at least one week, each consisting of one of three PAS protocols: PAS_{REST} (no active contraction in the left abductor pollicis brevis [APB]), PAS_{ACTIVE} (10% maximal voluntary contraction [MVC] of the left APB), and $PAS_{CONTROL}$ (10% MVC of left APB paired with sham TMS). PAS consisted of 180 pairs of left median nerve stimulation (at APB motor threshold) followed by TMS over contralateral M1 (~1mV intensity), with an inter-pulse interval based on the individual N20 latency + 5ms delivered at 0.25Hz. Measures of cortical excitability (motor evoked potential [MEP] peak-to-peak amplitude) and motor skill performance (reaction time) on the serial reaction time task (SRTT) were collected prior to PAS, directly following PAS and at 30 and 60min post-PAS. Motor skill retention was indexed by SRTT performance at a delayed (>1wk) retention test. **Results:** Significant effects of motor state during PAS on measures of cortical excitability and SRTT skill acquisition were not detected. A trend for enhanced SRTT performance at retention testing after PAS_{REST} was observed. **Discussion:** Preliminary results suggest that motor state does not appear to differentially modulate responsiveness to PAS. Traditional PAS approaches may contribute to enhanced motor skill retention. However, inter-individual variability in response to PAS for each protocol restricts conclusions drawn from the group-level results. Evaluation of individual response profiles may provide additional information to guide future

PAS interventions. Subsequent studies should evaluate the impact of PAS on the time course of motor skill learning in healthy individuals and the recovery of motor function following neurological insult.

Title: Can random number generation be taught implicitly?

Authors: *U. MAOZ, G. MERHOLZ;
Psychology, UCLA, Los Angeles, CA

Abstract: Human ability to be random, as the flipside of predictability, is important for various neuroscience fields, such as decision-making, volition, and theory of mind. So it is no surprise that it has drawn interest over the years. Most research finds human ability to be random lacking, with people underestimating the the chance likelihood of repeated events, for example. It is therefore probably that we could train human subjects to be more random by explicitly pointing out their deviations from randomness and asking them to correct those. But to what degree could humans be implicitly taught to be random?
To test this, we constructed a 3-part experiment. In all parts, subjects selected one of 3 options—rock, paper, or scissors—using the keyboard. In the first part of the experiment, we instructed subjects to generate a 100-long series of rock, paper, and scissors that would be as random as possible. They received no feedback on how random the series was. In the second part of the experiment, subjects played 100 trials of rock/paper/scissors against the computer. This time, they were told whether they won, tied, or lost. The computer used a prediction algorithm that searched for patterns in each subject's transitions between rock, paper, and scissors, taking into account also wins, ties, and losses. Thus, subjects' best strategy was to be as random as possible. Half the subjects were told of the algorithm, the others were not. In the third and last part of the experiment, subjects were once again instructed to generate a 100-long random series of rock, paper, and scissors, with no feedback. Before part 1 of the experiment, participants filled out a short questionnaire about their confidence and knowledge of randomness. After part 3, they

further filled out a short questionnaire about their experience and to gauged their own performance during the study. The objective was to test whether any learning that occurred during the game part also generalized to simple, non-competitive random sequence generation. We determined the degree of randomness of the sequences using tests for equiprobability of events outcome (one third each for rock paper and scissors); sequential independence (how well previous trials can predict the current trial); event symmetry; and repetition or repetition avoidance. Preliminary results suggest that some subjects are better able to create random sequences than others. There is also evidence that subjects do learn to become more random as the experiment progresses. We expect more control experiments to shed more light on the effect of implicit learning on random-sequence generation in humans.

Title: Audiomotor learning: facilitation of implitic sequence learning through explicit melody memorization

Authors: *L. JIMENEZ-DABDOUB[1], P. KIRK[2], R. BODAK[3], L. STEWART[2];
[1]Lab. of Psychology and Musical Arts-Unam, Ciudad DE Mexico, Mexico; [2]Psychology, Goldsmiths, Univ. of London, London, United Kingdom; [3]Aarhus Univ., Aarhus, Denmark

Abstract: Goldsmiths audio-motor coupling research group guided by Stewart is beginning to underpin all research previously done focusing on musicians. Now, we are paying attention to non-musicians as it might help understand audio-motor learning and music in the general population. Motor performance for playing a melody has been demonstrated to improve without any physical practice only by listening to a previously practiced piano piece (Lahav et al, 2006). In 2015, Stephan and colleagues conducted a study about motor sequence memories by exposing participants to associate four finger key-pressing movements to four tones (implicit learning); and for them to learn either a melody (explicit learning) to be congruent or incongruent to the motor sequence they would be tested on. The expected effect was to facilitate implicit memorization of a motor sequence. The present study aimed to approach similar findings but instead of having participants pressing keys, a series of four hand gestures (HG) were performed.

HG were recorded by placing two accelerometers in participants' right thumb and middle fingers. "The beneficial effect of sound on motor performance has also inspired the idea of music-supported therapy (MST)" (Stephan et al., 2015: 319). Hence, by using real gestures, we expect to create a bridge towards the possible clinical applications of the facilitation effects music could have in re-learning daily living tasks. Overall, results showed no significant differences in the mean response time (mRT) between group A (Congruent condition) and Group B (incongruent condition). This study does provide a step into the use of new musical devices to support motor rehabilitation. It is suggested to explore and create a more congruent space-pitch mapped gestures and including a rhythmic component to focus at. On the other hand, testing over time and through a cross-over design, application from Stephan and colleagues research would thorough review, which is actually being done by Bodak as her PhD research.

Title: A multi-channel, semi-chronic micromanipulator system for combined electrophysiological recording and optogenetic manipulation of neuronal activity in behaving, non-human primates.

Authors: *A. B. GOODELL, C. M. GRAY;
Gray Matter Res., Bozeman, MT

Abstract: In order to gain a greater understanding of the neural mechanisms that mediate cognitive function new approaches and technologies are needed to dramatically expand the ability to record and manipulate the activity of large numbers of neurons throughout widespread areas of the primate brain. To accomplish this objective, we have developed a multi-channel, semi-chronic micromanipulator system that permits the implantation of up to 32 independently movable optrodes in behaving non-human primates. This device is combined with a guide array for precisely controlled viral injections. Multiple microdrives can be implanted and flexibly configured to enable the long-term measurement and optogenetic manipulation of neuronal activity from distributed circuits spanning the depth and breadth of the brain.

The optrodes are fabricated by bonding a beveled optical fiber to a microelectrode with epoxy. Each assembly is then bonded to a non-round, threaded brass shuttle using conductive epoxy. Optrode position is controlled by rotation of a fixed leadscrew (125 μm/turn resolution) that advances or retracts the shuttle over travel distances up to 40 mm. The electrical signal from each electrode passes through the shuttle to the leadscrew and to a printed circuit board mounted on top of the microdrive. Each optical fiber is routed below the PCB to a custom connector assembly that is mounted on the actuator block of the microdrive. Sufficient slack is incorporated into the length of the optical fiber to account for the optrode travel. The actuator block, connector assembly and external housing are fabricated using 3D printing technology.
Ongoing work includes the design and testing of viral injection methods, the surgical removal of the dural membrane to facilitate the penetration of the delicate optrodes into the brain, and the incorporation of miniature, multi-channel optical fiber connectors. The completed system will enable precise spatio-temporal control of activity in distributed neuronal circuits.

Title: Light-evoked responses from channel rhodopsin-expressing neuronal cells studied by quantitative phase imaging

Authors: T. KIM[1], M. SHAN[1], V. NASTASA[1], M. WANG[2,3], P. SENGUPTA[2,4], *M. U. GILLETTE[5,2,3,4], G. POPESCU[1,2];

Abstract: Light stimulation of channelrhodopsin-2 (ChR2)-expressing neuronal cells causes cations to flow from outside to the cell interior thereby causing depolarization of the membrane and initiating a signaling cascade. These subtle and rapid events occur in millisecond to second

timescales, which makes it extremely difficult to detect them without an expensive electrophysiology system. Moreover, these systems also require a highly precise control during operation and are typically limited to single-point measurements. More recently, electrophysiology systems based on MEMS devices have been developed for multipoint detection of these signals. However, it remains challenging to acquire wide-field label-free imaging of these cells in action because of the required imaging speed and sensitivity. Recent advances in quantitative phase imaging (QPI) allow label-free live biological specimens to be imaged with sub-nanometer sensitivity and diffraction-limited resolution. A QPI technique called Spatial Light Interference Microscopy (SLIM) has been applied for studying neuronal network formation and dynamics and has proven its potential usefulness in neuroscience [Z. Wang et al., Opt. Exp., 19, 1016 (2011) & M. Mir et al., Sci. Rep., 4, 4414 (2014)]. This technique allows for wide-field imaging of live neuronal activities and can be used for measurement of rapid and subtle action potentials in optogenetically engineered cells. By implementing a projector and imaging a pattern onto the sample plane, we can excite individual ChR2-expressing cells with light with high spatial resolution. Using SLIM's label-free and wide-field imaging, the cellular signals generated as a response to this light stimulation are measured with a sub-nanometer sensitivity as they propagate through the cells. An increase in signal over a few seconds is measured from ChR2+ cells as a response to the blue light stimulation. On the other hand, no response was detected from ChR2- cells with blue light or from ChR2+ cells with red light stimulation. This new optical imaging technology offers the possibility for wide-field measurement of electrical events in neurons, and ultimately can help understand cellular signaling mechanisms post-stimulation and cellular dynamics at a higher resolution.

Title: Local field potentials reflect excitability of frontal cortical neurons to optogenetic stimulation of posterior parietal cortex

Authors: *R. SHEWCRAFT, D. A. HAWELLEK, K. A. BROWN, B. PESARAN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Population neuronal activity measured by the local field potential (LFP) may measure how well long-range synaptic input can drive local spiking due to changes in excitability. However, the need to causally control circuit activity while measuring its large-scale effects means this hypothesis has not been directly tested. We used large-scale recordings in frontal cortex (PFC and Brodmann areas 4 and 6) of awake monkeys to measure responses to optogenetic stimulation in posterior parietal cortex (Brodmann areas 5 and 7).
We implanted a 96-channel semi-chronic movable electrode array (SC96, Gray Matter Research) over the frontal lobe in two rhesus macaques and recorded single unit activity. We then injected AAV5-hSyn-ChR2(H134R)-EYFP (UNC Vector Core) into the superior and inferior parietal lobules of the PPC. We stimulated sites in PPC while simultaneously recording responses in PPC and across the frontal array. Stimulation of area 7 drove activity in prefrontal cortex. Stimulation of area 5 drove activity in premotor cortex.
We found 47 sites in frontal cortex with multi-unit activity (MUA) that was driven by parietal stimulation. For each MUA site, we measured how the phase of the frontal LFP varied with the probability of eliciting a spike in frontal cortex by computing the conditional probability of a spike occurring after stimulation given the phase at the time of stimulation. We found significant modulations in the alpha band (8-12 Hz) at 70% of sites (33/47, $p<0.05$), in the beta band (15-25 Hz) at 68% of sites (32/47, $p<0.05$) and in the gamma band (30-50 Hz) at 68% of sites (32/47, $p<0.05$). For each band, the preferred phase slightly preceded the LFP trough (334, 324 and 336 degrees, respectively), which would suggest that excitability peaks during periods of synchronized depolarization across the local neuronal population. We propose that the LFP in these bands measures the local sensitivity to synaptic inputs.
Does each frequency band independently modulate excitability, or are the alpha, beta and gamma bands correlated, providing a common mechanism for modulation? There was no significant difference in the proportion of modulated sites between bands ($p>0.05$, Fisher's exact test). In addition, we found that the phases at the time of stimulation were correlated (alpha-beta, 30% of sites; alpha-gamma, 36%; beta-gamma, 62%). While the extent to which neuronal excitability is reflected in LFP activity due to frequency-specific mechanisms remains unclear, our results demonstrate that frontal cortical LFP activity across a range of frequency bands reflects neuronal excitability to input from PPC.

Title: Closed-loop real-time all-optical interrogation of neural circuits *In vivo*

Authors: *Z. ZHANG, L. E. RUSSELL, A. M. PACKER, M. HAUSSER;
Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Since neural activity patterns are rapidly evolving and highly variable from trial to trial, it is crucial to be able to read out and interfere with these patterns in real time. Such closed-loop interventions would provide direct causal links between specific activity patterns and behaviour. Recently we described an all-optical method for circuit interrogation where populations of neurons are simultaneously recorded and addressable with single-cell resolution (Packer et al 2015). Here we close the loop between readout and stimulation by implementing a real-time feedback module, which consists of hardware and software tools to allow rapid configuration of stimulation patterns. We use this module to demonstrate dynamic, activity-guided circuit manipulations. Populations of neurons in mouse visual cortex coexpress GCaMP6s and C1V1 to permit fast two-photon calcium imaging and optogenetic stimulation respectively. A high-speed spatial light modulator enables precise photostimulation of multiple cells and rapid updates of the stimulation pattern. Real-time analysis of the raw data stream from the imaging channel is made possible with custom-written software. We then implement various types of feedback control logic to enable closed-loop manipulation of target populations. Here we demonstrate three categories of proof-of-principle experiments. First, we optically monitor single or multiple cells. Upon event detection we near-instantaneously trigger photostimulation to pre-defined targets. Second, we introduce ‘activity clamp’, whereby single and multiple cells are clamped at particular fluorescence levels through continuous on/off feedback control. Third, we demonstrate a conjunction of feedback control with sensory stimulation. Weak sensory stimulation can be selectively, optogenetically boosted if sensory-evoked activity fails to pass threshold. Our closed-loop approach will ultimately enable new classes of experiment, such as: correcting erroneous network trajectories recorded from animals performing decision-making

tasks; inducing plasticity in neural circuits by recruiting cells into functional ensembles; and processing functional connectivity maps online to update predictions and guide subsequent interrogation.

Title: Simultaneous multiwell optogenetic stimulation and microelectrode array recording for disease modeling and toxicological assays

Authors: I. P. CLEMENTS, *H. B. HAYES, A. M. NICOLINI, C. A. ARROWOOD, D. C. MILLARD, J. D. ROSS;
Axion Biosystems, Atlanta, GA

Abstract: Microelectrode arrays (MEAs) monitor and manipulate cultured cell activity *in vitro*, providing insight into neuronal network interactions to inform "disease-in-a-dish" models, stem cell characterization, toxicology screening, and drug safety and development. Recently-developed multiwell MEA systems (48, 96, or more MEA wells on a single microplate) enable high-throughput assessment of functional endpoints at greatly reduced time and cost. While network activity may be monitored under spontaneous conditions, stimulation of neural activity allows evaluation of evoked activity measures, reduces variability across wells, reduces assay duration by increasing activity levels, and enables creation of application specific protocols to assess features of network connectivity. Optogenetics integrates fast, light-activated channels (opsins) that allow targeted, precise manipulation of cellular activity, and provides advantages such as targeting of specific cell types, the ability to suppress activity, minimal stimulus artifact, and uniform stimulus delivery across a culture. Here, we demonstrate the application of Lumos, a commercial multiwell optical stimulation system, to enhance typical assays in toxicology screening and disease-in-a-dish models through optogenetic stimulation with Channelrhodopsin-2 (ChR2). These findings demonstrate the potential of optically-integrated multiwell MEA systems to enable high-throughput drug screening and phenotypic modeling of neurological diseases.

Title: Targeted optogenetic stimulation in the auditory pathway enables access to the tonotopic axis

Authors: *S. NARASIMHAN[1], A. HIGHT[2], X. MENG[3], A. EDGE[5], C. BROWN[6], D. LEE[4]; [1]Eaton Peabody Laboratory, Otolaryngology, Mass Eye and Ear Institute/ Harvard Med. Sch., Boston, MA; [2]Speech and Hearing Biosci. and Technol., Harvard Med. Sch. / Eaton Peabody Labs., Boston, MA; [3]Eaton Peabody Laboratories/ Otolaryngology, [4]Otology and Otolaryngology, Mass Eye and Ear Infirmary/ Harvard Med. Sch., Boston, MA; [6]Eaton Peabody Laboratory/ Otolaryngology, Massachusetts Eye and Ear Infirmary/ Harvard Med. Sch., Boston, MA

Abstract: Aim: The auditory brainstem implant (ABI) restores hearing sensations to individuals who are deaf and cannot benefit from a cochlear implant(CI) due to a damaged or abnormal auditory nerve or cochlea. Speech comprehension of ABI subjects is lower compared to those of CI subjects. A likely limiting factor of ABI is electrical current spread, which indiscriminately stimulates both excitatory and inhibitory neurons of the cochlear nucleus (CN), impeding the delivery of resolved frequency cues. We are exploring whether optogenetics, activating neurons with light instead of electricity, might provide activation of populations of auditory neurons carrying frequency specific cues. For each population, we test whether activation of the CN provides for frequency specific activation of response areas in the inferior colliculus (IC). So far, we have used 5 unique transgenic mouse lines.

Methods: Cell specific expression of opsins is obtained by crossing floxed ChR2 mice with the following 5 cre lines: Bhlhb5, Parvalbumine, Atoh1, Nestin and Vglut2. Surgical exposure of the CN is performed acutely in the transgenic mice. Blue light pulses are delivered by a diode laser at 28pulses/s. Light beams are focused with an adjustable laser collimator and beam location is shifted along the rostral-caudal and medio-lateral axes of CN. Multiunit activity is recorded from the IC using a single-shank,16-site recording probe placed along its tonotopic axis. Placement is confirmed with acoustic tones. Auditory brainstem responses (ABR) are also measured. The center of evoked activity in the IC with respect to stimulation location on CN is used to evaluate access to the tonotopic axis. Post-experiment histology is performed confirming opsin expression in the CN.
Results: Histology demonstrated unique patterns of opsin expression for each transgenic line. Light stimulation of the DCN evokes excitatory responses across the tonotopic axis in the IC for all lines except Vglut II, which exhibited inhibitory response patterns. Parvalbumin and Bhlhb5 lines, produce frequency specific evoked neural activity in the IC whereas the broadly expressed Nestin and Atoh1 produce nonspecific responses. Optically evoked ABRs (oABRs) depend on the neuronal populations stimulated in the CN.
Conclusion: Our experiments reveal that evoked responses depend on the type of neuronal population stimulated, exhibiting excitatory or inhibitory responses. This suggests that the selection of a promoter or transcription factor for targeting cell-specific opsin expression is essential for an optically-based ABI.

Title: Optogenetic, transient-sensing and chemogenetic mouse models available from The Jackson Laboratory.

Authors: *J. BECKWITH, S. ROCKWOOD, M. SASNER;
The Jackson Lab., Bar Harbor, ME

Abstract: The Jackson Laboratory (JAX) Mouse Repository distributes mouse lines with optogenetic and transient-sensing (calcium-, voltage-, glutamate-) technologies. Opsins are light-activated proteins that alter membrane potential in neurons, so that stimulation with light allows

rapid control of neuronal activity. Several mouse lines express improved/optimized opsins fused to fluorescent proteins. These include mice with channelrhodopsin expression directed by specific promoters. Additional control is available in mice with Cre- or Tet-dependent expression of channelrhodopsin or halorhodopsin variants.
Variants of GCaMP fluoresce in response to calcium binding and serve as an indicator of neuronal activation. These include the Thy1-promoter driven GCaMP3, GCaMP6f or GCaMP6s transgenic lines, the Tet-dependent GCaMP6f or GCaMP6s transgenic lines and the Cre-dependent GCaMP3, GCaMP5, GCaMP6f or GCaMP6s mouse lines.
Several strains utilize both Cre-lox and Tet-On/-Off functionality. Removal of a floxed-STOP allows Tet-dependent expression of channelrhodopsin (Chronos/EGFP), halorhodopsin (Jaws/EGFP), GCaMP6s, GCaMP6f or FRET chromophores sensitive to calcium (YCX2.60), voltage (VSFPB1.2) or glutamate (iGluSnFR).
This set features models created by the Allen Institute for Brain Science, the Genetically-Encoded Neuronal Indicator and Effector (GENIE) Project (Janelia/HHMI), Duke/MIT and several others. Transgenic lines from the Cornell Heart Lung Blood Resource for Optogenetic Mouse Signaling (CHROMus) are designed for combinatorial crosses enabling the coexpression of sensors and effectors, or red and green calcium sensors (*e.g.*, RCaMP and GCaMP8).
Designer receptors exclusively activated by designer drugs (DREADDs) are mutant G-protein coupled receptors activated by the pharmacologically-inert molecule clozapine-N-oxide. Several chemogenetic strains have Cre-, Tet- and/or FLP-inducible expression of M3Dq, M4Di or M3Ds.
The JAX Mouse Repository - a centralized facility for the development, rederivation, cryopreservation and distribution of mouse models to the international biomedical research community - adds hundreds of new strains annually. Repository holdings may be searched online (JAXMice database: jax.org/mouse-search). Researchers may donate their mouse strains using an online submission form (jax.org/donate-a-mouse). Please visit The Jackson Laboratory Resources for Optogenetics, Cre-dependent Optogenetic Tools and Cre Strains for Neurobiology (jax.org/optogenetics). The JAX Mouse Repository is supported by NIH, The Howard Hughes Medical Institute and several private charitable foundations.

Title: Multi-colour optogenetic manipulation of cAMP and cGMP signalling from synapse to circuits

Authors: *M. VALENCIA[1,2], T. T. LUYBEN[1,2], K. OKAMOTO[1,2];
[1]Lunenfeld-Tanenbaum Res. Inst., Mount Sinai Hosp., Toronto, ON, Canada; [2]Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

Abstract: Cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) are major intracellular signaling molecules that are modulated both positively and negatively and in connection with each other. In neurons, cAMP and cGMP play important roles in synaptic plasticity, learning and memory, however the precise details of their dynamic interaction are not fully known. To study the role of cAMP and cGMP interaction at the synapse, we established an optogenetic strategy to selectively activate cAMP and cGMP signalling using different colours of light.

For the multi-colour optogenetic approach, we validated the codon-optimized form of a bacterial photoactivatable adenylyl cyclase (PAC) and its mutant guanylyl cyclase (BlgC), which produce cAMP and cGMP, respectively, in response to blue light. To combine with these photoactivatable enzymes, we prepared and examined a far-red light-sensitive adenylyl (NIR-PAC) and guanylyl cyclase (NIR-PGC), and also a bacterial rhodopsin-guanylyl cyclase (RhGC) which is sensitive to green light. These photoactivatable enzymes were rapidly activated in the milliseconds order with the relevant wavelength of light and then inactivated upon its removal *in vitro*. We found that PAC and RhGC can be used together to selectively activate cAMP and cGMP with two different colours of light, enabling the precise regulation of their timing-dependent interaction.

To target the photoactivation at the single synapse level, we have used PAC or BlgC with two-photon laser light excitation. To expand this technique for multi-colour optogenetics using different wavelengths of excitation light, we tested the activity of each enzyme across the two-photon excitation spectra *in vitro.* We found that longer wavelengths of two-photon light (>1,000 nm) efficiently photoactivated RhGC and far-red light sensitive enzymes (NIR-PAC, NIR-PGC), while shorter wavelengths (up to 1,000 nm) well-activated the blue light-sensitive enzymes such as PAC.

These approaches allow non-invasive spatiotemporal manipulations of cAMP and cGMP signalling from target synapse to entire brain regions, enabling systematic analysis of their interactive function. We will discuss how these optogenetic technologies will serve as valuable tools for elucidating the role of cAMP and cGMP in living neurons.

Title: Optogenetic control of phosphodiesterase activity in living neurons

Authors: *F. BERGIN, K. OKAMOTO;
Lunenfeld-Tanenbaum Res. Inst., Toronto, ON, Canada

Abstract: Cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) are second messengers with a variety of essential physiological functions including synaptic plasticity which is critical for learning and memory. Phosphodiesterases (PDEs) are the enzymes that degrade cAMP and cGMP providing critical regulatory control of these second messengers and have been actively targeted for drug discovery for a variety of psychiatric and neurodegenerative disorders. However, the activity-dependent dynamics and pre-synaptic roles of cAMP and cGMP signaling are poorly understood due to a lack of methods available to selectively and spatiotemporally manipulate these second messengers. To overcome this limitation, we report optogenetic tools to manipulate PDEs activity by light to specifically degrade cAMP and cGMP. We designed photoactivatable PDE4 and PDE5 to hydrolyze cAMP or cGMP using a far-red light sensitive domain PAS-GAF-PHY and the catalytic domain of PDEs (Gasser *et al*, 2014). Upon milliseconds of applied LED light, photoactivatable PDE4 and PDE5 showed strong cAMP or cGMP degradation, demonstrating their rapid photoactivation and catalytic specificity *in vitro*. Furthermore, the photoactivatable PDEs demonstrated a rapid inactivation upon removal of light. PDEs exist as membrane bound or soluble forms, which results in important subcellular regulation of cAMP and cGMP signaling. In addition to the soluble photoactivatable enzymes, we created membrane bound photoactivatable PDE4 and PDE5 utilizing a membrane localization signal. The membrane bound photoactivatable PDEs also have similar light-dependent activity and localized to the cellular membrane in living neurons. For activation of photoactivatable PDEs at the target single synapse level in living tissues, we utilized two-photon microscopy. We examined the two-photon excitation spectra of photoactivatable PDEs *in vitro* to understand the optimal wavelength to activate each PDE. We found the longer two-photon excitation wavelengths (more than 1,000 nm) corresponding to the far-red light sensitive domain efficiently activated these PDEs *in vitro*, suggesting the ability to control its activation at single synapses. We will discuss their application in *in vivo* studies from synapse to brain level.

Title: *In vivo* application of an integrated multi-beam nanophotonic switch for high resolution optogenetic stimulation

Authors: *Q. LI[1], A. MOHANTY[2,3], M. A. TADAYON[2,3], M. LIPSON[2,3], A. KEPECS[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Dept. of Electrical Engin., Columbia Univ., New York, NY; [3]Sch. of Electrical and Computer Engin., Cornell Univ., Ithaca, NY

Abstract: The ability to optically turn on or off the activity of specific neural populations has revolutionized the investigation of neural circuits. Most applications, however, employ a single optical fiber to flood a large area of the brain with light, limiting the ability to selectively activate neurons with high spatial resolution in vivo. Using silicon photonics technology it is possible to miniaturize complex optical circuits on a silicon chip, resulting in a quantum leap in optical control, matching the scale and resolution currently achieved by electrical silicon probes for electrical recordings.

Here we developed and tested the first visible light multipoint-emitting nanophotonic switches for in vivo optogenetics. To enable selective activation of neurons using multiple, independently controllable optical beams, we used micro-switches that could route light toward different diffraction gratings. Fast and independent control over each beam was achieved via external micro-controllers. We demonstrated that the same technology previously used for switching light in the near infrared spectral range could be used for switching light in the visible, using the thermo-optic effect of silicon nitride, a material that is transparent to the visible spectral range. To characterize the probe performance in mammalian brain in vivo, anaesthetized mice expressing ChR2 in PV+ inhibitory interneurons (PV-Cre x Ai32 mice) is used. The demonstrated probe employs a 1x4 multipoint-emitting nanophotonic switch (emitter size: 20 x 20 μm, 250 μm interbeam distance) coupled to a tungsten electrode array. The probe could be readily inserted and lowered into cortex. By applying two external microcontrollers to arbitrarily direct 472nm blue light to 4 output grating light emitters we could independently activate single ChR2-expressing PV interneurons throughout layers 2-6 of visual cortex in vivo. The activated PV interneurons showed robust spike firing with short first spike latency (1.475 +/- 0.063 ms, mean +/- sem) and low jitter (0.031 +/- 0.003 ms, mean +/- sem). In conclusion we successfully show our ability to use external microcontrollers to arbitrarily direct light to multiple densely spaced illumination points along the shank. Scaling it up to a larger number of beams (e.g.128) is expected to be straightforward since these devices are defined lithographically, enabling high-resolution optical stimulation in deep brain regions.

Title: Precision optogenetic stimulation using directional light from a multichannel optrode

Authors: ***J. J. WHEELER**[1], J. REGISTER[2], C. SEGURA[2], J. LEBLANC[2];
[1]Draper Lab., Boston, MA; [2]Draper Lab., Cambridge, MA

Abstract: In this work, we evaluate a method of light steering in small volumes of nerve tissue for optogenetics techniques and present a microfabricated device for the purpose. Optical simulations were carried out using Monte Carlo techniques with consideration to both scattering and absorption using the Henyey-Greenstein and Beer-Lambert models, respectively. The parameters of tissue volume, emission geometry, emitter size, and wavelength were varied in the simulation study. Data from the analysis was then used to drive the design of multimode waveguide structures made from photo-patternable polymers with the goals of minimizing both bending radii and insertion loss for compact geometries. Structures were fabricated using standard UV lithography with careful consideration to materials selection. The work has shown how multiple light emitters could be used to selectively activate small regions of tissue when greater spatial discrimination is needed.

Title: A fully integrated optrode based on multipoint emitting tapered optical fibers: the "fibertrode"

Authors: *L. SILEO[1], M. PISANELLO[1], B. L. SABATINI[2,3], M. DE VITTORIO[1], F. PISANELLO[1];
[1]Inst. Italiano di Tecnologia, Arnesano, Italy; [2]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [3]Howard Hughes Med. Inst., Boston, MA

Abstract: We present a new technological paradigm to realize fully integrated optrodes for simultaneous multipoint optogenetic control of neural activity and multisite single unit extracellular recording. The device, composed by a multipoint emitting tapered optical fiber (MPF) [Pisanello et al, Neuron 82, 1245 (2014)] along with multiple electrodes for extracellular recording, is realized by means of combined focused ion beam induced deposition and milling. The result is a fully integrated optrode (hereafter referred to as "fibertrode") with a tip cross-section <1μm and allowing for multipoint control and monitor of neural activity simultaneously. The technology is based on multiple focused ion beam milling and ion beam induced deposition processes performed on the MPF covered with alternating layers of metal and insulator thin films. The main advantage of the approach is the possibility to obtain from the same multilayered optical fiber a geometrical combination of photo-stimulation volumes and electrical recording sites which is tailored from time to time to the actual target region to be investigated. Moreover, points of illumination and points of electrical recording can be realized at any location on the non-planar surface of the taper, in contrast to other approaches in which the technology used constraints their arrangement on a plane configuration [Neuron 86, 106 (2015)]. In this study, the reliability for use in acute experiments of microelectrodes realized with the proposed technology is first demonstrated in vitro by testing their impedance-vs-time characteristics in saline physiological solution, which gave results comparable with those of commercial Michigan arrays. In order to exemplify the versatility of the approach, a number of different configurations were then realized with one, two or three microelectrodes combined with different optical windows geometries (a big single window or multiple apertures), with microelectrodes and optical windows fabricated on the same face or on opposite faces of the taper surface. Microelectrode performances were independent on the number, type and placement of the optical windows. Spontaneous activity was successfully recorded in head restrained mice validating the presented technology for its acute use in vivo and opening the way to experiments of open-loop and closed loop recordings realized with minimally invasive and fully integrated fibertrodes designed to suit the topography of the target region.

Title: Shielded coaxial optrode arrays

Authors: ***M. J. NAUGHTON**[1], J. R. NAUGHTON[2], M. J. BURNS[2], T. CONNOLLY[2], J. A. VARELA[2], J. A. VARELA[2], J. M. MERLO[2], T. C. CHILES[2], J. P. CHRISTIANSON[2]; [1]Dept. of Physics, [2]Boston Col., Chestnut Hill, MA

Abstract: Recent progress in the study of the brain has been greatly facilitated by the development of new tools capable of minimally-invasive, robust coupling to neuronal assemblies. Two prominent examples are the microelectrode array, which enables electrical signals from large numbers of neurons to be detected and spatiotemporally correlated, and optogenetics, which enables the electrical activity of cells to be controlled with light. In the former case, high spatial density is desirable but, as electrode arrays evolve toward higher density and thus smaller pitch, electrical crosstalk increases. In the latter, finer control over light input is desirable, to enable improved studies of neuroelectronic pathways emanating from specific cell stimulation. Here, we introduce a coaxial electrode architecture that is uniquely suited to address these issues, as it can simultaneously be utilized as an optical waveguide and a shielded electrode in dense arrays. Using optogenetically-transfected cells on a coaxial microelectrode array, we demonstrate the utility of the shielded architecture by recording cellular currents evoked from optical stimulation. We also show the capability for network recording by radiating an area of individually-addressed coaxial electrode regions with cultured cells covering a section of the extent.

Title: Tetherless magnetothermal deep brain neuro-stimulation and -silencing to modulate behavior in awake, unrestrained mice

Authors: *A. PRALLE, R. MUNSHI, I. CASTELLANOS-RUBIO, S. QADRI;
Physics, Univ. At Buffalo, SUNY, Buffalo, NY

Abstract: Precise remote, tetherless stimulation of deep brain circuits evoking specific behaviors in unrestrained subjects would facilitate neuroscience research of brain circuits underlying behavior and emotion. Using bioconjugated superparamagnetic nanoparticles and a heat-sensitive cation-channel, we demonstrate how the energy of magnetic fields can be transduced into evoking robust locomotion in awake, freely moving mice. Stimulation in the motor cortex evoked ambulation, deep brain stimulation in the striatum caused rotation around the body-axis, and even deeper stimulation near the ridge between ventral and dorsal striatum caused freezing of gait. The animals respond within seconds of field onset, and the behavior persists for the duration of the field. By combining the magnetic nanoparticle heating with a heat-sensitive chloride channel, we cause remote, magneto-thermal silencing of neurons. In a place preference assay, we show that this remote silencing can in-vivo modulate behavior of freely moving mice. Membrane binding of the nanoparticles allows for high spatial control with minimal nanoparticle volumes. The presented approach provides genetically and spatially targetable activation of neuro-circuits deep inside the brain without any tether into the brain or any surgical implantation of any device.

Title: Key residues in fluorescent protein reverses the polarity of voltage sensitivity in the voltage indicator ArcLight

Authors: *J. PLATISA[1,2], G. VASAN[1,2], V. A. PIERIBONE[1,2];
[1]The John B Pierce Lab., New Haven, CT; [2]Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Genetically encoded calcium indicators (GECIs) produce unprecedentedly large signals which make them the only indicators to allow routine optical recording of single neuron activity *in vivo* in rodent brain. Genetically encoded voltage indicators (GEVIs) offer a more direct measure of neuronal electrical status, however the signal to noise characteristics and signal polarity of the probes developed to date have precluded routine *in vivo* use. We applied directed evolution to target areas of the fluorescent protein in the GEVI ArcLight to create the first GFP-based GEVI (Marina) that exhibits a $\Delta F/\Delta V$ with a positive slope relationship. We found that only three rounds of site-directed mutagenesis produce a family of 'positively going' GEVIs with voltage sensitivity comparable to that seen in the parent indicator ArcLight. Voltage sensitivity and good membrane localization of Marina allows for detection of single action potentials and subthreshold events in spontaneously active mammalian neurons *in vitro.* This shift in signal polarity is an essential first step to producing voltage indicators with signal to noise characteristics comparable to GCaMPs and support widespread use *in vivo.*

Title: Mouse homecage self directed motor learning and brain imaging: training, software, and hardware.

Authors: F. BOLANOS[1], G. SILASI[1], J. D. BOYD[1], J. LEDUE[1], S. H. SCOTT[2], *T. H. MURPHY[1];
[1]Univ. British Columbia, Vancouver, BC, Canada; [2]Queens, Kingston, ON, Canada

Abstract: Automated assessment of rodent behaviour is desired as it reduces experimenter bias, facilitates high throughput, avoids disrupting circadian rhythms and eliminates stress introduced by experimenter handling. We developed an automated mouse lever pulling task that mice can perform 24 hrs a day in the home cage to assess forelimb function (see image with 4 mice in cage). The apparatus consists of a small chamber attached to the outside of the home cage, which contains a recessed lever that the mice can access with their forelimb. The lever is attached to the axle of a rotary encoder (or torque motor) allowing us to measure lever position during each pulling event. An RFID sensor on the roof of the training compartment detects a unique RFID tag that is implanted subcutaneously in each mouse at the nape of the neck. To encourage task participation, mice are water restricted, and a solenoid attached to a drinking spout dispenses a ~10µl drop of water upon the successful completion of a lever pull. In the initial phase of training mice receive a water reward for just entering the training compartment, while subsequent phases require the mice to hold the lever in a rewarded position for incrementally longer durations and a smaller range of movement. Individualized performance is logged and task parameters are controlled by custom software written in Python running on a Raspberry Pi keeping costs low and the footprint small. Mice enter the training chamber ~300 times in a 24 hr period and perform over 500 trials once they have acquired the task. The number of successful trials increased during the first week of training, and on average it takes ~7 days of unsupervised training for mice to acquire a 1 second hold duration on the lever. Future experiments will introduce perturbations to lever position during the hold period to assess properties of voluntary motor control. We are exploring adding the sensory-motor lever task to similar cages that

support automatic head-fixation and brain imaging (Murphy et al. 2016 Nature Commun.) to permit automated brain circuit assessment in the context of the forelimb task.

Title: Effects of optogenetic activation of ventral tegmental area neurons on locomotor activity and temperature in TH-Cre rats treated with amphetamine or raclopride

Authors: ***R. RICE**[1], Z. MESSER[2], S. WHITEHOUSE[2], E. N. OTTEM[3], A. J. PRUS[2]; [1]Psychology, Virginia Commonwealth Univ., Benzonia, MI; [2]Psychology, [3]Biol., Northern Michigan Univ., Marquette, MI

Abstract: The mesolimbic dopamine pathway is an important structure to study for understanding the rewarding effects of drugs of abuse and for elucidating the neurotransmitter mechanisms of mental disorders, such as schizophrenia. The recent development of optogenetic techniques provides a high precision approach for evaluating behavior following selective stimulation of mesolimbic dopamine neurons. The present study sought to examine the behavioral effects of a dopamine agonist and antagonist during activation of mesolimbic dopamine neurons. Male TH-Cre rats were used to express Channelrhodopsin-2 (ChR2), through viral mediated gene deliver, in the ventral tegmental area (VTA). ChR2 was activated using 465nm (blue) light via fibers installed dorsal to the VTA, which led to a significant increase in locomotor activity in an open field and body temperature compared to when the light was deactivated. Amphetamine (i.p.) significantly increased locomotor activity to a far greater extent than light activation in saline-treated rats; the effect of amphetamine did not differ between the activation or deactivation of light. Amphetamine also did not increase body temperature compared to saline. The dopamine $D_{2/3}$ receptor antagonist raclopride did not attenuate light-induced increases in locomotor activity or body temperature, although only a small sample size was available during this phase of the study. As expected, these results demonstrate that selective activation of mesolimbic dopamine neurons enhances locomotor activity and body temperature, although amphetamine produced a much greater increase in locomotor activity than light. These findings may correspond to differences in dopamine release elicited by enhancing the firing rate of dopamine neurons versus the effects of amphetamine at axon terminals. The lack of inhibition by raclopride of light-induced locomotor activity may either be due to a low sample size or may indicate that other receptors, such as D_1 receptors, may mediate these effects.

Title: Virus, opsin, and immunomodulation selection for optogenetic control of peripheral motor function

Authors: *J. J. WILLIAMS[1], A. L. VAZQUEZ[2], C. WIRBLICH[4], M. J. SCHNELL[4], A. B. SCHWARTZ[3];
[1]Systems Neurosci. Inst., [2]Dept. of Radiology, [3]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Microbiology and Immunol., Thomas Jefferson Univ., Philadelphia, PA

Abstract: The incorporation of light sensitive opsins into peripheral motor nerves offers a promising alternative to traditional functional electrical stimulation in restoring lost motor function. Gene therapy to express such optogenetic constructs for functional optical stimulation of muscles has been successfully demonstrated in non-transgenic rodents. However, the procedure for transducing opsins into peripheral motor nerves is technically difficult, and only a limited catalog of proven constructs in this context exists to date. To realize a robust clinical outcome for this approach, it will be necessary to demonstrate expression in primate peripheral nerves which has not yet been achieved. In light of this need, our present study examines the efficacy of several viral vectors and opsins in transducing nerves sensitive to functional optical stimulation. Here, we discuss ongoing experiments and results with several AAV-based vectors (serotypes 6 and 9) as well as a non-replicating rabies virus (NRRV) vector. In addition, we present results from constructs utilizing one of two opsins: the traditional channel rhodopsin (ChR2) as well as the more recently described Chronos. Finally, we will describe our protocol and results for administering dexamethasone as an immunosuppressant to facilitate virus transduction into motor nerve cells. Hopefully, our findings will provide valuable insight into approaches that will translate well to primate peripheral motor gene therapy.

Abstract: The complex anatomical structures of individual neurons and their synaptic connections form the signal transmission and processing pathway of the nervous system, and therefore are basis for understanding brain functions. However, existing imaging methods always need to compromise the speed, and signal-to-noise ratio and thus is difficulty to cover the huge extension of neurons in mammalian brain with a resolution sufficient to identify connection sites (the pre- and postsynaptic structures). Here we proposed a so-called chemical sectioning (CS) method, a tomographic imaging method, that enables systematically reconstruct the integral morphology of individual neurons, even across a whole-mouse-brain, at synaptic resolution. With the help of sparse labeling, for the first time, we show the successful reconstruction of individual neurons extending axonal projections throughout the brain, including all dendrites, centimeter-extended axonal main stems, terminal arborizations, intensive dendritic spines and axonal boutons, and putative synapses. Our method enables quantitative analysis of the morphology, projections, and connectivity of genetically defined neurons. This method will shed light for neuroscience studies like cell type, neural circuits and neuronal computations.

Title: Serial two-photon tomography for three-dimensional vasculature reconstruction of mouse cochlea

Authors: *D. LAZIC[1,3], K. KISLER[1], A. AHUJA[1], P. SALEHI[2], P. S. TSAI[4], R. A. FRIEDMAN[2], B. V. ZLOKOVIC[1];

Abstract: Understanding the spatial distribution of various cell types that occurs in physiological and pathological conditions is of great importance. Although many two-dimensional immunostaining techniques are widely used to reveal cellular architecture in different organs, many cell distribution patterns, such as vasculature, are not readily appreciated in two-dimensions. Serial two-photon (STP) tomography is a powerful technique that combines automated serial sectioning and two-photon microscopy imaging of fluorescently labeled tissue throughout the whole organ, providing three-dimensional (3D) high resolution datasets down to sub-micron level. Normal functioning of cochlea is dependent on adequate blood supply and disruption of cochlear vasculature and blood flow appear to be linked to hearing impairment. Studying of the mouse cochlear vascular network and blood flow is challenging due to its small size, complex spiral shape, and location deep in the inner ear, making it poorly accessible for *in vivo* imaging studies. Here, we describe a method using STP tomography to generate 3D vascular reconstruction map of the mouse cochlea. We injected six week-old C57BL/6 mice with DyLight 594-conjugated tomato lectin in superficial femoral vein to label perfused blood vessels. Following paraformaldehyde perfusion, the cochlea was dissected and subjected to further fixation, decalcification and clearing steps. Whole cochlea was covalently mounted in agarose and scanned on STP tomography. Vascular density, diameter and length were analyzed using customized Volumetric Image Data Analysis (VIDA) MatLab script. Overall, the use of this novel STP tomography method and analysis of vasculature network offers a relatively straightforward and fast assessment of the mouse inner ear vascular architecture. In addition, this approach can address many important questions regarding vascular organization in different conditions such as aging, noise exposure and ototoxicity, all of which can contribute to hearing loss.

Abstract: Serial two-photon tomography (STPT), a technique that produces large-scale, three-dimensional images of intact brain tissue, is expanding the capacity to investigate brain-wide circuit mechanisms associated with neurological and psychiatric disorders as well as brain injury. The UT Southwestern Whole Brain Microscopy Facility (WBMF) (http://www.utsouthwestern.edu/education/medical-school/departments/neurology/research/microscopy-facility/index.html), part of the newly established Peter O'Donnell Jr. Brain Institute, is coordinating research efforts by several laboratories that are investigating the circuit basis of brain disorders across the micro-, meso-, and macro-scales of inquiry. The facility houses two TissueCyte 1000 STPT microscopes capable of producing high-resolution (minimum voxel size less than 1 μm^3) images of entire rodent brains subjected only to standard perfusion fixation procedures in preparation for imaging. Here, we report progress towards imaging and analyzing region- and cell-type specific projections in mouse brains. We have now optimized sample preparation and imaging conditions for a variety of tissues, including adult brain, early postnatal brain and spinal cord. Submitting laboratories used several techniques to introduce fluorophores into neurons of interest, including anterograde and retrograde fluorescent dyes, anterograde and retrograde viral injections, and transgenic mice that express Cre recombinase in a cell type-specific manner. To probe the changes in regional and cell type-specific projections that occur after various nervous system perturbations, STPT-based circuit tracing was used in conjunction with genetic models of neuropsychiatric disease and experimentally-induced brain injury. Preliminary results across several experimental paradigms establish the utility of this approach for identifying circuit-level dysfunction in complex brain disorders. Future work will incorporate computational strategies for automated analyses of features of interest in whole brain datasets (e.g. cell body quantification, axon tract length). We ultimately hope to apply our facility's large-scale, high-throughput model for brain-wide connectivity analysis to identify therapies that improve neural circuit connectivity in models of neuropsychiatric and neurodegenerative disorders.

Title: Serial OCT scanner : comparing 3D histology to *In vivo* imaging in the entire mouse brain

Authors: *A. CASTONGUAY, J. LEFEBVRE, P.-L. TARDIF, P. DELAFONTAINE-MARTEL, P. POULIOT, F. LESAGE;
École Polytechnique De Montréal, Montreal, QC, Canada

Abstract: In the study of brain anatomy and function, histological examination remains the gold standard to fully comprehend in vivo measurements. For this purpose, a serial OCT scanner was designed to image large 3D sections of biological tissues at microscopic resolution. OCT imaging reveals changes in refractive indices, giving rise to high contrast between white and grey matter in the mouse brain. METHODS: Serial imaging of mice brains embedded in agarose blocks was performed by cutting through brain tissue using a vibratome. The vibratome sequentially cut slices in order to reveal new tissue to image, overcoming the limited light penetration encountered in optical microscopy of biological tissues. Raw data was then post-processed to stitch each individual acquisition and obtain a reconstructed volume of the brain. To validate the ability of the scanner to provide a reliable representation of the in vivo brain, 4 wild type mice were used. The brains were first imaged in vivo with a 7 Tesla MRI scanner. Mice were then sacrificed, perfused with 4% PFA and re-imaged with the MRI scanner to assess deformations caused by fixation. Finally, brains were extracted, fixed in agarose and imaged using the serial OCT scanner. Template brains for each imaging modality (MRI in vivo and ex vivo, OCT scanner) were obtained using Advanced Normalization Tools (ANTs), which was also used to measure morphometric changes between imaging modalities. For each modality, whole brain volume, cortical volume, white matter vs grey matter ratio and deformation fields between modalities were analysed. RESULTS: Preliminary results show little variation in whole brain volume between MRI in vivo (343,3 ± 5,8 mm^3) and ex vivo brains (344.0 ± 15.3), suggesting little deformation caused by perfusion. The ratio of cortical volume over whole brain volume remained constant between every modality (MRI invivo : 27,4 ± 1,2 %, MRI ex vivo : 25,2 ± 2,1% , slicer : 26,5 ± 0.7 %). CONCLUSION: Serial microscopic scanners proved to be a novel massive histological imaging technique able to accurately represent in vivo measurements.

This proof of principle study will pave the way for further work requiring histological analysis in the whole brain and correlation to in vivo measurements.

Title: OPT: light sheet fluorescence microscopy with increased spatial resolution

Authors: ***A. NARASIMHAN**, K. UMADEVI VENKATARAJU, D. F. ALBEANU, P. OSTEN;
Cold Spring Harbor Lab., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: We have designed a custom microscope, called Oblique Plane Tomography (OPT), that operates on the principle of light sheet fluorescence microscopy (the sample is illuminated with a scanned thin light beam to generate a planar light sheet and images are acquired by wide-field fluorescence microscope placed perpendicular to it), but the illumination/detection paths are oriented obliquely (45°) with respect to the tissue surface. This oblique orientation allows for imaging the surface of the brain to ~400 μm depth in an XY raster pattern. Once the raster scan is completed, the brain is translated to an integrated vibratome to section the imaged tissue. The raster scan and automated sectioning is repeated iteratively to obtain whole brain coverage. Since tissue scattering limits the light penetration depth, we modified and optimized a clearing protocol based on the CUBIC protocol for clearing the brains [1]. Based on the current instrument configuration, a cleared adult mouse brain is imaged within ~10 hrs at 0.4 X 0.4 X 5 μm voxel resolution with overlapping regions for image registration and reconstruction. We use this custom built OPT to understand the connectivity of local and long-range individual neurons at single-cell resolution in the olfactory system. It is known that mitral cells (MTs) from a single glomerulus project randomly in the piriform cortex, but project to spatially distinct regions in the cortical amygdala [2]. What is not known, however, is the projection and spatial distribution of individual MTs to other regions of the brain. We use a sparse labeling approach using Sindbis

virus to trace the projections of the MTs in the whole brain. Additionally, to address the question as to whether there is any target-area specification at the level of single MTs to anatomically distinct regions such as piriform cortex or cortical amygdala, we use a reterograde targeting using CAV-DIO-mCherry, in each of the target areas to identify populations of cells that do and do not send collaterals. These viral approaches will elucidate the role of MT's in olfactory information processing.

Title: Generation of whole brain atlas for the cholinergic system via fluorescence micro-optical sectioning tomography

Authors: ***X. LI**[1], B. YU[2], Q. SUN[1], M. REN[1], Y. ZHANG[1], J. YUAN[1], Q. LUO[1], H. ZENG[3], H. GONG[1], Z. QIU[2];

Abstract: The cholinergic system in the brain plays crucial roles in regulating motor functions and cognitive behaviors by modulating neuronal excitability. The 3-dimensional atlas of cholinergic neurons in the whole brain scale would be valuable to further understand the cholinergic system. Here we report the generation of the comprehensive whole-brain atlas for

cholinergic neurons by fluorescence micro-optical sectioning tomography (fMOST). With ChAT-IRES-Cre mice and Cre-dependent reporter line, cholinergic neurons were genetically fluorescent labeled, while almost all GFP-labeled subcortical neurons were choline acetyltransferase immunoreactive cells. We acquired the complete distribution of these GFP labeled neurons across different brain regions after reconstructing the whole-brain map precisely, including the characterization of intrinsic cholinergic cells of the cerebral cortex. Furthermore, we reconstructed the morphology of cholinergic neurons in the cortex, which showed layer-specific difference. These analyses provide a foundation for further functional dissection of the cholinergic system in the brain.

Title: Systematic comparison of ultrastructural and antigenic preservation of cortical tissue embedded in Lowicryl HM20 and LR White resins

Authors: ***M. M. NAUGLE**[1], K. N. PARKER[1], S. M. DAVIS[1], R. SERAFIN[1], F. COLLMAN[1], S. J. SMITH[1], R. J. WEINBERG[2];

Abstract: There is a well-known trade-off between ultrastructural and antigenic preservation in plastic-embedded tissue. Here we compare two acrylic resins, LR White (generally considered especially effective for maintaining antigenicity) with Lowicryl HM20 (reputed to provide particularly good ultrastructure). After verifying these impressions of “reciprocal” performance for the two resins, we hypothesized that it might be possible to gain benefits offered by each resin by preparing mixtures. We find that LR White and Lowicryl are fully miscible; importantly, the mixtures polymerize effectively in the cold with UV light into blocks suitable for ultrathin sections. We used immunofluorescence on ultrathin section arrays to evaluate antigenicity, and scanning electron microscopy to examine ultrastructural preservation. Based on

initial promising results, we are investigating a wider range of mixtures for both antigenic and ultrastructural preservation.

Title: Storing and analyzing large array tomography datasets in the cloud

Authors: ***A. D. BADEN**[1], F. COLLMAN[2], K. LILLANEY[1], J. T. VOGELSTEIN[1], R. BURNS[1];
[1]Computer Sci., Johns Hopkins Univ., Baltimore, MD; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: As automated methods for array tomography data collection improve, a multi-terabyte dataset can now be collected in as little as a few days. Specialized software is required to be able to store, visualize, and analyze this data. For example, the NeuroData Project currently hosts 100+ terabytes of public data spread across its cloud and local storage platforms. In this poster, we detail our current data processing pipeline with respect to array tomography. Using tools developed in conjunction with the NeuroData team, our pipeline supports storing multi-terabyte datasets in the cloud (NDStore), on-demand analysis and visualization of multi-channel datasets in the web browser (NDViz), and associating metadata with images using a rich and generalizable metadata framework (RAMON). Users can also download and upload data and run analysis tasks using ndio, our Python interface to NDStore services. Our data processing pipeline is briefly summarized as follows. First, 3D volumes (i.e. imaging tiles that have been stitched, aligned, and registered) are ingested into the NDStore spatial database. NDStore is optimized for quick, localized access to specific spatial regions. NDStore also enables the use of several additional services. For example, the NDStore histogram service allows the user to generate a

histogram using a background process. Once the histogram is generated, users can compute statistics across the entire dataset using only the histogram. We demonstrate several use cases, including setting a rough intensity range for converting 16-bit images to 8-bit images, and doing semi-automated quality control across a large number of imaging sessions. After ingest, data is available for use in our other web-based tools. NDViz supports dynamic visualization, maximum intensity projections, brightness / contrast image processing, and on-demand false coloring of multiple channels in the web browser. NDViz also supports dynamic, clickable metadata and annotation overlays. For example, we demonstrate uploading and visualizing the results of a synapse detection algorithm on an Array Tomography dataset using NDStore and NDViz. Our web tools also support creating links to specific views, allowing us to share data with collaborators by sending a hyperlink instead of a multi-terabyte volume.
Finally, we discuss next steps, including integrating an automated volume reconstruction pipeline, which would piece together the individual tiles into a stitched, registered, and aligned volume.

Title: Query based probabilistic synapse detection in immunofluorescence data

Authors: ***A. K. SIMHAL**[1], C. AGUERREBERE[1], F. COLLMAN[2], J. T. VOGELSTEIN[3], K. D. MICHEVA[4], R. J. WEINBERG[5], S. J. SMITH[2], G. SAPIRO[1];
[1]Electrical Engin., Duke Univ., Durham, NC; [2]Synapse Biol., Allen Inst. for Brain Sci., Seattle, WA; [3]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [4]Mol. and Cell. Biol., Stanford Univ. Sch. of Med., Stanford, CA; [5]Cell Biol. and Physiol., Univ. of North Carolina, Chapel Hill, NC

Abstract: The systematic examination of synaptic organization within large (> 1 mm^3) modules of brain containing millions of synapses requires robust techniques for synapse detection. Electron microscopy (EM) is the gold standard modality for synapse detection, but data acquisition is much slower and more expensive than with immunofluorescence (IF). The introduction of array tomography enables acquisition of hyperspectral proteometric data with IF, allowing identification of multiple synapse subtypes. This creates a need for effective synapse detection algorithms suitable for IF-only data.

The molecular diversity of synapses makes creating a canonical synapse model very challenging. Traditional machine learning techniques need large amounts of labeled training data for each potential subclass, which is often not available. Therefore, synapse detection algorithms must incorporate synaptic proteometric diversity and neuroscience knowledge.

We present a query-defined probabilistic synapse detection algorithm. For each excitatory synapse subtype, the user selects synaptic markers and synapse punctum sizes to consider. The output is a probability map; each voxel is the probability that it belongs to a synapse. This model-based algorithm incorporates fundamental biological knowledge of synapses and how they are manifested in the immunofluorescence data, providing detections with confidence values.

We evaluated the proposed approach on two conjugate array tomography datasets (for which synaptic identification had been confirmed with EM). Using six different query structures, we detected ~93% of PSD-95-expressing excitatory synapses, a level of accuracy comparable to a human experts. This fundamental approach opens the door to data-driven discovery of new synapse types and their density in a probabilistic fashion. The methods developed for this application are readily applicable to other datasets. All data, code, and data derivatives will be made available after publication through the NeuroData website, neurodata.io.

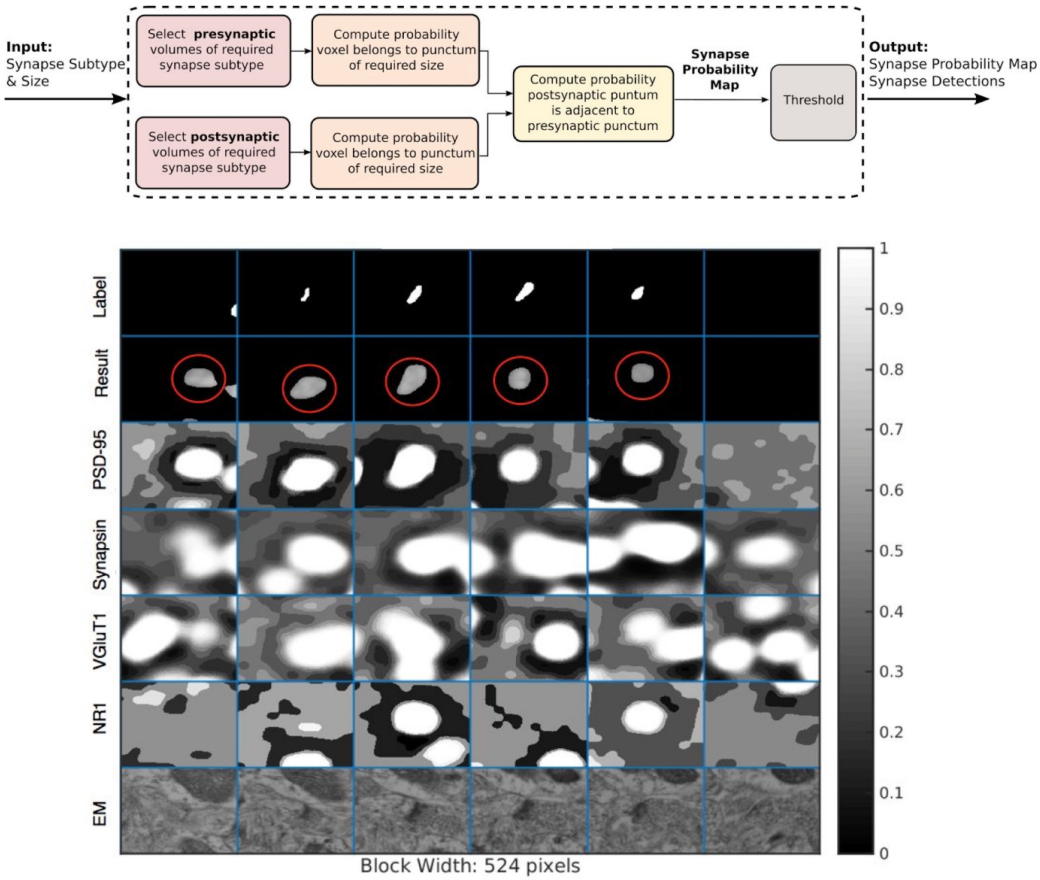

Figure 1. Top: Fundamental steps of the probabilistic synapse detection algorithm. **Bottom:** Example of a synaptogram. Each row is a channel and each column is a slice. Slices are spaced 70 nm apart and each pixel in a "window" is 2.33 nm x 2.33 nm. The number of pixels is given underneath the axis. 'Label' refers to the expert manual annotation of the synaptic cleft. 'Result' is the probabilistic output of the proposed synapse detection algorithm. The synapse detection is circled in red.

Title: ndparse: tools and interfaces for scalable neuroscience discovery

Authors: *W. R. GRAY RONCAL[1,5], J. MATELSKY[2], M. PEKALA[5], D. M. KLEISSAS[5], J. T. VOGELSTEIN[3,4], G. D. HAGER[2];
[2]Computer Sci., [3]Biomed. Engin., [4]Inst. for Computat. Med., [1]Johns Hopkins Univ., Baltimore, MD; [5]Res. and Exploratory Develop., JHU Applied Physics Lab., Laurel, MD

Abstract: The field of structural connectomics seeks to generate high-resolution maps of the brain, across various sensor modalities and scales ranging from mesoscale to nanoscale. The number of data challenges and algorithms is exploding, and users must decide on a processing pipeline without an easy way to explore alternatives and integrate new methods. However, many pipelines follow a predictable pattern: begin with a collection of images, align and stitch into a volume, format for compliance with a database or filesystem, process using computer vision and machine learning, and upload the result.
We introduce ndparse, a software toolkit that provides common interfaces and best practices for many of the use cases neuroimagers face when trying to extract knowledge from their data. We have written thin layers around popular tools and developed new protocols and algorithms to facilitate the generation of results in a standard, modular format. We include support for alignment and stitching (e.g., terastitcher), membrane detection (e.g., keras, theano), neuron segmentation (e.g., gala), object detection (e.g., ilastik, vesicle), post-processing, evaluation, and knowledge extraction.
ndparse is flexible and extensible to new algorithms, and it can be used with a variety of schedulers and meta-schedulers. Our interfaces facilitate reproducible and interoperable science and enable rapid prototyping and optimization. The community is invited to develop new functionality by submitting pull-requests at github.com/neurodata/ndparse. ndparse is compatible with ndio [github.com/neurodata/ndio], which greatly simplifies data access with local files or remote endpoints (e.g., NeuroData, DVID, S3).
We demonstrate the utility of this package via a use-case for graph generation in EM data. In this framework we show that work that previously required many lines of custom code can be run with only a few lines of descriptive python, black-boxing the underlying algorithms and simplifying the computational expertise required for scalable scientific discovery.

Title: Fast, automated array imaging for synaptomics and connectomics

Authors: ***S. J. SMITH**, O. GLIKO, R. SERAFIN, S. SESHAMANI, M. NAUGLE, K. PARKER, S. DAVIS, K. LEPAGE, H. PENG, J. TING, E. LEIN, F. COLLMAN;
Synapse Biol., Allen Inst. For Brain Sci., Seattle, WA

Abstract: This poster describes an automated high-throughput array tomography platform designed to image cubic-mm-scale volumes of brain tissue (such as cortical physiology slices) by both multi-channel super-resolution fluorescence and electron microscopy. Fluorescence imaging of tomography arrays at a rate of 10,000 4.2-megapixel tiles per hour has been demonstrated and full automation of stain/wash/strip cycles is expected to allow unattended accumulation of 20 or more distinct fluorescence channels. Array tomography also allows for voxel-conjugate scanning electron microscopy (SEM) of selected array sub-regions after fluorescence imaging. Software now under development will allow for the automation of SEM sub-region selection driven by machine vision analysis of prior fluorescence images. We'll also describe progress toward automated image quality control and pre-processing software designed to enable robust streaming of fully restored fluorescence and SEM image tiles into the cloud for volume reconstruction, analysis and storage.
This array tomography platform is expected to image the entirety of mm3 volumes with 100 nm isotropic, multichannel voxels in a matter of days, with conjugate SEM imaging of thousands of sub-regions acquired in similar time periods. With use of appropriate antibodies targeting synaptic and cell-type-specific proteins, such image data will allow quantitative analysis of diverse synapse populations in mouse and human cortical tissue at the single-synapse level. In specimens where sparse subsets of neurons are labeled by fluorescent dyes or proteins,

reconstruction of complete neuronal arbors and their associated synaptic connections is expected to yield rich "shotgun" samples of cortical local circuit connectivity.

Abstract: Highly validated antibodies that exhibit robust and specific immunoreactivity form the core of many neuroscience research projects. However, in many cases the immunoreactivity of antibodies can be profoundly influenced by sample preparation conditions, such that each antibody needs to be validated for efficacy and specificity in the specific application and sample preparation conditions in which it will be used. Array tomography (AT) is a technique that allows for an unprecedented combination of high resolution and deep proteomic dimensionality for subcellular localization of large sets of proteins in brain, features particularly relevant to the characterization of large populations of mammalian brain synapses. In general, sample preparation for AT has aspects distinct from those used to validate antibodies for use in other applications. As such, the efficacy and specificity of any given antibody for use in brain AT must be empirically determined, and in many cases available antibodies that have demonstrated efficacy and specificity in other applications are not useful for immunolabeling of brain AT samples. We have undertaken a concerted effort to both validate large sets of existing monoclonal antibodies, and to develop and validate novel monoclonal antibodies, with a unique

focus on directly assaying their efficacy and specificity in AT. We have also evaluated which of the most commonly used non-AT antibody validation procedures exhibit the highest value for predicting which monoclonal antibodies will exhibit efficacy and specificity in brain AT sections. These studies will allow for the development of a substantial set of renewable reagents that are available to the research community for use in applications employing immunolabeling of brain AT samples.

Title: Imaging human brain cytoarchitecture with quantitative optical coherence tomography

Authors: ***D. A. BOAS**, C. MAGNAIN, H. WANG, E. KONUKOGLU, B. FISCHL, S. SAKADZIC;
Martinos Ctr. Biomed Imaging, Harvard Med. Sch., Charlestown, MA

Abstract: No current imaging technology allows us to directly and without significant distortion visualize the microscopic and defining anatomical features of the human brain. *Ex vivo* histological techniques can yield exquisite planar images, but the cutting, mounting and staining that are required components of this type of imaging induce distortions that are different for each slice, introducing cross-slice differences that prohibit true 3D analysis. We are overcoming this issue by utilizing Optical Coherence Tomography (OCT) with the goal to image whole human brain cytoarchitectural and laminar properties with potentially 3.5 μm resolution in block-face without the need for exogenous staining. From the intrinsic scattering contrast of the brain tissue, OCT gives us images that are comparable to Nissl stains, but without the distortions introduced in standard histology as the OCT images are acquired from the block face prior to slicing and

thus without the need for subsequent staining and mounting. We have shown that laminar and cytoarchitectural properties of the brain can be characterized with OCT just as well as with Nissl staining. A current limitation is that we presently integrate the signal over more than 50 μm in the axial direction to achieve sufficient contrast. We will present our recent advances to improve the axial resolution while maintaining contrast. Improvements are being obtained by developing speckle reduction procedures. In addition, we are beginning to obtain quantitative maps of the optical scattering coefficient, an intrinsic property of the tissue. We hypothesize that these quantitative maps will improve our contrast to the structural features of the brain and permit more isotropic resolution mapping of the volumetric features, enabling for example, the automated segmentation of neurons from multiple cm^3 of human brain tissue.

Title: Functional imaging of VIP interneuron activity in behaving mice

Authors: *Z. SZADAI[1], H. PI[2], G. KATONA[3], T. TOMPA[4], A. KEPECS[2], B. ROZSA[1]; [1]IEM-HAS, Budapest, Hungary; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [3]Pázmány Péter Catholic Univ., Budapest, Hungary; [4]Femtonics Ltd., Budapest, Hungary

Abstract: Vasoactive intestinal polypeptide (VIP) demarcates a small, unique population of inhibitory interneurons, making up 1-2% of all neocortical neurons. VIP interneurons are mainly located in the superficial layers of the neocortex and provide inhibition onto other inhibitory interneurons, most SOM and a fraction of PV neurons, thus disinhibiting principal cells. While the circuit impact of VIP interneurons has been well characterized, less is understood about their behavioral function. Here we set out to examine how VIP interneurons respond during simple choice behaviors. Measuring of sparse interneuron populations as the VIPs, is a challenging imaging task. Our aim was to record activity of over 100 interneurons simultaneously, while mice are behaving. We developed an improved 2P 3D acousto-optic microscope, and new scanning methods capable of measuring hundreds of neuronal somata. As a result, we measured simultaneously the activity of Gcamp6f - labeled VIP neurons in a 450 μm x 450 μm x 650 μm large volume. The half-cubic-millimeter scan range, with a high scanning speed (up to 500 pts per kHz), with less than 400 nm resolution in the center core and less than 1.9 μm × 1.9 μm × 7.9

μm resolution throughout the entire scanning volume allows us a very precise functional mapping at different areas and depths of the mouse neocortex. We also developed a high-precision motion artifact compensation algorithm to make possible valid measurement of small neural tissue volumes during activity. Here we present the results, analysis and interpretation of this series of measurements along with the motion-compensation algorithm and its possible uses in in vivo experiments with behaving animals.

Title: Cellular-level resolution of barrel cortex borders using calcium imaging

Authors: ***M. T. KAUFMAN**, S. MUSALL, A. K. CHURCHLAND;
Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Brain areas are traditionally defined posthumously by cytoarchitecture, histological markers, or neural projection patterns. Our ability to identify areas in vivo is more limited. One common technique is wide-field functional imaging, which relies on repeated presentation of sensory stimuli and averaging across neural responses. However, this approach provides limited spatial resolution and is only viable for areas with clear stimulus tuning. To address this issue, we used two-photon calcium imaging in awake mice to detect column borders at cellular resolution based on neural correlation patterns. We imaged the spontaneous activity of ~1,000 neurons at a time in barrel cortex of GCaMP6f transgenic animals. Neurons were identified automatically, using a published variant of constrained non-negative matrix factorization. We then examined the correlation patterns between neurons' activity using low-dimensional embedding techniques or formal clustering methods (inspired by Kiani et al., 2015 Neuron). In

many datasets, this approach revealed clearly identifiable barrel borders that were consistent across several imaging depths and repeated imaging over days. When visible, borders of individual barrels were mostly clear-cut with little intermingling of cells or obvious gradients at the transitions. The locations of individual barrels were also consistent with results from wide-field imaging when stimulating individual whiskers. As expected, the correlations between neurons also tended to smoothly decrease with distance. The strength of correlation with distance was often well fitted by a double-exponential distribution. Both the exponential falloff and individual barrel structure were much weaker at superficial imaging planes less than 150 um deep. In summary, our results demonstrate that noise correlations can be used to identify column borders at cellular resolution in vivo. Our method does not require specific stimuli to assess correlation between neurons and might therefore be particularly useful to identify higher-order brain structures with more complex tuning properties. Further, our classification of single neurons provides insight into the sharpness of functional borders, which is of particular interest when studying borders between different brain areas.

Title: Cortex-wide cellular-resolution imaging with ultra-large cranial window reveals regional differences in state-dependent modulation in behaving mice

Authors: *B. S. HUANG, A. BELLAFARD, S. VRONTOU, P. GOLSHANI;
Dept of Neurol., UCLA Sch. of Med., Los Angeles, CA

Abstract: Behavioral states, such as locomotion and startle, have been shown to increase cortical neuronal excitability and network activity, in a process involving cortex-wide release of neuromodulators (e.g. norepinephrine) from subcortical nuclei such as the locus coeruleus. However, it is unclear whether these state-dependent modulations exert a homogeneous global effect on the entire cortex, or regional differences in circuit architecture could produce heterogeneous local responses. Two-photon calcium imaging in head-fixed behaving mice has

enabled studies of state-dependent circuit dynamics at cellular resolution, but one current limitation is the need to restrict imaging to a pre-selected region-of-interest. This targeted approach may obscure potential regional differences in state-dependent modulations. To overcome such limitation, we developed a cortex-spanning cranial-window preparation that provides long-term cellular-resolution access to the entire dorsal cortical surface of adult mice. We also incorporated right-angle microprisms within our ultra-large window to image regions such as the mPFC (medial prefrontal cortex), ACC (anterior cingulate cortex), and RSCm (medial retrosplenial cortex) that are buried within the midline fissure. To study state-dependent modulations, we implemented a simple startle paradigm to head-fixed mice that were free to run and rest on a spherical treadmill. Using transgenic GCaMP6-expressing mice, we imaged calcium activity in layer-2/3 pyramidal neurons across the cortex along the anterior-posterior axis. We analyzed neuronal activity during spontaneous vs. startle-induced locomotion and found distinct regional differences to these state-dependent modulations within individual animals.

Title: Calcium imaging of hippocampal cell activity in behaving rats

Authors: *G. BLAIR, A. G. HOWE, D. AHARONI, S. FLORES, T. SHUMAN, P. GOLSHANI, H. T. BLAIR;
Psychology, UCLA, Los Angeles, CA

Abstract: We have used the UCLA miniscope (miniscope.org) to image calcium dependent fluorescence activity bilaterally in the rat hippocampus during open foraging behavior. Rats were infused with a GCamp6f AAV virus (0.6 ul per hemisphere) directly in the CA1 pyramidal cell layer. A week later, GRIN lenses (5 mm length x 2 mm diameter) were implanted on the dorsal surface of the hippocampus centered at coordinates -3.6 posterior and +/- 2.9 lateral to bregma, after vacuum aspiration of the overlying cortex. The white matter of the corpus callosum was also removed, but the white matter of the alveolus overlying the hippocampus was left intact. Lenses were lowered to make gentle contact with the surface of the alveolus, then secured in

place with a combination of cyanoacrylate glue and bone cement. Ten days after lens implantation, a base plate (for holding the miniscope) was mounted over the GRIN lens at an angle optimized for viewing the field of fluorescent neurons. After recovery, real time imaging was carried out with the miniscope as rats foraged for 20 mg food pellets in an open field. Using these methods, we have successfully measured activity-dependent fluorescence changes in hippocampal neurons, some of which exhibit spatially selective firing. It remains unclear whether these neurons are pyramidal cells in the CA1 layer, because the pyramidal layer lies at a depth of 300-400 um below the lens surface, which is near the limit of the effective imaging depth for the lens. Further studies are in progress to determine whether the hippocampal pyramidal layer lies within the range of imaging depth using this approach.

Title: *In vivo* image of DRG neurons: a new way to investigate pain pathways.

Authors: ***A. P. LUIZ**[1], E. C. EMERY[1], Q. MILLET[1], X. DONG[2], J. N. WOOD[1]; [1]Dept. of Med., WIBR/University Col. London, London, United Kingdom; [2]Sch. of Med., Howard Hughes Med. Institute/Johns Hopkins Univ., Baltomire, MD

Abstract: New approaches to investigate pain mechanisms could facilitate our understanding of different pain pathways. Here we describe a novel method for studying DRG neuronal function, *in vivo*, using GCaMP imaging. Mice expressing GCaMP3 under the DRG neuron-specific

promoter Pirt were used to investigate DRG physiology *in vivo*. Pirt-GCaMP3 mice (8-10 weeks) were anaesthetised (ketamine/medetomidine: 120/1.2 mg/kg) and the L2-L5 section of the vertebral column was exposed. Transverse and superior articular processes of the vertebra were removed in order to visualise the DRG. Once exposed, the animal was fitted to a custom spinal clamp and fixed to a single-photon confocal microscope (Leica SP8). The trunk of the animal was slightly raised to reduce respiratory noise. Once the animal was stable, various tactile and noxious stimuli were applied to the ipsilateral rear paw and any associated changes in neuronal activity were recorded as a function of GCaMP fluorescence. To explore the utility of the model, *in vivo* imaging was performed on mice lacking the sodium channel $Na_V1.8$. DRG from $Na_V1.8^{-/-}$ mice showed reduced responses to mechanical stimulation compared to WT mice, consistent with reported behavioural data. Interestingly, there was no difference in response to cold stimulation (0^oC), which was supported by acetone and cold plate behavioural assays. Overall, these results present a novel method for studying DRG neuron function *in vivo*, which can be used to further investigate discrete pain pathways.

Title: Activity-dependent CLARITY whole brain analysis reveals long-range wiring and molecular signatures of prefrontal ensembles mediating positive or negative valence experience

Authors: *L. YE[1,2,3], W. ALLEN[1,4], K. THOMPSON[1], Q. TIAN[5], B. HSUEH[1], C. RAMAKRISHNAN[1], A.-C. WANG[1], J. JENNINGS[1], A. ADHIKARI[1], C. HALPERN[6], I. WITTEN[1], A. L. BARTH[7], L. LUO[2,4], J. A. MCNAB[5], K. DEISSEROTH[1,2,3];

Abstract: A major challenge in understanding the cellular diversity of the brain has been linking activity during behavior with standard cellular typology. For example, it has not been possible to determine if the principal neurons in prefrontal cortex that are differentially active during distinct experiences represent separable cell types (based on anatomy and molecular properties), nor is it known if these differentially-active cells actually exert distinct causal influences on behavior. Here we report development of fast and scalable CLARITY technologies, tailored for large-scale behavioral cohorts, to enable automatic intact-brain cellular resolution activity mapping and quantitative brainwide axonal projection analysis. Combined with transgenic activity labeling (ArcTRAP) or single-component activity-dependent virus (c-fos-CreER or -ChR2 AAVs) strategies, this system allows us to connect neuronal activity in cells reporting on behavioral experience with measures for both brainwide wiring and molecular phenotype of the same cells. We first performed whole brain activity mapping using ArcTRAP mice labelled with positive (cocaine administration) or negative (foot shock) valence and found that both experiences recruited activity in the mPFC (2.6 and 1.8 fold increase in TRAP cell numbers in cocaine and shock groups, respectively, compared to home cage, n=5 per group, $p<0.05$). Importantly, these experiences in mPFC are represented by cell populations that are similarly positioned, but differ in causal impact on behavior (as determined by activity-dependent optogenetics and real-time place preference, n=10-14 per group, mean preference change for cocaine: 1.3x +/- 0.1, Wilcoxon p=0.0006; for shock: 0.8x +/- 0.1, Wilcoxon p=0.002), long-range wiring (i.e., cocaine-activated population preferentially projects to the NAc compared to shock-activated population, as determined by CLARITY projection analysis, n=6 per group, $p<0.05$), and gene expression profile—with the major molecular discriminant being expression of the adaptation-linked transcription factor NPAS4. These findings illuminate the cellular logic of mPFC information processing and adaptive behavior, and may point the way to cell type-specific understanding and treatment of disease-associated states.

Title: Probing the brain-wide neural dynamics of passive coping behavior

Authors: *A. S. ANDALMAN[1], V. M. BURNS[2], M. BROXTON[3], B. POOLE[4], S. J. YANG[5], L. GROSENICK[4,8], M. LOVETT-BARRON[4], T. N. LERNER[4], N. PICHAMOORTHY[4], P. MOURRAIN[6], M. LEVOY[3,9], K. DEISSEROTH[6,10,7];

Inst., Stanford, CA

Abstract: Hopelessness is a diagnostic criterion for major depression and can manifest as a *maladaptive* discounting of the value of effort in the present. Yet, in the context of an inescapable adverse environment, similar discounting can be *adaptive* as a means to conserve energy and minimize risk, and is a commonly observed behavioral response across species. In rodents, both the forced swim test and the tail suspension test cause a transition to passive coping in which minimal energy is expended. The transition to passive coping in rodents is therefore not only a validated assay for clinical antidepressant effects, but also a conserved behavioral state transition of substantial adaptive value and basic-science interest.
To advance understanding of the neural dynamics associated with passive-coping states, we developed a protocol to induce passivity in the larval zebrafish (13-16 dpf). With exposure to inescapable shocks, we found that the fish enter a passive coping-like state in which movement is

reduced compared to controls (n=24; -1.78 mm/s, $p<0.001$). We found that as in rodents, the onset of this state can be delayed by prior exposure to the acute experimental antidepressant ketamine (n=16; 6 min, $p<0.001$). To measure neural dynamics associated with this passive coping state, we used light field microscopy to acquire synchronous whole-brain measurements of neural activity in fish expressing a genetically encoded Ca^{2+} indicator pan-neuronally. We observed that our protocol causes a pronounced suppression of brain-wide neural activity (n=5; 83% of control, $p <0.005$). The time-course of this suppression was similar to the time-course of the behavioral effects, and prior exposure to ketamine was found to delay the suppression. Finally we tested whether this experience could have lasting effects on future responses to aversive stimuli. We tested this by examining behavioral and neural responses to intermittent probe shocks in fish three hours after exposure to the shock protocol. We found that the average speed of naïve fish was unaffected, but previously-exposed fish exhibited reduced speed (n=13; -0.6 mm/s, $p<0.01$), revealing stable behavioral plasticity consistent with increased passivity in response to aversive stimuli. In addition, calcium imaging revealed that neurons in the ventral/lateral habenula (only in previously-exposed fish) exhibited slowly-ramping increases in neural activity in response to the intermittent aversive stimuli (n=10; 272% of control, $p<0.05$). Together, these experiments provide brain-wide, cellular-resolution and real-time insight into the mechanisms of both immediate and long-lasting passive-coping responses.

Title: Piezo-assisted cranial surgery: a novel technique for improving cranial window surgeries in rodents.

Authors: *J. M. LAWSON, R. M. MIKOFSKY, S. CLARK, D. SULZER;
Sulzer Lab. - Neurol., Columbia Univ., New York, NY

Abstract: Piezosurgery is a relatively new technique that utilizes high frequency vibrations to remove bone without damaging soft tissue. This has been extensively applied to maxillofacial and dental surgery in humans. This technique, however, has not been applied to creating chronic optical windows for multiphoton imaging in mice. Multiphoton microscopy is a widespread technique used to image neurons *in vivo*. The two main current techniques to prepare the bone for chronic imaging are cranial window surgery and thin skull preparations. Both of these techniques utilize a high speed drill that can increase the risk of damaging the brain tissue. These traditional cranial surgical techniques can be difficult to perform, time consuming, and require extensive training. We have developed a novel method for applying piezosurgery (Mectron) to optimize cranial window preparations for improved multiphoton imaging in mice. Overall, our method is easier to learn, has a greater average success rate, and allows for higher precision over traditional cranial window surgery. Furthermore, this technique allows for shorter surgeries, minimizing surgery-related complications with the animal. Piezo-assisted cranial surgery has the potential to expand the use of multiphoton imaging *in* vivo by improving outcomes of cranial window surgery in rodents and allowing for more extensive imaging in previously understudied brain regions.

Abstract: Understanding brain function requires novel imaging methods such as 3D random-access point scanning that can simultaneously read out neural activity on both the dendritic and somatic scales. Our 3D AO scanning method can increase measurement speed and signal-to-noise ratio by up to 6-9 orders of magnitude, but suffers from one main disadvantage:

fluorescence information is lost during brain movement in awake, behaving animals as the amplitude of brain motion is much larger than the diameter of a single excitation spot. In this work we present a novel fluorescent imaging technology, 3D drift AO scanning microscopy, which can extend each scanning point to small 3D lines or surface or volume elements, preserving fluorescence information for fast off-line motion correction. Our method effectively eliminates *in vivo* motion artifacts, allowing fast 3D measurement of over 100 dendritic spines with 3D lines, over 100 somata with squares and cubes, or multiple spiny dendritic segments with surface and volume elements in moving animals. Finally, a four-fold improvement in total excitation efficiency resulted in a large, about 500µm × 500µm × 650µm, scanning volume with genetically encoded sensors.
We used the new technology to record activity of inhibitory neurons in the moving brain of behaving animals. We revealed a new, broadcasted signaling pathway which activates learning mechanism through the entire neocortex during reward and punishment.

Title: Temporal precision of deconvolution when imaging slow Ca^{2+} indicators

Authors: *J. B. ISSA, M. BEN-JOHNY, D. T. YUE;
Johns Hopkins Univ., Baltimore, MD

Abstract: Calcium indicators represent the dominant fluorescence reporter of neuronal activity as they afford superior signal-to-noise and correlate reliably with electrical activity. A major limitation, however, is the temporal resolution of Ca^{2+} indicators. Whereas transmembrane voltage during a neuronal action potential is fast, on the order of one millisecond, associated Ca^{2+} signals are much slower, lasting tens of milliseconds. Compounding this problem are the slow binding kinetics of Ca^{2+} indicators, especially genetically encoded Ca^{2+} indicators (GECIs). A potential solution is to deconvolve the fluorescence signal using a kernel that describes the

impulse response of the Ca^{2+} indicator, yielding an estimate of the underlying spike train of the neuron. One widely used method, termed fast non-negative deconvolution, assumes a single-exponential decay as the kernel. However, for many GECIs, the on-kinetics of binding cannot be assumed to be instantaneous, especially under fast imaging. Here we ask whether the biophysically-realistic properties of GECIs can be simplified for use in a computationally fast deconvolution strategy and how well such an algorithm performs on both simulated and real data. First, we formulate a biophysical model that explains the temporal dynamics of Ca^{2+} indicators. Second, we develop an optimal deconvolution algorithm, which we test on simulated data to determine the maximal amount of temporal resolution that could be observed under experimental conditions. Third, we test our model and assumptions on publicly available *in vitro* data where Ca^{2+} imaging and whole cell patch clamping were performed simultaneously. Finally, we test our model on *in vivo* data from the mouse auditory cortex. We find that, while slow binding kinetics do limit the temporal resolution of spike inference from deconvolution, precision on the order of milliseconds can be achieved even with 'slow' indicators such as GCaMP6s, thus opening the door for studies on temporal encoding when utilizing Ca^{2+} imaging.

Title: Alterations in sensory-activated cerebral blood flow following brain injury in mice

Authors: *H. JANG[1,2], M. YE[2], S. HUANG[2], D. X. HAMMER[2], C. G. WELLE[2,3], J. A. N. FISHER[1,2];
[1]Dept. of Physiol., New York Medica Col., Valhalla, NY; [2]Div. of Biomed. Physics, U.S. Food and Drug Admin., Silver Spring, MD; [3]Departments of Neurosurg. and Bioengineering, Univ. of Colorado Denver, Aurora, CO

Abstract: Traumatic brain injury (TBI) is a leading cause of death and disability in persons under the age of 45 years. Symptoms of brain injury might not appear until days or weeks following the incident and may go unnoticed as patients may appear to have recovered, despite acting or feeling differently. However, quantitative "gold standard" biomarkers for diagnosing TBI, particularly mild TBI (mTBI), are lacking. Clinical imaging modalities, namely magnetic

resonance imaging (MRI) and computed tomographic (CT) imaging, provide quantitative and anatomically specific data, however changes due to mTBI can be more difficult to detect with standard imaging protocols. Recent work has demonstrated that sensory evoked electroencephalographic (EEG) potentials can be utilized to detect and monitor acute brain injury (Fisher et al., *IEEE Trans. Neural Sys. Rehab.* 2016). Evoked hemodynamic and metabolic responses to the same somatosensory stimuli, which have been recorded using non-invasive near infrared (NIR) optical techniques, are also potential biomarkers. Although work on the diagnostic potential of EEG and on NIR optical techniques have been largely in isolation of each other, the two techniques measure signals—electrical activity and the ensuing hemodynamic and metabolic response—that jointly report the function of the "neurovascular unit," a fundamental dynamic coupling between individual neurons and nearby microvasculature that comprises electrophysiological interaction, mechanical connectivity, chemical signaling, among many other factors. We sought to explore whether a correlate of these injury-induced alterations in sensory activation could be detected at the level of local cerebral blood flow (CBF). Diffuse correlation spectroscopy (DCS) is an emerging portable diffuse NIR modality that has been used for measurements of CBF (Durduran & Yodh, *NeuroImage* 2014). Among other optical techniques, DCS has the unique advantage of being sensitive primarily to CBF in microvasculature. We explored potential sensory-activated CBF biomarkers *in vivo* by performing continuous DCS measurements during somatosensory stimulation of the median nerve in mice following controlled cortical impact (CCI). A 3D-printed miniaturized probe that housed micro-prisms permitted stable fixture of light-emitting source and detector-coupled fibers against the skull region overlying the somatosensory cortex. Our preliminary results demonstrate in mice that somatosensory-evoked CBF detected optically can potentially serve as useful diagnostic biomarkers for rapid detection of sublethal brain injury.

Title: Propagating network activity assessed in a tangential cortical slice

Authors: *C. C. LEE;
Comparative Biomed. Sci., Louisiana State Univ. Sch. of Vet. Med., Baton Rouge, LA

Abstract: The propagation of activity in the cerebral cortex relies on both local and long-range network connections. In this manner, information is communicated among different cortical stations to integrate incoming sensory streams with ongoing network activity. The propagation of such activity across the cerebral cortex relies on both the network architecture and the balance of excitatory and inhibitory inputs. To approach the characterization of propagating cortical activity, we employed an in vitro tangential slice preparation of the sensory neocortex in the mouse. We utilized flavoprotein autofluorescence to measure the spatial and temporal activity following network perturbation. In addition, we employed laser-scanning uncaging via glutamate uncaging to probe functional connectivity in these tangential slices. We found widespread but variable flavoprotein activity in our tangential slices, but with limited patterns of convergent inputs to single neurons. Our results suggest that in this preparation, local connectivity may be sufficient to propagate activity across the cortical surface and influence computational processes on a global scale.

Title: Application of gradient index lens for *In vivo* fluorescent microscopy of retinal ganglion cells

Authors: *D. BUICKIANS[1], A. KREYMERMAN[2], E. HUYNH[1], Y. GONG[1], H. CHEN[1], J. L. GOLDBERG[2];
[1]Bioengineering, UCSD, La Jolla, CA; [2]Ophthalmology, Stanford, Palo Alto, CA

Abstract: Subcellular pathological changes that manifest as a consequence of disease or injury within the central nervous system are often captured post-mortem using conventional or electron microscopy. This has fundamentally limited our understanding of neuronal processes that precede or progress during neuronal dysfunction and degeneration. Recent biomedical imaging technology such as 2-photon or confocal microscopy, has proven to be effective in capturing images of CNS disease related changes, with high magnification and resolution. Using these imaging techniques, events such as mitochondrial transport and fission/fusion deficits, axonal swelling, and eventual axon fragmentation/breakdown have been proven as hallmarks for many neurodegenerative diseases or traumas. However, due to physical accessibility, invasive procedures, and/or the low resolution of externally applied imaging technology (i.e. optical coherence tomography, heidelberg confocal scanning laser ophthalmoscopy MRI), sites within the CNS such as the retina, optic nerve and various deep brain regions, have proven to be more difficult to image. Consequently, cellular level in vivo microscopy (IVM) has been limited to mostly superficial structures, leaving many of the CNS regions susceptible to degenerative diseases or injury unstudied. To ovefrcome the current limitations in cellular level IVM, we have been adapting common 2-photon or confocal microscopy with gradient index (GRIN) optical lens. GRIN lens have small diameters and moderate lengths, while maintaining relatively high numerical apertures. Here we present our current design and preliminary evidence for the application of grin lens for in vivo imaging of the optic nerve and retina. Here we show that, coupled with minimally invasive surgery, the physical properties of GRIN lens confer imaging properties difficult to reach CNS structures with high spatio-temporal resolution. Future studies will focus on imaging of the peri/intra-axonal/dendrite changes that accompany retinal ganglion cell degeneration in rodent optic neuropathy modeling.

Abstract: Vascular pathologies represent the leading causes of mortality worldwide. Cerebral hypoxia is a condition that often manifests as a result of these medical conditions. Remarkably, the nervous system has evolved mechanisms to compensate for oxygen deprivation. For example, the dilation of existing vessels and the growth of new vessels are two prominent physiological processes that play a critical role in the maintenance of cerebral homeostasis. Recently, exercise has been shown to induce a mild state of hypoxia in the brain, leading to several robust morphological changes within the cerebrovascular system. Thus, exercise serves as a viable model for investigating hypoxia-induced adaptations. The present study introduces spectral domain optical coherence tomography (SD-OCT) as a novel technique for examining these micro-level changes in the rat motor cortex. SD-OCT produces high resolution, 3D angiograms, and allows for moderately invasive imaging within the same animal at multiple time points. The independent effect of exercise training on cerebrovascular structure and function has never been explored using SD-OCT. Thus, the primary goal of this study was to determine the relative efficacy of SD-OCT utility. To validate SD-OCT, we employed it in the examination of exercise-dependent changes in blood vessel density and real-time capillary dilation during a laboratory-induced condition of hypoxia. In addition, histology data was collected to provide comparative measures for statistical analyses. At the start of this investigation, animals were randomly assigned to one of two groups: 26-week voluntary exercise (VX), or an inactive control (IC). Upon completing the exercise treatment, animals were anesthetized and prepared for imaging. Vascular anatomy and blood velocity data was captured during three experimental conditions: [1] normal oxygen baseline, [2] hypoxia, and [3] normoxia. A two-way analysis of variance revealed a significant difference in total blood vessel density between treatment groups, independent of condition. That is, VX animals had a greater density of blood vessels in the scanned region of interest when compared to IC. These findings were confirmed using unbiased stereology techniques to analyze tissue in the scanned region of interest. Furthermore, statistical analyses revealed a significant increase in small arteriole diameter in both VX and IC animals. However, the dilation captured by SD-OCT was significantly greater in VX animals when compared to IC. In sum, exercise induces potent adaptations that promote greater flexibility during hypoxia. Moreover, these micro-level changes can be effectively probed using SD-OCT.

Title: Alterations in cerebral metabolism observed *In vivo* using fluorescence lifetime microscopy of intrinsic NADH

Authors: *M. A. YASEEN[1], S. SAKADŽIĆ[1], J. SUTIN[1], W. WU[1], B. FU[1], H. UHLIROVA[2], A. DEVOR[2], D. A. BOAS[1];

Abstract: Monitoring cerebral energy metabolism at a cellular level is essential for guiding our understanding of healthy brain function and its pathological alterations. In this study, we resolve specific alterations in cerebral metabolism utilizing minimally-invasive 2-Photon fluorescence lifetime imaging (2P-FLIM) measurements of reduced nicotinamide adenine dinucleotide (NADH) fluorescence, collected in vivo from the exposed cortices of anesthetized rats and mice. Time-resolved lifetime measurements enables distinction of different components contributing to NADH autofluorescence. These components reportedly represent different enzyme-bound formulations of NADH. Our observations from this study confirm the much-repeated hypothesis that NADH FLIM can identify specific alterations in cerebral metabolism. Using time-correlated single photon counting (TCSPC) equipment and a custom-built multimodal imaging system, 2-photon fluorescence lifetime imaging (FLIM) was performed in cerebral tissue with high spatial and temporal resolution. Animals were anesthetized, mechanically-ventilated, and their cerebral cortices were exposed through a sealed cranial window. Multi-exponential fits for NADH fluorescence lifetimes indicate 4 distinct components, or 'species.' We observed distinct

variations in the relative proportions of these components before and after pharmacological-induced impairments to several reactions involved in anaerobic glycolysis and aerobic oxidative metabolism. Classification models developed with experimental data correctly predict the metabolic impairments associated with bicuculline-induced focal seizures in separate experiments. Compared to traditional intensity-based NADH measurements, lifetime imaging of NADH is less susceptible to the adverse effects of overlying blood vessels. Evaluating NADH measurements will ultimately lead to a deeper understanding of cerebral energetics and its pathology-related alterations. Such knowledge will likely aid development of therapeutic strategies for neurodegenerative diseases such as Alzheimer's Disease, Parkinson's disease, and stroke.

Title: Facilitating the adoption of oxygen partial pressure imaging with two-photon microscopy

Authors: ***S. SAKADZIC**[1], T. V. ESIPOVA[2], M. A. YASEEN[1], A. DEVOR[1,3], S. A. VINOGRADOV[2], D. A. BOAS[1];

Abstract: The assessment of brain oxygenation on the microscopic level has the potential to transform our understanding of important clinical problems, such as stroke, Alzheimer's disease, dementia, chronic hypertension, and brain cancer, facilitating the development of new therapies and helping to improve clinical imaging and treatment protocols. Until now, no technology has been capable of microscopic oxygen imaging in the brain with high spatial and temporal resolution. Over the past several years we have developed a method, termed two-photon phosphorescence lifetime microscopy of oxygen (2PLM), which has the unique capability of fulfilling this niche. This is the only imaging method that allows high resolution mapping of brain oxygenation in real time.
2PLM of oxygen is a combination of state-of-the-art two-photon enhanced phosphorescent

probes and a unique variant of two-photon laser scanning microscopy - both of which are not presently available commercially. The transformative power of 2PLM of oxygen has been demonstrated in several high-impact publications [1-7], producing great interest in the neuroscience community. With the help of the NIH R24 grant mechanism, we are setting up a self-sustaining resource that will promote widespread use of the two-photon oxygen imaging technology, making this new powerful method available to a broad group of neuroscience researchers.

Title: Two-photon microscopy measurement of cerebral metabolic rate of oxygen using periarteriolar oxygen concentration gradients

Authors: S. SAKADZIC[1], M. A. YASEEN[1], R. S. JASWAL[1], E. ROUSSAKIS[2], A. M. DALE[3], R. B. BUXTON[4], S. A. VINOGRADOV[2], D. A. BOAS[1], *A. DEVOR[3,1];

Abstract: *Objective.* The cerebral metabolic rate of oxygen ($CMRO_2$) is an essential parameter for evaluating brain function and pathophysiology. Measurements of $CMRO_2$ with high spatio-temporal resolution are critically important for understanding how the brain copes with metabolic and blood perfusion changes associated with various clinical conditions, such as stroke, periinfarct depolarizations, and various microvasculopathies (e.g., Alzheimer's disease, chronic hypertension). $CMRO_2$ measurements are also important for understanding the physiological underpinnings of functional Magnetic Resonance Imaging signals. However, the currently available approaches for quantifying $CMRO_2$ rely on complex multimodal imaging and mathematical modeling. Here, we introduce a novel method that allows estimation of $CMRO_2$ based on a single measurement modality - two-photon phosphorescence lifetime microscopy (2PLM) imaging of the partial pressure of oxygen (PO_2) in cortical tissue.
Methods. We measured the baseline $CMRO_2$ in anesthetized rats, and modulated tissue PO_2 levels by manipulating the depth of anesthesia. $CMRO_2$ is estimated by fitting the changes of tissue PO_2 around cortical penetrating arterioles with the Krogh cylinder model of oxygen diffusion.
Results. Using this method, we obtained a mean baseline $CMRO_2$ of 1.71 ± 0.16 μmol cm^{-3} min^{-1}, within the error bounds of previously reported $CMRO_2$ under similar anesthesia in rats measured by MRI (2.5 ± 1.0 μmol cm^{-3} min^{-1}) [1]. To experimentally manipulate $CMRO_2$, we modulated the level of anesthesia by applying isoflurane (2%) on top of the ongoing alpha-chloralose anesthesia. Adding isoflurane resulted in the measured $CMRO_2$ decreased from 1.56 ± 0.07 μmol cm^{-3} min^{-1} (alpha-chloralose only) to 1.38 ± 0.07 μmol cm^{-3} min^{-1} (combined alpha-chloralose and isoflurane).
Conclusion. Our study demonstrates that we can estimate $CMRO_2$ using the Krogh cylinder model based on a single measurement modality - periarteriolar tissue PO_2 measurement by two-photon microscopy in a single plane perpendicular to the vessel axis. With this method, no measurements of blood flow are required for the $CMRO_2$ estimation. This method has a spatial resolution of approximately 200 μm and it may provide $CMRO_2$ measurements in individual cortical layers or within confined cortical regions such as in ischemic penumbra and the foci of functional activation.

Abstract: Objective: Study the diffusion and flow parameters in the brain extracellular space at the different stage of glioma in the C6 modeling rats’ brains using the tracer-based MRI. Methods: 16 adult male SD rats bearing glioma which were implanted C6 cells in the striatum were randomly divided into two groups. Both were examined using the tracer-based MRI and routine MR imaging, with one group bearing the glioma in 10 days, and the other group were 20 days. The flow and diffusion parameters of the brain interstitial space were examined, and the dynamic distribution and the clearance of the probe molecules were continuously monitor in Real-time using MRI. The parameters were compared between two groups. Results: The tumor size were increased, but the maximum volume of distribution (Vd max) in the brain interstitial space were not statistically different in the two groups. The clearance of the probe in 10 days group was faster than that in 20 days group with a shorter half time of (0.86±0.23h vs. 1.64±0.12h, $t=5.91$; $p<0.001$) hours. Conclusion: The diffusion and flow properties within the tumor are both ruined as glioma grows, which can be detected using tracer-based MRI.

Title: Optical coherence elastogram of mouse cerebral cortex

Authors: Y. CHANG[1], J. KIM[2], J. HWANG[2], Y.-S. OH[3], *C. SONG[4,1];
[1]Robotics Engin., [2]Information and Communication Engin., [3]Brain and Cognitive Sci., [4]DGIST, Daegu, Korea, Republic of

Abstract: Mechanical properties of the brain tissue including its elasticity may be altered during the progress of various neurological disorders including Alzheimer disease, hydrocephalus, neuroinflammation, and stroke. To detect subtle changes in the elasticity of the soft brain tissue, advanced modality is required for high resolution assessment. Here, we present an optical coherence elastographic (OCE) system capable of measuring the elasticity of cerebral cortex. This approach achieves more accurate measurement rather than magnetic resonance elastography or ultrasonic elastographic imaging.
The proposed OCE system capable of measuring the elasticity is based on fiber optic spectral domain optical coherence tomography (SD-OCT). A broadband laser source with a center wavelength of 830 nm is used. Spectral interference signals are acquired by a line CMOS camera with 4096 pixels in a home-built spectrometer. A non-contact immersion type transducer is used to generate short duration acoustic radiation force to the cerebral cortex. The displacements of the cerebral cortex are measured while acoustic radiation force is applied to the cerebral cortex. The dissected mouse cortex tissue was mounted on the plastic plate filled with saline solution. The displacements of various sub-regions in the cortex are measured. The measured displacements are used to calculate Young's modulus which indicates the stiffness throughout the cerebral cortex.
The OCE system allowed to measure the elasticity of sub-regions in the mouse cerebral cortex. Mapping any elastic change in the CNS with the OCE system may open up an unprecedented window to monitor the physiological abnormality in the brain. To map biomechanical properties of the brain may contribute to our understanding of the physiological responses as well as the pathophysiological changes in the brain.

Title: Novel skull optical clearing for *In vivo* imaging of neural circuitry in mice cerebral cortex

Authors: *D. ZHU, Y. ZHAO, C. ZHANG, T. XU;
Britton Chance Ctr. for Biomed. Photonics,Wuhan Natl. Lab. for Opt, Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: *In vivo* two-photon microscopic imaging of cerebral cortex in fluorescent protein transgenic mice have shown great potential for understanding of a broad array of neurobiological phenomena, especially the dynamics of individual synapses and the functional organization of cortical maps in learning and memory and various brain diseases. Regarding the imaging performance always suffers from the turbid skull above the cortex, various cranial windows, such as removed skull, cranial window, thinned-skull cranial window, and polished and reinforced thinned skull window were developed to improve imaging performance. However, these models are not options available for infantile mice due to the vulnerability of young animals. Actually, the critical period for cortical development for young mice is always a matter of concern. The peak of anatomical and physiological plasticity of dendritic spines occurs during the third week. Up till now, the plasticity of neural infactile mice circuitry less than one month has not been studied very well. In this work, we developed an innovative skull optical clearing method, which can make the skull transparent by topically treatment with skull optical clearing agents instead of craniotomy. Through the clearing skull, we could image the dendritic protrusions of infactile mice *in vivo*. Our preliminary data showed the strong dynamics of cortex circuitry in three-week old mice. Besides, a skull optical clearing method was developed for imaging cortical neural circuitry of adult mice. In addition, the safety of skull optical clearing methods was approved by dynamical monitoring the blood flow and observation of inflammation reaction.

Title: Taking Pixies of whiskers: Real time optical tracking of mouse behavior

Authors: L. BLANCO[1], M. A. NASHAAT[1], H. ORABY[1], M. E. LARKUM[1], *R. N. SACHDEV[2];
[1]NeuroCure Ctr. for Excellence, Humboldt Universitaetz zu Berlin, Berlin, Germany; [2]Charite-Berlin, Berlin, Germany

Abstract: Rodents explore their environment with their whiskers. Motion of whiskers is typically monitored by EMG or by high speed videography. However EMG does not give information about individual whisker movement and high speed videography does not provide real-time information. Here we have customized and extended an off the shelf optical tracking system, the Pixy camera, and use it in a novel approach to study whisker use in mice. Head-fixed mice were trained to move their whiskers to make contact with a piezo film sensor in response to an auditory cue. Two adjacent whiskers were painted in different colors with UV fluorescent paint, and illuminated with dark / UV light. Using the Pixy camera, we tracked multiple whisker trajectory at 50 Hz (resolution of Pixy), and aligned whisker motion with cue onset and whisker contact. We simultaneously recorded mouse behavior with a color high-speed camera. The high-speed video was then played back in slow motion for Pixy based tracking of the colored whisker's trajectory. The resulting offline video data had higher temporal resolution. Our analysis of one hundred trials, 10 minutes, of both online and offline data reveals that, on average, whiskers on one side move in a highly correlated way, but the whisker in contact with the sensor shows different amplitude and dynamics than the adjacent whisker. We propose that this method can be used for simultaneous detection of multiple dimensions of behavior, including motion of the whole animal, and whisker, limb or head movement.

Title: Development and discussion of dti phantom for nerve fiber tracking.

Authors: ***S. YOKOYAMA**, T. HIROYASU, S. HIWA;
Doshisha Univ., Kyotanabe-Shi, Japan

Abstract: [Purpose]
In this paper, the DTI-phantom which was developed for evaluating fiber tracking methods was discussed. Recently diffusion tensor fiber tracking shows many suggestions for analyzing brain functions. However, diffusion tensor fiber tracking methods have several defects and they have to be resolved. Real detailed structure of nerve fiber in brain is unknown and nerve fiber phantoms should be utilized for evaluating fiber tracking methods.
In the previous study the phantom which is consisted of Dyneema fiber whose thickness diameter is 15 [μm] was proposed. The thickness of the nerve fiber in brain is 0.2[μm] to 20[μm] in diameter. Thus, Dyneema fiber is a little thick to simulate nerve fiber.
In this research, fibers who has hollows and whose thickness is 5.4 [μm] was used for the phantom. In the experiment, the developed phantom was used to evaluate the fiber tracking methods.
[Methods]
The fiber diameter for phantom is 5.4 [μm] and the phantom fascicle was consisted of 12 million fibers. Two straight phantoms which were made of hollow fibers and Dyneema fibers were compared to measure the performance of hollow fibers.
Then kissing phantom was also developed. Kissing structure is often observed in brain and two bundled nerve fibers are touching together.
Since this two bundled fibers are kissing at one point, tracking method often tracks in wrong directions. The simple kissing phantom whose two fibers are just touched has already been proposed.
In this research, kissing phantom whose bundled fibers were touched intertwined and this structure is much more similar to real brain nerve structure.
This phantom was called meshed kissing phantom.

The simple and meshed kissing phantoms were developed and the fiber tracking algorithm was applied to the measure DIT results. The results were compared and discussed.
[Result]
The results of different types of two straight phantoms were compared. Then the performance of the phantom which was consisted of hollow fibers showed the higher ability to express the nerves.
The results of two different types of kissing phantoms showed the differences.
In the meshed kissing phantom, a lot of tracking were occurred.
This result described that the meshed kissing phantom is much more similar to real brain nerves compare to the simple kissing phantom.
[Conclusions]
In this research, DTI phantom whose fiber diameter is 5.4 [μm] which is similar to real nerve fiber and who has hollows were developed and discussed.
Then, DTI phantom which has kissing structure was also developed and measured.
From the experiments, results showed that the developed DTI phantom can be used for evaluating fiber tracking methods.

Title: Persistent alterations in cognitive and cortical function following maternal deprivation

Authors: ***S. S. JANETSIAN**[1], N. M. TIMME[1], B. F. O'DONNELL[3], C. C. LAPISH[2,4,5]; [2]Psychology, [1]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [3]Indiana Univ., Bloomington, IN; [4]Stark Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [5]Inst. for Mathematical Modeling and Computat. Sci., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Early life trauma is a risk factor for a number of neuropsychiatric disorders, including schizophrenia (SZ) and depression. Animal models have played a critical role in understanding how adverse events early in life may evoke changes in biomarkers of altered brain function and altered behavioral phenotypes that resemble these neuropsychiatric disorders. However, since SZ

is a complex condition with a multifactorial etiology, it is difficult to model the breadth of this condition in a single animal model. Considering this, it is necessary to develop rodent models with clearly defined subsets of pathologies observed in the human condition and their developmental trajectory. The current study assessed how an early life traumatic event alters cognition and brain function to better understand what neural systems might be compromised following these events. On postnatal day (PD) 9, male rat pups were maternally deprived (MD) for 24-hours or were left undisturbed. In Exp. 1, social interaction (SI), temporal memory, and recognition memory were tested in adulthood. In Exp. 2, electrophysiological recordings were obtained from the prefrontal cortex (PFC), vertex, and temporal cortex (TC) during a paired-click paradigm to assess the effects of MD on sensory gating and shared information using information theoretic analyses. Decreased SI and impaired temporal and recognition memory were observed in MD animals. In Exp. 2, MD animals had a blunted gating response during the paired-click paradigm compared to controls, which was most pronounced in the TC. Shared information was reduced following MD when examined immediately prior to or after the click and was most pronounced between the PFC-vertex and TC-vertex. These data shed light on the underlying changes in neural processing that lead to impaired temporal/recognition memory in MD animals. Impairments in the ability of each brain region to maintain and share information in the absence of the stimulus could reflect alterations in neural processing that lead to a less robust representation of each object, thereby preventing the detection of the novel one. Importantly, these data suggest that the deficits in auditory gating are not attributable to deficits in early sensory processing but rather a systems level phenomenon that is required to map contextual information to sensory stimuli. Lastly, these data suggest that neurodevelopmental perturbation early in life was associated with long-lasting alterations in cognition and brain function in adulthood. As such, this model may provide a useful tool to further explore the neural basis of early life trauma that may result in mental psychiatric disorders, including SZ.

Title: Functional human neurons derived from iPS cells display a range of unique and “exciting” MEA phenotypes.

Authors: *K. P. MANGAN, C. KANNEMEIER, E. ENGHOFER, J. MA, S. DELAURA, C. CARLSON;
Cell. Dynamics, Intl., Madison, WI

Abstract: As many of the underlying mechanisms in neuronal disorders and neurotoxicity affect the electrical properties of the nervous system, there is an increasing demand for more biologically-relevant cell models coupled with scalable electrophysiological techniques to understand and measure neuronal activity and network connectivity. Multi-electrode array (MEA) platforms enable electrically active excitable cell types to be monitored in real-time. Although primary rodent cortical neurons are the most widely-accepted cell source for MEA, recent advances in iPSC technology now provide access to previously unattainable human neural cell types and offer a unique source of relevant and assayable cells.
Using a panel of highly pure iPSC-derived neural cell types, we are able to detect a range of different phenotypes on the MEA platform. The catalog cell types available include GABAergic (inhibitory) cortical neurons, glutamatergic (excitatory) cortical and induced neuronal (iN) cells, midbrain dopaminergic neurons (excitatory), and astrocytes (glia). This poster focuses on MEA functionality of these cells individually or in co-culture. We find that both complex patterns of spontaneous electrical activity and the degree of synchronous bursting depend on the ratio of excitatory to inhibitory cells (the "E/I ratio") within the culture. To help illuminate this finding, we track the evolution of a synaptically-driven culture over time and analyze changes in numerous parameters that define neuronal MEA activity, such as mean firing rate, channel burst rate, or network bursting percentage. Interestingly, basal media and supplements have an extraordinary effect on MEA assay performance. Similarly, addition of astrocytes to cultures of pure neurons dramatically impacts the functional phenotype and further promotes network-level synchrony. Finally, with a range of baseline MEA phenotypes established, we tested the pharmacological effects of compounds targeting key receptors, such as GABA, AMPA, and NMDA. Overall, these human iPSC-derived neuronal cultures responded appropriately to known agonists and antagonists (e.g. bicuculline, AP5/DNQX, and kainic acid).
An imbalance in the E/I ratio in the brain is associated with numerous neurological abnormalities and deficits. Currently-used non-human cell models on the MEA are limited in their ability to broadly address different human diseases *in vitro*. The data presented here demonstrate that human iPSC-derived neuronal cell types are rising to the challenge of becoming a reliable and predictive tool for use in drug discovery, disease modeling, and neurotoxicity applications.

Title: Electrical Stimulation on Amygdala for animal's behavior control

Authors: *Y. LEE[1], Y. CHO[2], Y. LEE[2], S. KIM[2], J. LEE[2], S. JUN[2,3];
[2]Electronics Engin., [3]Brain and Cognitive Sci., [1]Ewha Womans Univ., Seoul-City, Korea, Republic of

Abstract: Stimulating the branch of the medial forebrain bundle (MFB) is frequently used to train animal's behavior, because MFB is dopaminergic pathway which makes animal feel pleasure and reward. Stimulating amygdale nucleus (AMY), the site of inducing fear, is also used for training animal by punishing animal which goes wrong direction. In this study, we used stimulations for training animal's behaviors in response to signals for direction. The effectiveness of the AMY stimulation for behavior control was compared with that of previous methods. Sprague-Dawley rats are used as experimental animals and surgery is performed to implant electrodes in their brain in order to watch animals' behaviors under freely moving condition. Each pathway is electrically stimulated with a multi-channel microelectrode array (tungsten, 254 μm). Stimulation of somatosensory cortex is used for directional cues in which direction to go. We divide three groups by electrical stimulation site standards, neural pathway of reward (Group R), fear (Group F) and both (Group B). Effectiveness can be measured by the rate of correct directional decision making, and the number of days finishing the training session until the success rate is over 75%. Our results demonstrate that using both stimulation is the best method for training animal. This study not only integrate existing methods and but also prove advanced effectiveness of integrated method. As a result, it can be expected to accelerate animal's behavior related experiments.

Title: Implantable neural recording and stimulation for in-vivo electrophysiology

Authors: *J. C. MORIZIO, V. GO;
Triangle Biosystems, Inc, Durham, NC

Abstract: Over the last decade, wireless technology advancements for neural recording and stimulation continue to improve with respect to data rates, power consumption, weight and size thus inspiring new experiments for *in-vivo* electrophysiology research on freely moving rodents. In this presentation, we introduce a neural recording system using telemetric implantable capsules that can record from 5 to 64 channels of EEG, EMG, ECG, and single units or spikes signals simultaneously in real time. In addition, we present an implantable neural stimulation system which includes full duplex digital transceiver capsules that can stimulate 2 channel or 16 channel constant current bipolar pulses or 2 channel optogenetic stimulation. Key design challenges and trade-offs of these implantable wireless technologies will be explained. Sub-system components and accessories will also be described that include electrodes and neural interfaces, as well as low noise integrated CMOS electronics, RF transceiver circuitry, 90-day packaging, coating processes and inductive powering technologies. Test data and electrical specifications for each of the implantable technologies will also be presented. DAQ analysis software used for neural recording and stimulation for pattern definition and triggering will conclude the presentation.

Title: A high-throughput system to characterize functional connectivity between cortical areas

Authors: ***M. PARSA**[1], M.-R. DEHAQANI[3], B. MUMEY[1], C. STENGEL[4], B. NOUDOOST[2]; [1]Dept. of Computer Sci., [2]Cell Biol. and Neurosci., Montana State Univ., Bozeman, MT; [3]Sch. of Cognitive Sci., Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of; [4]Neuralynx Inc., Bozeman, MT

Abstract: Despite a thorough mapping of the anatomical connectivity between brain regions and decades of neurophysiological studies of neuronal activity within the various areas, our understanding of the nature of the neural signals sent from one area to another remains rudimentary. Orthodromic and antidromic activation of neurons via electrical stimulation ("collision testing") has been used in the peripheral nervous system and in subcortical structures to identify signals propagating along specific neural pathways. However, low yield makes this method prohibitively slow for characterizing cortico-cortical connections. We employed recent advances in electrophysiological methods to improve the efficiency of the collision technique between cortical areas. There are three key challenges: 1) maintaining neuronal isolations following stimulation, 2) increasing the number of neurons being screened, and 3) ensuring low-latency triggering of stimulation after spontaneous action potentials. Our system addresses these issues using recent improvements in on-line tetrode-based isolations, linear array electrodes, and the processing speed of data acquisition hardware systems. We have developed a software package for on-line isolations and stimulation triggering, which operates in conjunction with a Hardware Processing Platform (HPP). The HPP is a system on a chip solution enabling real-time re-programming. Employing the HPP programmable device for template matching both accelerates spike sorting and provides the low-latency triggering of stimulation required to produce collision trials. Recording with a linear tetrode array electrode allows simultaneous screening of multiple neurons, while the software package coordinates efficient collision testing of multiple user-selected units across channels. This high-throughput connectivity screening system will enable researchers working with a variety of animal models and brain regions to

identify the functional properties of specific projections between cortical areas in behaving animals.

Title: The influence of behavior training on motor cortex activation

Authors: *J. LEE[1,2], Y. CHO[2], Y. LEE[2], S. KIM[2], S. JUN[2,3];
[1]Ewha Womans Univ., Seoul-City, Korea, Republic of; [2]Dept. of Electronics Engin., [3]Dept. of Brain and Cognitive Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: As basic research for neural prostheses or neuroscience studies, there have been many approaches to modulate the animal behaviors through artificial control. Among various ways, one of the most popular method to control animal behaviors is to stimulate the dopaminergic reward system of brain. In this study, we electrically stimulate the mesolimbic dopaminergic pathway involved in reward, pleasure and habituation. We focused to investigate the influence of habituation toward motor cortex activation throughout the several repeated training periods. The rat movement according to the stimulation, and the local field potential recorded from motor cortex during the forced moving session, is carefully observed and compared. The medial forebrain bundle (MFB) area was electrically stimulated with a tungsten stimulating electrode array (200 μm diameter). The neural activities of the motor cortex region of the rat, including hindlimb and forelimb area, are simultaneously recorded using tungsten recording electrode array (100 μm diameter) during experiments. The relationship between the stimulation of MFB and the neuronal activation of motor cortex is carefully investigated. As a result, after the repeated training session the motor cortex activation increased while the rat received the reward stimulation.

Title: Feasibility and dose tolerability of high definition transcranial direct current stimulation in healthy adults

Authors: C. A. TURSKI[1], A. KESSLER-JONES[1], B. HERMANN[1], *D. HSU[1], J. E. JONES[1], S. SEEGER[1], R. CHAPPELL[2], C. IKONOMIDOU[1];

Abstract: Transcranial direct current stimulation (tDCS) enables noninvasive electrical stimulation of the cortex via electrodes placed on the subject's skull. High definition tDCS (HD-tDCS) allows for precise generation of electrical fields over selected cortical areas using multiple electrodes. tDCS has been shown to improve motor learning, visuomotor coordination, probabilistic classification and boost memory in humans. Most studies using HD-tDCS have administered stimulation to one brain area for a small number of sessions (up to 10). The safety, feasibility and tolerability of stimulation of multiple brain regions per session using HD-tDCS over long periods of time have not been established. The purpose of this trial was to study feasibility, tolerability, and safety of HD-tDCS applied over 2-4 different brain regions at each session and administered daily for a total of 20 sessions in healthy adults. Five healthy adult subjects were recruited, 2 females and 3 males (mean age 23.4 y). Subjects underwent physical and neurological examination, electrocardiogram, electroencephalogram and IMPACT test before study initiation, during the study and at completion of the study. Four networks were stimulated using HD-tDCS, left and right temporooccipital and left and right frontal. Sessions 1-10 included stimulation of both temporooccipital networks (1 mA in week 1 and 1.5 mA in week 2 over 20 min/network). Sessions 11-15 included 20 min long stimulation of all 4 networks at 1.5 mA/network and sessions 16-20 consisted of 2 stimulation cycles on each day of all 4 networks at 1.5 mA/network. All subjects completed the trial. Adverse events reported were tingling at the site of stimulation during stimulation (5/5), transient redness at the frontal electrodes (1/5), the feeling of being stimulated for 2 hrs after one session (1/5) and one incident of headache during stimulation which resolved when stimulation was discontinued (1/5). There were no abnormalities detected on EKG, EEG, physical and neurologic examination. The scores in the

immediate post-concussion assessment and cognitive (IMPACT) test were similar before and after the 20 stimulation sessions. This pilot trial demonstrates that prolonged daily stimulation of multiple brain regions over 4 consecutive weeks using HD-tDCS is feasible and well tolerated in healthy adults.

Title: Biomarkers of tissue damage during electrical stimulation in rat sciatic nerve.

Authors: *P. TAKMAKOV[1], D. X. HAMMER[2], C. G. WELLE[3], S. VASUDEVAN[2]; [1]CDRH-OSEL-DBCMS, [2]CDRH-OSEL-DBP, FDA, Silver Spring, MD; [3]Dept. of Neurosurg., Univ. of Colorado Denver, Aurora, CO

Abstract: There is an emerging interest in exploring neuromodulation of peripheral nervous system (PNS) for clinical applications, as it relays central command-and-control signals to almost all of the body organs. Neuromodulation of PNS is an attractive target due to relatively simple anatomy and ease of access, which enables precise targeting with a hope of fewer side effects and less invasive surgical procedures. One of the limits of electrical neuromodulation is the risk of tissue damage at high stimulation levels.
Classical studies that have documented these effects and established rules for safe electrical stimulation were conducted over half a century ago (Lilly et al., 1955) primarily in the CNS. Since then, surprisingly little progress has been made in identifying the mechanism(s) of tissue damage. Moreover, while the results obtained in CNS were translated to PNS, there is evidence that a different parameter space defines damage in PNS (McCreery et al., 1992).
In this study we evaluate neural tissue damage in rat sciatic nerve during electrical stimulation through optical, functional and histochemical measurements. Exposed sciatic nerve in anesthetized animals was stimulated over a range of charge density and charge per phase parameters (McCreery et al., 1990). The stimulation was accompanied by real-time quantitative Optical Coherence Angiography (qOCA), among other traditional behavioral and histological measures. qOCA in particular, allows observation of changes in blood vessels and to determine the potential impact of vasoconstriction on tissue damage during stimulation. Seven days post stimulation, functional damage to the nerve was characterized using walking track analysis,

followed by immunohistochemical evaluation of tissue damage. The characterization of the tissue damage in rat sciatic nerves with several biomarkers allows more comprehensive assessment of tissue response, which can be used to evaluate the safety of electrical stimulation protocols and explore the mechanisms of PNS nerve damage.

Title: Magnetoelectric thin films for neural stimulation

Authors: *A. WICKENS[1], J. T. ROBINSON[2];
[1]Applied Physics, [2]Rice Univ., Houston, TX

Abstract: A method to remotely stimulate neurons would allow for the study of deep brain regions in freely moving animals and lead to potential applications in new forms of treatment for disorders such as Parkinson's disease. For clinical applications, techniques that do not require genetic manipulations are most desirable. The two primary clinically approved neuromodulation techniques used to treat neurological diseases are transcranial magnetic stimulation (TMS) and deep brain stimulation (DBS). TMS makes use of the property that magnetic fields can pass through tissue without attenuation but uses strong magnetic fields (1-3 Tesla) and is unable to specifically stimulate areas deeper in the brain. To target these areas DBS uses implanted electrodes with wires extending through the skull to deliver a local electrical signal. These wires

can cause damage to other brain areas and leave the tissue unenclosed following implantation. An ideal neuromodulation device would be enclosed in the tissue after implantation and externally activated to deliver a specific electrical signal to a deep brain region. Using the magnetoelectric coupling between a magnetostrictive and piezoelectric material we propose the use of magnetoelectric thin films as a novel neuromodulation device. This device will allow for specific less-invasive neural modulation by the application of a small external magnetic field that is transformed to a local electric field.
To create a biocompatible magnetoelectric film we bonded a piezoelectric material polyvinlydene fluoride and a magnetostrictive material Metglas. We then encapsulated the films to make them biocompatible. These films can generate voltages above three volts under resonant conditions using alternating magnetic fields with an amplitude of about 2 mT. We can also design the film geometry to resonate at different frequencies, which allows us to independently control multiple stimulation channels on a device. We have also shown these films to be biocompatible *in vitro* using cell viability assays over a period of seven days with no loss of device functionality.
In conclusion, these biocompatible magnetoelectric devices can convert magnetic fields that can penetrate the brain into electric fields that interact with surrounding cells to modulate their activity. This technology has many prospective applications including the exploration of neural networks and the modulation of neural activity in freely moving animals. Magnetoelectric materials could also be developed into a novel deep brain stimulation treatment for neural disorders like Parkinson's disease using devices that cause less neural damage compared to current electrodes.

Title: Effects of transcranial magnetic stimulation of FEF on neurophysiological activity in contralateral FEF

Authors: *S. J. LEHMANN[1], B. D. CORNEIL[2];
[1]Robarts Res. Inst. / Univ. of Western, London, ON, Canada; [2]Western Univ., London, ON, Canada

Abstract: Transcranial magnetic stimulation (TMS) allows non-invasive perturbation of neural activity, induced by a rapidly changing magnetic field. Both single pulse and repetitive TMS (rTMS) modulate behavioral output in both humans and animals, including non-human primates (NHPs). Despite being an important methodology in cognitive neuroscience and offering a potential treatment for neurological disorders like neuropathic pain, depression, or stroke, a precise understanding of the effects of TMS on neural activity in an interconnected brain network, and how such effects influence behavior, is largely lacking. To overcome this gap, we are developing an animal model of TMS, focusing on the oculomotor network in NHPs. Previous work has shown that delivering single-pulse TMS to the frontal eye fields (FEF) evokes feed-forward neck muscle responses, likely through the downstream superior colliculus, that can be used to optimize TMS location over the frontal cortex, and verify an effect of TMS. Now having a reliable means of delivering TMS to the FEF, we are applying TMS either in a rapid pattern (e.g., single- or double-pulse TMS delivered at a precise time during a behavioral task), or in a repetitive pattern (e.g., 1-Hz TMS for 10-15 minutes). Our current focus is to examine the effects of TMS of one FEF on neuronal activity in the contra-lateral FEF during performance of an intermixed pro- and anti-saccade task. We present data from 14 recording sessions, using a semi-chronic multi-electrode approach. During the task, single pulse TMS-FEF was delivered at 70-75% motor-threshold (defined by TMS-intensity needed to evoke hand-muscle responses when stimulating the monkey's primary motor cortex); delivery was applied at various times of the task, ranging between 30 and 80ms before target appearance. As a control, we recorded activity from the same neurons while stimulating either primary motor cortex ("brain-control") or 3 cm above the monkey's head ("sham-control") with the same intensity. Preliminary results revealed a diversity of effects on task related single-unit spiking activity (N=58) after TMS-FEF, with TMS influencing activity following visual target presentation, and saccadic activity preceding the execution of pro- and anti-saccades. These results are further contributing to the optimization of our experimental approach, and highlight the challenges in trying to differentiate specific from non-specific effects of TMS on neuronal activity.

Title: Using electrical stimulation and recordings from the cortical surface to infer principles of cortical communication

Authors: *L. CROWTHER[1], P. BRUNNER[2], A. L. RITACCIO[2], G. SCHALK[1,2,3]; [1]Wadsworth Ctr., Albany, NY; [2]Albany Med. Col., Albany, NY; [3]State Univ. of New York, Albany, NY

Abstract: The principles that govern large-scale cortical communication are still largely unclear. To better understand these principles, it is necessary to establish anatomical connectivity between different areas in the cortex and determine how functional connectivity between these areas is affected by modulatory processes, in particular oscillatory activity. Electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) lack either the spatial or temporal resolution to accurately study these properties and can only provide correlational rather than causal evidence. In the present study, we have developed methods that combine direct electrical stimulation of the cortex with electrocorticographic (ECoG) recordings. Specifically, we apply trains of discrete electrical stimuli (300 us pulse duration, 500 ms inter-stimulus period, current amplitudes up to 15 mA) to the surface of the brain while recording cortical activity with high-density ECoG grids (inter-electrode distance 3-10 mm, center to center). To date, we have performed this procedure in 6 patients that underwent clinically indicated placement of subdural electrodes. Our methods allow us to identify the cortical locations whose population-level activity is changing as a result of the electrical stimulation, and allow us to quantify the magnitude of this effect. Ongoing work is identifying the causal role of oscillatory activity in modulating the effect of electrical stimulation. Future studies will test the hypothesis that this effect is increased during the oscillatory trough or when oscillatory power is low.

Title: Generating complex neural patterns with multi-site electrical microstimulation

Authors: ***S. TAFAZOLI**, K. LETAI, T. J. BUSCHMAN;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Electrical microstimulation is often used as a tool for mapping sensory-motor functions and studying the neuronal basis of cognition. However, the majority of this has been through stimulation of a single site; it is largely unknown how multi-site microstimulation affects cortical microcircuits. To test this, we combine simultaneous multi-electrode recordings with multi-site stimulation in anesthetized mice. Stimulation and recording were performed with 32-channel silicon probes placed in either visual or parietal cortices. Using 16 channels for recording and 16 channels for stimulation allowed us to simultaneously record from small populations of single neurons while patterning stimulation at nearby sites. We found one can reliably elicit different patterns of neural activity across the population of record neurons, depending on which stimulation sites were activated. In addition, the dimensionality of the stimulation evoked responses was similar to that observed during baseline activity. Finally, multi-site stimulation was largely non-linear and difficult to predict from single site stimulation alone. These findings suggest multi-site microstimulation can produce a multi-dimensional neural response and provides the building block for probing complex cognitive functions and neural dynamics.

Title: Focused ultrasound at 43 MHz inhibits action potential firing in hippocampal brain slices

Authors: ***M. L. PRIETO**[1], D. V. MADISON[1], B. T. KHURI-YAKUB[2], M. C. MADUKE[1];
[1]Dept. of Mol. and Cell. Physiol., [2]Edward L. Ginzton Lab., Stanford Univ., Stanford, CA

Abstract: Ultrasound neurostimulation is a promising technology for modulating brain activity *in vivo.* To guide the development of this new technology, we seek to understand the physical

and biophysical mechanisms underlying the effects of ultrasound (US) on action potential firing. These mechanisms are poorly understood, partly because single-cell electrophysiological data on the effects of US on neural activity have been unavailable. Here we describe an experimental set-up that allows stable patch-clamp recording from brain slices in the presence of focused US stimulation at 43 MHz and intensities up to 50 W/cm^2, and we report preliminary results describing the effects of US at 50 W/cm^2 on neurons from the CA1 region of the rat hippocampus. We find that US inhibits action potential activity, reducing the number of spikes fired during a depolarizing current step while increasing the latency to the first spike and the interval between spikes. Since the effect of US on neural activity *in vivo* is typically an increase in action potential firing, this result suggests that in the context of *in vivo* brain circuits US may potentiate firing by reducing the activity of inhibitory neurons. We also find effects of US on the action potential waveform: the peak voltage is reduced and the width is decreased, while the initial rising phase is relatively unaffected. In addition, a slight reduction of the steady voltage level during the current step is apparent during the US stimulus when several trials are averaged. Together, these results suggest the hypothesis that US increases the activity of Ca^{2+}-activated K^+ channels, which play a prominent role in determining action potential width. US could activate these channels directly, or indirectly through increased activity of Ca^{2+} channels. We will report on the results of experiments to test this hypothesis along with additional experiments to determine the physical modality through which US affects neural activity.

Title: Effect of iTBS on cortical and corticospinal excitability in healthy subjects: a TMS-EEG-EMG study

Authors: *T. GEDANKIEN, P. J. FRIED, A. PASCUAL-LEONE, M. SHAFI;
Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Noninvasive brain stimulation techniques, such as Transcranial Magnetic Stimulation (TMS) and intermittent Theta Burst Stimulation (iTBS), enable the characterization of cortical

and corticospinal reactivity in humans. TMS coupled with electromyography (EMG) allows for the recording of motor evoked potentials (MEPs), while TMS and encephalography (EEG) permit recording of TMS-evoked EEG potentials (TEPs). While it has been shown that TBS over the primary motor cortex (M1) can induce changes in cortical and corticospinal reactivity, the relationship between such TBS-induced changes remains poorly understood. In this study, we examine the correlation between MEPs and early TEPs from single-pulse TMS before and after iTBS to the left M1 in 8 healthy subjects. TMS was targeted to the hand region of M1 using the MRI-guided Nexstim eXimia navigated brain stimulation system and a Nexstim eXimia figure-of-eight biphasic coil. MEPs were recorded from the first dorsal interosseous (FDI) of the right index finger via Ag-AgCl surface electrode-pairs. TMS single pulses were delivered at 120% of the resting motor threshold (RMT; 5/10 $\geq$ 50 μV). EEG was recorded with a 60-channel TMS-compatible EEG device, and impedances were kept below 5kΩ. A passive-cooling figure-of-eight coil attached to a MagPro X100 stimulator was used to deliver iTBS (total of 600 pulses) at 80% of active motor thresholds (AMT; 5/10 $\geq$ 200 μV during isometric contraction). Prior to and following iTBS, participants received 3 blocks of 30 TMS single pulses at 120% RMT. Peak-to-peak amplitudes of each recorded MEP and TEP were averaged for each subject. Of the 8 subjects, 4 demonstrated an MEP increase >50% after iTBS, and are labeled “MEP responders”. The other 4 showed MEP change of <10%, and are termed “MEP non-responders.” In the 4 MEP responders, there was a significant increase in the magnitude of the TEP P30 amplitude (mean pre = 4.1 μV; mean post = 6.1 μV; $p < 0.001$). In contrast, in the 4 MEP non-responders, there was no significant change in TEP P30 amplitude (mean pre = 3.53 μV; mean post = 1.8 μV; $p > 0.2$). Across all 8 subjects, the percentage change in TEP P30 amplitude was significantly correlated with the percentage change in MEP amplitudes ($r=0.82$; $p < 0.05$), suggesting that iTBS-induced changes in cortical and corticospinal plasticity are linked. Our results demonstrate that when iTBS induces changes in corticospinal reactivity, cortical reactivity is similarly modulated. The changes in EEG measures of cortical reactivity are correlated with conventional MEP changes. Going forward, concurrent TMS-EEG may be used to directly evaluate cortical plasticity mechanisms in non-motor brain regions.

Title: A multi-channel electrode for chronic recording and safe current-steered stimulation

Authors: *B. PEARRE[1], S. MOORMAN[2], J. SHEN[3], T. GARDNER[3];
[1]Biol., Boston Univ., Cambridge, MA; [2]Biol., [3]Boston Univ., Boston, MA

Abstract: Electrical control of the brain facilitates a variety of therapeutic and scientific goals, from treating sensory, motor, and cognitive defects to exploring the effects of disrupting or subtly modifying the brain's behaviour in real time. These procedures are limited by the brain's reaction to foreign matter: over a period of months, glia encapsulate the electrodes, isolating them from neurons, allowing monitoring and control of the brain only over large spatial scales---often on the order of millimeters. Small electrodes (< 10 um) minimise encapsulation, and thus can both record single neurons for many months and precisely stimulate small groups of neurons. However, the high impedance of small electrodes can require stimulation voltages that exceed the water hydrolysis point.

We have developed an electrode design in which groups of electrodes support each other during insertion and then splay randomly in the brain, allowing long-term small-spatial-scale recording and stimulation [Guitchounts 2013].

We describe the splaying properties of these electrode arrays in the brain. We present preliminary results showing that these electrodes remain capable of recording individual spikes for a year after implantation, even when also used to stimulate.

We present preliminary evidence that the spatial scale of the splaying is sufficient to allow the steering of current between the electrodes, and that this allows a degree of high-dimensional control over the brain's response to stimulation. We show that appropriate control of the electrode array can produce neural responses while keeping stimulation voltages below safety limits. Furthermore, we demonstrate controllable differentiation between responses, even in an upstream brain area.

Thus these multichannel, spatially distributed, micron-scale arrays allow long-term single-unit recordings, enabling new experiments investigating how the brain changes on long timescales. In addition, current-steered control of stimulation inputs allows fine-grained control over small groups of neurons, permitting a wide variety of optimisations, such as controlling the brain to some set of desired responses, or minimising the voltage or energy required in order to achieve the desired result.

Title: Types of neurons recruited and activity patterns elicited by single pulse transcranial magnetic stimulation in motor cortex of alert rhesus macaques

Authors: *M. V. SMITH[1], J. KIM[1,6], E. M. GRIGSBY[7], N. GOSWAMI[1], D. WONG[1], J. M. BERNABEI[1,6], A. V. PETERCHEV[1,2,3], W. M. GRILL[1,3,4], M. A. SOMMER[1,4,5]; [1]Biomed. Abstract: Transcranial magnetic stimulation (TMS) is a safe, non-invasive method of brain stimulation that induces a transient electric field in cerebral cortex. Its precise effects on single neuron activity are unknown, however, which limits the rational design of TMS protocols. Here we recorded from the primary motor cortex (M1) of two alert rhesus macaques while simultaneously delivering single pulses of TMS from a MagStim Rapid2 stimulator. TMS was applied at varying intensities (10%-90% of maximum machine intensity in 10% increments) using custom coils (Mueller et al. 2014) in two configurations: “stim” TMS to induce a focal electric field at the recording site, and “sham” TMS to replicate auditory and cutaneous effects while inducing minimal electric field at the recording site. Our aims were to quantify the dose-response curves to TMS across several dimensions of neuronal response, the categories of neural response patterns to TMS, and the differential responses of inhibitory vs. excitatory neurons. We previously showed that the population response of M1 neurons to TMS is a transient burst of excitation followed by a pause in activity and that the incidence of this “canonical” response increases with TMS intensity (Grigsby et al. SfN 2015). Building on that result, we analyzed the stim and sham dose-response curves across multiple dimensions of the response, including the burst phase, the pause phase, the initiation time, and degree of trial-to-trial synchronization. In each dimension, stim vs. sham differences appeared near motor threshold (~60% machine intensity). We quantified the categories of response patterns using k-means clustering and found several distinct, yet consistent, clusters of activity profiles. In addition to the canonical response, many neurons showed prolonged excitation or inhibition following TMS. Finally, using Gaussian mixture models and related methods on the peak widths and depolarization rates of action potential waveforms, we sorted our dataset into putative excitatory neurons, putative inhibitory neurons, and putative axons. All were activated by single pulse TMS, but response

profiles differed between neural elements in distinct ways, e.g. briefer pauses for inhibitory neurons than excitatory neurons. In summary, the uniform population response of M1 neurons arises from myriad individual neural response patterns that individually obey dose-response relationships, fall into distinct categories, and are associated to some extent with putative cell type. The results inform a more mechanistic understanding of the effects of TMS in the primate brain.

Title: Selective inhibition of nicotinic acetylcholine receptor subtypes by chemical additives used in tobacco and nicotine delivery products

Authors: Y. A. KURYSHEV[1], C. WU[1], *N. B. FEDOROV[1], C. KNIGHT[1], G. E. KIRSCH[1], C. S. LEGGETT[2], A. L. MOTTER[2], M. S. ORR[2], L. C. ARMSTRONG[1];

Abstract: The effects of nicotine on the mammalian central and peripheral nervous system are mediated via activation of nicotinic acetylcholine receptors (nAChRs). The positive reinforcing effects of nicotine appear to be mediated primarily by the α4β2 subtype, and secondarily by α6-containing subtypes, due to their preferential expression in the regions of the brain responsible

for reward. Flavorings and odorants added to nicotine delivery products might also modulate nicotine's effects on nAChRs. Menthol, a coolant commonly added to tobacco products, has been shown to augment the biological effects of nicotine, paradoxically by antagonizing nicotine's activity at certain nAChRs. To screen more efficiently for modulatory effects of additives, we have developed high throughput automated electrophysiology assays, on the IonWorks Barracuda™, for the α4β2, α3β4, α3β4α5, α6/3β2β3 and α7 nAChRs. We employed these assays to analyze the agonist and antagonist effects of 70 commonly used flavorants and odorants added to cigarettes, smokeless tobacco products and e-cigarette liquids. We detected significant antagonist activity (IC_{50} values < 100 μM on at least one subtype) with 20 of those compounds. Notably, farnesene and farnesol, which impart a green apple flavor, were strongly inhibitory, with farnesol exhibiting broad effects and farnesene selectively inhibiting α6/3β2β3. Consistent with previous studies, we found menthol to inhibit nAChR activities with IC_{50} values from 25 μM (α4β2) to 110 μM (α7). Other potent and broadly inhibitory tobacco additives were nonivamide (IC_{50} values from 1.1 μM at α7 to 9.5 μM at α6/3β2β3) and γ-dodecalactone (IC_{50} values from 7.8 μM at α4β2 to 30 μM at α7). The citrus odorants citronellal, citronellyl acetate and citronellyl formate, inhibited α4β2 with moderate potency (IC_{50} values of 28 to 35 μM) and the other nAChRs more weakly. The differential potencies of these compounds on different nAChR subtypes have the potential to influence the rewarding properties of nicotine.

Title: Dendritic effects of theta-burst induced plasticity during direct current stimulation

Authors: ***D. LING**[1], G. KRONBERG[2], A. RAHMAN[3], M. BIKSON[3], L. PARRA[3]; [1]Biomed. Engin., The City Col. of New York, Oakland Gardens, NY; [3]Biomed. Engin., [2]The City Col. of New York, New York, NY

Abstract: Transcranial direct current stimulation (tDCS) is a noninvasive technique that uses scalp electrodes to apply weak constant current to treat a multitude of neurological disorders.

Despite widespread adoption, little is known about the physiological mechanisms by which long term effects are achieved. Electric fields are known to cause local depolarization and hyperpolarization of neuronal compartments. tDCS is therefore thought to act via polarization of neuronal somas, leading to changes in excitability. However, our group has previously shown that DCS effects on long-term potentiation (LTP) and depression (LTD) can be dependent on dendritic location, implying a role for dendritic membrane polarization. In this previous work we used constant trains of synaptic activity to induce plasticity. However, other common plasticity induction protocols are thought to better mimic in vivo synaptic activity and operate via different cellular machinery. Here we show that DCS also modulates LTP induced by theta-burst stimulation (TBS) in CA1 of rat hippocampal slices. By examining these effects in different dendritic compartments we extend our previous work on the role of dendritic membrane polarization in determining these effects. This study highlights the importance of considering both the pattern of underlying synaptic activity and the role of dendritic effects in determining long-term tDCS outcomes.

Title: Large-scale circuit mapping in macaque mesolimbic and basal ganglia systems with multi-site patterned intracortical microstimulation

Authors: *S. QIAO, K. A. BROWN, B. FERRENTINO, B. PESARAN;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Existing approaches to treat neuropsychiatric disorders, such as surgery and medications, can often help alleviate the worst effects of symptoms, but they rarely offer precise, effective and personalized therapeutic solutions and suffer side effects. Psychiatric disorders, such as treatment-resistant depression and anxiety, have diverse cognitive and behavioral components, reflecting dysfunction distributed across multiple brain regions in interconnected

networks. The development of novel neurotechnologies for treating these disorders depends critically on understanding and manipulating the dynamics of neural circuits across large-scale brain networks. To meet this need, we developed a large-scale custom-designed semi-chronic stimulation and recording microdrive device to precisely target and modulate brain regions in cortical and subcortical reward processing networks of the non-human primate (NHP) performing a reward-guided reinforcement learning and decision-making task. The device provides a flexible platform for exploring and mapping detailed functional connectivity between these brain regions via open-loop multi-site patterned intracortical microstimulation (ICMS). We implemented a temporal and spatial multi-site patterned ICMS framework combining single-pulse and tetanic (100 or 200 Hz, 50 ms-10 min) stimulation to specifically investigate the neuronal dynamics and functional connectivity of the brain regions related to the orbitofrontal cortex (OFC). We illustrate this ICMS framework by mapping and manipulating the functional connectivity across some putative pathways between the lateral OFC (lOFC) and caudate nucleus (CN), anterior cingulate cortex and CN, and lOFC and external globus pallidus (GPe). We found that a 250 ms, 200 Hz bipolar tetanic stimulation (20 μA, 100 μs biphasic charge-balanced square waveform) in the corpus callosum near the CN was able to suppress the neural responses in the CN evoked by the bipolar single-pulse stimulation (30 μA, 100 μs) in the lOFC. We also observed enhanced neural responses in the GPe due to the bipolar single-pulse stimulation (40 μA, 100 μs) applied at a node in the lOFC after a 500 ms, 100 Hz bipolar tetanic stimulation (30 μA, 100 μs) delivered at another node in the lOFC. This work offers new insights into how the effects of electrical stimulation at particular nodes, frequencies, and durations will cascade throughout the mesolimbic and basal ganglia reward pathways. The results have implications for the rational design of therapeutic patterns of closed-loop stimulation based on a circuit-level understanding of the neuropsychiatric conditions.

Title: Comparison of two types of neuromuscular electrical stimulation for the reduction of contraction-fatigue of the quadriceps muscle.

Authors: *F. CLAVERIA-GONZALEZ[1,2], R. KASSAM[1], T. BARSS[1], D. COLLINS[1,3]; [1]Physical Educ. and Recreation, [2]Rehabil. Med., [3]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Introduction: Neuromuscular electrical stimulation (NMES) can produce contractions to increase functionality and reduce secondary complications for people with spinal cord injury. Unfortunately, the benefits of NMES are limited by rapid contraction-fatigue. A promising new approach developed to reduce contraction fatigue is sequential NMES (sNMES). sNMES involves rotating stimulation pulses between multiple electrodes over a muscle belly. Accordingly, different subpopulations of motor units are recruited by each stimulating electrode which reduces motor unit discharge frequencies, metabolic demand and contraction fatigue. The most common way to deliver sNMES involves five electrodes; four cathodes over the proximal quadriceps femoris muscles (Q) and a common “fixed” anode located proximal to the knee (FIX sNMES). Presently we test a modified form of sNMES which involves four electrodes over the Q muscle bellies. Instead of having a fixed anode, the anode and cathode are rotated among the four electrodes in a "chasing" pattern (CHASE sNMES). We think that this rotation of anode and cathode will recruit Q motor units more selectively and with less overlap than FIX sNMES. Therefore, we hypothesized that CHASE sNMES will reduce contraction-fatigue of the Q, compared to FIX sNMES. Methods: Four human participants (2 males and 2 females; 27.5±7.7years) were recruited. The two types of sNMES were tested in different sessions on separate days. Each session incorporated a fatigue protocol consisting of 170 contractions (0.3 s "on", 0.7 s "off"). Contraction-fatigue was quantified by the fatigue index (FI: peak torque during the last five contractions divided by the peak torque during the first five contractions multiplied by 100). A dependent T-test was performed to test for statistical differences between FIs for each NMES condition (FIX versus CHASE sNMES). Results: Initial results showed no significant difference in FI between FIX sNMES and CHASE sNMES (71±11.5, and 69±11.1 respectively). Accordingly, by the end of the fatigue protocol FIX sNMES and CHASE sNMES resulted in no difference in contraction-fatigue. Conclusion: Therefore, CHASE sNMES may be preferred during rehabilitation since four electrodes are easier to apply and it reduces costs than 5 electrodes (FIX sNMES). In addition, another important factor that should be considered for application to clinical settings is discomfort during sNMES. Therefore, our next step will to compare this outcome between FIX sNMES and CHASE sNMES.

Title: Activity-dependent axonal hyperpolarization contributes to neuromuscular electrically-induced contraction fatigability

Authors: *M. J. LUU[1,2], K. E. JONES[1,2], D. F. COLLINS[1,2];
[1]Fac. of Physical Educ. and Recreation, [2]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada

Abstract: There are numerous benefits in using neuromuscular electrical stimulation (NMES) as a rehabilitation tool to improve the quality of life for those living with a neurological disease or motor-impairment. Unfortunately, these benefits are limited by rapid muscle contraction fatigability. Contraction fatigability during NMES is explained, in part, by decreases in excitability of motor axons (axonal hyperpolarization) under the stimulating electrodes, resulting in fewer motor units responding to the NMES. When this occurs, the threshold current required to produce a target compound muscle action potential (CMAP) increases. The present study was undertaken to determine the time course and extent to which axonal hyperpolarization contributes to contraction fatigability when stimulating at different frequencies. Seven healthy participants took part in this study. In separate sessions, NMES was delivered at 20, 40, or 60 Hz to the common peroneal nerve to generate 480 contractions of the tibialis anterior (TA) muscle over 8 min. Contraction fatigability was measured by the decline in torque over time. Axonal hyperpolarization was measured as changes in the threshold current required to produce a CMAP of ~30% of maximum. Threshold current was measured every second, before and during the 8 min of NMES. NMES was delivered at an intensity larger than the current tracking pulse in order to ensure that only fatigued populations of axons were being tested. Single supramaximal pulses were delivered over the TA to measure the peak twitch torque during NMES. A multiple regression analysis was done to determine the relative contributions of nerve and muscle to the declining torque output. Results show that there was an increase in threshold current during NMES due to axonal hyperpolarization, and the magnitude and rate of change was frequency-dependent. The largest current increase occurred with 40 Hz NMES, and the smallest with 20 Hz NMES. Threshold current increased faster with 60 Hz NMES and slower with 20 Hz NMES. Contraction fatigability was strongly predicted by changes in threshold current at all frequencies, and less so by changes in the muscle's maximal torque output. Axonal hyperpolarization plays a role in NMES-induced contraction fatigability and the magnitude and time course of this change

is frequency dependent. The results of these experiments provide insight into the biophysical changes that occur in axons during NMES and may be useful to improve the efficacy of NMES by minimizing contraction fatigability. This is particularly important for those individuals that use it as a therapeutic tool, thereby helping to improve their quality of life.

Title: Contraction fatigue associated with three types of neuromuscular electrical stimulation delivered to produce a range of contraction amplitudes

Authors: *E. N. AINSLEY[1,2], S. K. HARING[1], D. J. MILLER[1], M. J. WIEST[1], A. J. BERGQUIST[3], D. F. COLLINS[1,2];
[1]Fac. of Physical Educ. and Recreation, [2]The Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [3]Toronto Rehabil. Inst., Toronto, ON, Canada

Abstract: Neuromuscular electrical stimulation (NMES) can be applied over a muscle belly (mNMES) or nerve trunk (nNMES) to produce contractions for rehabilitation. However, rapid contraction fatigue, which manifests as a decline in torque over time, often limits its effectiveness. This fatigue is due, in part, to the high discharge rates of motor units during stimulation. To minimize fatigue, we developed interleaved NMES (iNMES), which involves alternating stimulating pulses between the mNMES and nNMES sites, thereby reducing motor unit discharge rates. The purpose of the present experiments was to compare the fatigue associated with nNMES, mNMES and iNMES of the tibialis anterior (TA) muscle at various torque amplitudes in order to generate a simulation protocol to minimize fatigue when using

NMES. This experiment is ongoing, with iNMES data being currently collected (not presented in this abstract). Each of 9 healthy subjects participated in 12 sessions with each session conducted on separate days. Within each session, participants initially performed 2 maximum isometric voluntary contractions (MVC) of ankle dorsiflexion. Trains of stimulation (duration = 0.3s; pulse width = 500μs; frequency = 40 Hz) were delivered and stimulation amplitude was adjusted to generate either 5%, 15% or 25% of a MVC or the maximal tolerated stimulation amplitude (Max). A fatigue protocol consisting of 170 trains for one of the 4 contraction amplitudes was then conducted. Contraction fatigue was quantified by the fatigue index (FI) where FI was calculated as the average torque of the last 10 trains of the fatigue protocol divided by that during the first 10 trains. In this way, a smaller fatigue index indicates more fatigue. The FI's for mNMES at 5%, 15%, 25% and Max were 0.85±0.26%, 0.77±0.14%, 0.69±0.11% and 0.65±0.11%, respectively. The FI's for nNMES at 5%, 15%, 25% and Max were 1.07±0.48%, 0.82±0.13%, 0.78±0.22% and 0.61±0.17%, respectively. Qualitatively, larger contractions resulted in greater contraction fatigue which is consistent with the theory that motor unit recruitment during NMES follows Henneman's size principle. We anticipate that iNMES will generate less fatigue than mNMES and nNMES during low contraction amplitudes and will have a similar level of fatigue in comparison to mNMES and nNMES during larger contraction amplitudes. The results of this study have important implications for in reducing fatigue during NMES for rehabilitation.

Title: Behavioral discrimination of channel specific microstimulation for central auditory neuroprostheses

Authors: ***R. VERNER**, E. BARTLETT;
Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Neuroprostheses offer the potential to restore a modicum of sensation back to individuals in need. One major way in which sensation is restored consists of placing electrodes to enable spatial segregation along the one or two-dimensional axes representing the sensory epithelium and fundamental stimulus dimension, namely, frequency along the cochlea for hearing or skin region for somatosensation. Part of the reason for the ongoing success of the cochlear implant is its ability to adequately stimulate specific regions along the tonotopic axis of the cochlea, allowing for adjacent channels to stimulate groups of neurons in different frequency bands, though with partial overlap. Moving more centrally from the cochlea, the tonotopic axis remains, but the way in which electrical stimulation permits behavioral discrimination is poorly understood. For example, Auditory Brainstem Implants have shown reduced efficacy for behavioral perception as compared to cochlear implants, are far more difficult to implant, and occasionally stimulate undesirable nearby structures (Brackmann et al. 1993). Primary auditory cortex (A1) may be a more desirable stimulation target due to the ease of access and low risk of stimulating non-auditory regions. A1 stimulation may also serve as a model for other sensory cortical neuroprostheses and central neuroprostheses, where there are multiple cell types and intra-areal microcircuits, such as the cortical columnar microcircuits. To understand the potential for cortical prostheses and potential bases for perceptual variability, we examined interchannel discrimination in a rat behavioral model. Our data suggest rats can discriminate between stimuli presented on adjacent electrode sites separated by 125 microns (d'=2.15, s.d. 0.24) in layer 4. When repeated in layers 2-3, rats failed to discriminate between sites even up to 375 microns apart, which was the limit of our array (d'=0.32, s.d. 0.75). This result suggests that layer 4 cortical microstimulation has the potential to generate fine resolution across a stimulus dimension. Given this, careful consideration of local circuitry, stimulation parameters, and regions targeted by microstimulation can overcome many of the performance obstacles typically seen with central neuroprostheses.

Abstract: Enhancing functional motor recovery after localized brain injury is a widely recognized priority in healthcare as disorders of the nervous system causing motor impairment, such as stroke, are among the most common causes of adult-onset disability. Restoring the physiological function of a dysfunctional brain to improve the quality of life is a primary challenge in scientific and clinical research and will be driven through innovative therapeutic approaches. Recently, techniques using brain stimulation methodologies have been employed to promote post-injury neuroplasticity for the restitution of motor function. One type of stimulation, activity-dependent stimulation (ADS), has been shown to modify existing functional connectivity within either healthy or injured cerebral cortex and has been used to increase motor recovery following cortical injury. The aim of the present work is to investigate the ability of intracortical ADS to potentiate functional connectivity between *distant* cortical locations in the healthy brain within a single four-hour recording session in anesthetized rats. Spontaneous and evoked activity within layer V of rat pre-motor cortex (rostral forelimb area, RFA) was extracellularly recorded using a 16-contact microelectrode and analyzed following treatment of ADS driven by RFA activity or Gaussian-distributed (i.e., Random) stimulation approximating the ADS frequency. Two areas within S1 (forelimb or barrel field, FL or BF) were chosen alternately for stimulation to assess the efficacy of the stimulation on different cortical locations. We quantified first-order statistics of sorted neurons (e.g., mean firing rate and inter-spike interval distribution) and estimated functional connectivity within RFA by using cross-correlation related measures as well as the coupling of each recorded neuron to the population activity (Okun *et al.*, 2015). All stimulation protocols induce changes in the subsequently recorded activity of RFA. Our results suggest that stimulation of either BF or FL area induces differential changes in RFA activity, which may be the result of different degrees of anatomical connectivity between RFA and the two sensory regions. ADS is be more effective than Random stimulation, further strengthening the idea that ADS can be used to modulate cortical connectivity and is potentially a powerful tool to enhance neuroplasticity after injury. These investigations are critical for understanding the neurophysiological effects of ADS, as well as providing a foundation for assessing the optimal stimulation parameters for treatment following brain injury.

Abstract: Optimal control techniques can be used to find reduced energy input current stimuli that produce a desired neuron membrane voltage response. The technique in [1, 2] produces a range of stimuli which balance tracking error and input current stimulus energy. Optimal stimuli produce similar membrane voltage responses as those produced by higher energy stimuli both in simulations and in experimental work [3]. In [3], lower energy optimal stimuli were found *a priori* using models based on qualitative behavior of neurons; in the work presented here, model parameters are adjusted at the electrophysiology rig based on membrane voltage responses of a leech neuron to input stimuli. Optimal control is then applied to this experimentally informed model to find and apply optimal stimuli during the experimental session. The effectiveness of input current stimuli found using an experimentally informed neuron model is examined and compared to non-optimal stimuli as well as stimuli computed *a priori*.

Title: Sinusoidal electrical stimulation to modulate neural activity in freely behaving animals

Authors: ***Y. A. CHO**, Y. LEE, Y. LEE, J. LEE, S. JUN;

Abstract: Electrical pulse is commonly used in neuroprostheses in order to modulate neural activities. However, there have been well-known issues of rectangular waveform stimulation in terms of both electrode corrosion and tissue damage. We attempted to improve those drawbacks using sinusoidal stimulation instead of pulse stimulation. Recent in vivo studies have revealed that the performance of sine wave stimulation was significantly more efficient than biphasic pulse stimulation limitedly in retina experiments. Our previous study also presented that electrical sinusoidal stimulation has advantages not only in the effective stimulation but also in the ease of artifact removal using a filter with corresponding frequency. In the present study, electrical sine wave stimulation was applied to a freely moving animal to observe neural activities in several brain areas. Manually manufactured stimulation electrodes (180m diameter) were implanted in the ventral tegmental area (VTA), and recording electrodes (100m diameter) were inserted in both nucleus accumbens (NAc) and primary motor cortex (M1). Local field potentials (LFPs) was investigated to show the difference of power discharged before and after VTA stimulation. In addition, long-term stimulation using sinusoidal waveforms and pulse train will be experimented for immunohistological analysis. This study is anticipated to show that the sinusoidal waveform stimulation is electrode- and tissue-protective method.

Title: Targeting the therapeutic properties of cannabidiol: focus on depression and pain.

Authors: G. GOBBI[1], R. MCLAUGHLIN[1,3], *D. DE GREGORIO[2], R. OCHOA-SANCHEZ[1], L. LUONGO[4], S. MAIONE[4];

Abstract: Background: Recently, there has been an increased interest in exploiting the therapeutic properties of cannabis and its derivatives, even if their precise therapeutic indications have not yet been completely elucidated in preclinical and clinical studies. Cannabidiol (CBD), the primary non-psychotropic constituent of cannabis, is thought to have antidepressant and analgesic effects (Metchoulam et al., 2007, Chem Biodivers. Aug;4(8):1678-92), *via* a multi-target mechanism of action, including the serotonergic 5-HT1a subtype receptor (Rock et al., 2012, Br J Pharmacol. Apr;165(8):2620-34). The aim of this study was to investigate the effect of CBD on 5-HT neurons of Dorsal Raphe Nucleus (DRN), attempting to further characterize its presynaptic serotonergic mechanism involved in both allodynia/hyperalgesia and in depression-like behavior. **Methods:** Using *in vivo* electrophysiology, we studied the effect of acute (0.05-1.0 mg/kg, i.v.) and chronic (5.0 mg/kg/day) treatment with CBD on 5-HT DRN electrical activity in adult male Sprague-Dawley rats (PND 70). The 5-HT_{1A} receptor antagonist WAY100635 (0.3 mg/kg, i.v.) and the CB_1 receptor antagonist AM251 (1.0 mg/kg, i.v.) were also injected prior to CBD. Forced Swim Test (FST) and spared nerve injury (SNI) were also done to test the antidepressant and analgesic properties of CBD, respectively. Dynamic Plantar Aestesiometer and Plantar Test were employed to test the anti-allodynic and anti-hyperlagesic effect, respectively after 3, 7 and 14 days post SNI. **Results**: Cumulative injection doses of 0.1-1.0 mg/kg led to a decrease in 5-HT DRN firing activity ($P<0.001$, n=9). This inhibitory effect of CBD was prevented by pretreatment with WAY100635 ($P=0.13$, n=4), but not AM251 ($P<0.001$, n=4). Chronic treatment with CBD (5.0 mg/kg/day for 7 days) increased the firing rate of DRN 5-HT neurons ($P<0.001$), but not the number of spontaneously active 5-HT neurons ($P=0.1$). Acute and chronic (7 days) treatment with CBD did not affect immobility ($P=0.4$, n=8) nor swimming time ($P=0.6$, n=8) in the FST in naïve rats. In contrast, chronic treatment with CBD (5.0 mg/kg/day) prevented mechanical allodynia ($P<0.05$) and thermal hyperalgesia ($P<0.05$) after 3, 7 and 14 days post-SNI in CD1 mice. **Conclusion**: These data confirm that acute CBD

administration decreases the firing rate of 5-HT neurons via the 5-HT_{1A} receptor stimulation and increases the firing rate of 5-HT neurons after 7 days of treatment. This regimen did not affect depressive behavior, but was effective in preventing allodynia and hyperalgesia associated with a neuropathic pain condition.
