Title: Regulation of non-coding RNA contributes to the complete cessation of cell proliferation of neuron-like cells

Authors: *T. IMAMURA[1], N. YAMAMOTO[2], K. AGATA[3], K. NAKASHIMA[1];
[1]KYUSHU UNIV, Fukuoka-Shi, Japan; [2]Hoshi Univ., Tokyo, Japan; [3]Gakushuin Univ., Tokyo, Japan

Abstract: Neurons do not proliferate once their fate is determined. This is because if they proliferated, newly generated neurons might cause electronic noise that would disturb the already existing finely tuned neuronal cell network. Similarly, de-regulation of cell cycling mechanisms in cells other than neurons may increase the risk of tumor formation. In order to avoid such de-regulation, genomic DNA that defines genes involved in the cell cycling is set appropriately according to given environmental contexts. In addition to the genes that encode proteins, next generation sequencing technique allows to find a large group of “non-coding RNAs (ncRNA)” transcribed from genomic DNA. We have found that bidirectional promoters are the major source of gene activation-associated ncRNA. PC12 cells offer an interesting model for understanding the mechanism underlying bidirectional promoter-mediated cell cycle control. Nerve growth factor (NGF)-stimulated PC12 cells elongate neurites, and are in a reversible cell-cycle-arrested state. In contrast, these cells irreversibly differentiate and cannot re-enter the normal cell cycle after NGF plus cAMP treatment. In this study, using directional RNA-seq, we found that bidirectional promoters for protein-coding genes with promoter-associated ncRNA (pancRNA) were enriched for cAMP response element consensus sequences, and were preferred targets for transcriptional regulation by the transcription factors in the cAMP-dependent pathway. A spindle-formation-associated gene, *Nusap1* and *pancNusap1* were among the most strictly co-transcribed pancRNA-mRNA pairs. This pancRNA-mRNA pair was specifically repressed in irreversibly differentiated PC12 cells. Knockdown (KD) and overexpression experiments showed that *pancNusap1* positively regulated the *Nusap1* expression in a sequence-specific manner, which was accompanied by histone acetylation at the *Nusap1* promoter. Furthermore, *pancNusap1* KD recapitulated the effects of cAMP on cell cycle arrest. Thus, we conclude that pancRNA-mediated histone acetylation contributes to the establishment of the cAMP-induced transcription state of the *Nusap1* locus and contributes to the irreversible cell cycle exit for terminal differentiation of PC12 cells.

Title: Role of Meis1 in the cerebellar development

Authors: ***T. OWA**, M. HOSHINO, S. TAYA;
Dept. of Biochem. and Cell. Biol., Natl. Inst. of Neurosci. NCNP, Kodaira, Japan

Abstract: Although there have been many studies on the development of cerebellar granule cells, its molecular machinery is still elusive. We found that Myeloid ecotropic viral integration site 1 (Meis1) was strongly expressed in all cells in the granule cell lineage during development, including mitotic granule cell precursors (GCPs) in the outer external granule layer (EGL) and posto-mitotic granule cells (GCs) in the inner EGL, molecular layer (ML) and inner granule layer (IGL). We generated Meis1 conditional knockout mice by crossing with Atoh1-Cre-Tg line, where *Meis1* gene was specifically deleted in the granule cell lineage. In Meis1$^{fl/fl}$; Atoh1-Cre-Tg mice, the size of the cerebellum was smaller than that of wild type littermates. The structure of the cerebellum was disorganized. The cKO cerebella have multiple small lobuli. We occasionally observed ectopic EGL, (clusters of mitotic GCPs) in the ML and/or IGL, that expressed Atoh1. We suspect that those ectopic EGL may be account for generating extra tiny lobuli. These results suggest that Meis1 is involved in cerebellar granule cell development. We are now crossing Meis1 $^{fl/fl}$ mice with other Cre driver lines, which will be also introduced.

Title: Pax6d is necessary and sufficient for retina lineage specification

Authors: *Y. TAO[1], J. CAO[2], S.-C. ZHANG[3];
[1]Dept. of Neurosci., Univ. of Wisconsin Madison, Madison, WI; [3]Dept. of Neurosci., [2]Univ. of Wisconsin - Madison, MADISON, WI

Abstract: Pax6 is required for the specification of multipotent retinal progenitors. However, the role of Pax6 isoforms in retinal development is not defined. By creating human embryonic stem cell (hESC) lines that lack isoform-specific PAX6 and those that inducibly express specific PAX6 isoforms under the full PAX6 knockout background using CRISPR/CAS9, we examined the roles of PAX6 isoforms in retinal progenitor specification from human embryonic stem cells (hESCs), which mimics the human retinal development process in vitro. Human ESCs with complete deletion of PAX6 fails to enter into the retina fate and generate photoreceptor cells. Cells with PAX6 isoform d (PAX6D) knockout exhibit the same phenotype as the full knockout while pax6 a/b isoform knockout shows normal retina lineage specification. Furthermore, inducible expression of PAX6D rescues the capacity of Pax6 full knockout cells to produce retinal cells. Ectopic expression of PAX6D in neural progenitor cells results in generation of retinal cells. Our study has thus revealed that PAX6D is necessary and sufficient for retina lineage specification.

Title: Elucidation of neural stem cell character of caudal cell mass in developing chick embryo

Authors: *E.-S. LEE[1], J. LEE[1], S. KIM[1], H. PARK[1], J. PHI[2], S.-K. KIM[2], Y. HWANG[1], K.-C. WANG[2];
[1]Seoul Natl. Univ., seoul, Korea, Republic of; [2]Div. of Pediatric Neurosurg., Seoul Natl. Univ. Children's Hosp., seoul, Korea, Republic of

Abstract: Caudal cell mass (CCM) has been known to be the main player in secondary neurulation forming the secondary neural tube. This suggest CCM may have the character of neural stem cell (NSC). However, evidence of CCM's character as NSC has not been shown. The neural potential of CCM was assessed by confirming *in vitro* culture of neurospheres from CCM throughout the stages of secondary neurulation (Hamburger and Hamilton (H-H) stages 12 to 32). We further evaluated whether there was spatiotemporal diversity in the neural potential of the developing central nervous system by quantification of the *in vitro* neurosphere culture results from the brain, upper spinal cord, lower spinal cord, and CCM from various stages of development.
CCM was capable of in vitro neurosphere formation, which were able to differentiate into neuron, astrocyte, and oligodendrocyte, and able to self-renew. This provided evidence that CCM had characteristics of NSC. When the quantitative outcome of neurosphere formation from CCM of various stages was evaluated, the number of cultured neurosphere was greatest at H-H stage 28 for CCM. For brain, the greatest number of neurospheres was formed at stage 16. Considering the trend of increase in the number of neurospheres for brain, spinal cord, and CCM, the neural potential seemed to follow a cephalo-caudal direction as development proceeded.
This study showed that neurospheres can be cultured *in vitro* from CCM of various stages, supporting its character as NSC. The spatiotemporal diversity of NSC character was also shown, reflecting the dynamic process of neurulation during development.

Abstract: Neural stem cells are characterized as self renewing cell populations with the ability to differentiate into the multiple tissue types of the central nervous system (CNS). These cells can differentiate into mature neurons, astrocytes, and oligodendrocytes. This category of stem cells has been shown to be an effective treatment for neurodegenerative diseases such as Parkinson's disease and following traumatic injury to the CNS such as traumatic brain injury, stroke, and spinal cord injury. Most treatment studies with neural stem cells in animal models use embryonic brain derived neural stem cells. This approach presents both ethical and feasibility issues for translation to human patients. Adult sources of tissue are a more practical source of stem cells for transplantation therapies in humans.
Some adult tissues such as bone marrow and adipose tissue contain discrete populations of multipotent and embryonic like stem cells. Of these stem cell populations, some are able to respond to neuronal growth factors and can be expanded *in vitro*, forming neurospheres analogous to cells harvested from embryonic brain tissue.
Here, we describe a method for the collection and culture of adipose tissue which results in a population of neural stem cells that are able to be expanded *in vitro* and be differentiated into neuronal-like cells. These adipose derived cells display a similar phenotype to those derived from embryonic sources. When differentiated into neurons, cells derived from adipose tissue show spontaneous spike activity which is similar in waveform to the embryonic brain derived cell lines but show higher frequencies of spiking and bursting activity.

Abstract: During cortical development many genes and signaling pathways are active but their functions and interconnections are poorly understood. The protooncogene Ski is a central integrator of signal and transcriptional activities through its interactions with different partners. In order to assess the role of Ski, we are comparing the dynamics of various signaling pathways in the presence and absence of Ski during cortical developmental. We use in vivo transgenic marking of Ski-deficient neural stem cells (*Hes5::GFP; Ski*$^{-/-}$) and committed neuronal progenitors (*Tbr2::GFP; Ski*$^{-/-}$) to identify, isolate (FACS sorting), and analyze the cells by RNA-Seq. Analyses of the sequencing results revealed distinct patterns of misregulation of pathways in the absence of Ski over time. Moreover, ISMARA (Integrated System for Motif Activity Response Analysis) allowed us to identify the transcription factors that show divergent activity profiles in Ski Wt and Ski KO neural stem and committed progenitor cells at given time points.
Additionally, to evaluate the cell autonomous effects of Ski in progenitor cells, we are performing *in utero* electroporation experiments knocking-down or over expressing Ski at different stages of development.

Title: Mechanistic insights into regulation of the neuron-glia cell fate switch in the developing hippocampus by transcription factor Lhx2

Authors: *B. MURALIDHARAN[1], B. ROY[1], M. KERUZORE[2], D. PARLIER[2], U. MAHESHWARI[1], S. PRADHAN[3], K. KARMODIYA[3], L. D'SOUZA[1], S. GALANDE[3], E. BELLEFROID[2], S. TOLE[1];

Abstract: Regulation of the neuron-glia cell fate switch is a critical step in central nervous system development. Previously, we showed that LIM-HD transcription factor Lhx2 is a

necessary and sufficient regulator of this process in the developing hippocampus. Loss of Lhx2 causes premature astrogliogenesis, and overexpression of Lhx2 prolongs neurogenesis (Subramanian et al., 2011). The mechanism of Lhx2 action is unknown.
To identify genome-wide targets of Lhx2 at the onset of hippocampal neurogenesis, we performed ChIP-sequencing using E12.5 hippocampal primordia. We identified 6.4T as a potential Lhx2 target. Mimicking Lhx2 loss and gain of function, conditional mutants of 6.4T display enhanced GFAP in the hippocampus, and 6.4T overexpression promotes neurogenesis and suppresses astrogliogenesis. Significantly, this function of 6.4T is preserved in the absence of Lhx2, indicating that 6.4T acts downstream of Lhx2 and is sufficient to rescue Lhx2 loss of function.
The Lhx2 binding site lies within an enhancer in the 3'UTR of 6.4T in a highly conserved region across xenopus, chick, mouse, and human. A fragment of this enhancer including the Lhx2 binding site is sufficient to drive expression of a reporter transgene selectively in the hippocampus. Together, our data suggest that the Lhx2-6.4T pathway may be part of an evolutionarily conserved mechanism in the hippocampus that suppresses astrogliogenesis until neurogenesis is complete.

Title: Identifying gene regulatory networks during human neural induction

Authors: ***L. DUTAN POLIT**[1], G. COCKS[1], L. W. STANTON[2], S. HAVLICEK[2], S. SUBRAMANIAM[3], M. GERSTEN[4], J. PRICE[1], N. J. BUCKLEY[5];

Medicine, Nano engineering, [4]Dept. of Bioengineering, UCSD, California, CA; [5]Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: Neural induction is the earliest event in the formation of the human nervous system. Identifying the gene regulatory networks that govern this process is fundamental to our understanding of the establishment of neuronal phenotype and is also essential to our ability to manipulate human IPSCs to produce neural stem cells (NSCs) specified toward particular neuronal fates. Human iPSCs readily undergo neural induction in the presence of inhibitors of BMP signaling toward NSCs fated to an anterior forebrain fate. We have found that inclusion of inhibitors of canonical WNT signaling switches specification of the NSCs to an olfactory placodal fate, destined to produce GnRH-positive hypothalamic neurons. Transcriptome data was captured at multiple time points during 8 days of neural induction. We have used these data to identify gene expression signatures unique to NSCs specified to these alternate fates. We are currently modeling these data to produce gene regulatory networks and use them to infer pathways that drive specification of neural stem cells toward to anterior cortical or olfactory placodal fates.
Key words: Olfatory placode, GnRH neurons, anterior forebrain, gene regulatory network.

Title: Embryonic neurogenesis in the olfactory placode

Authors: *N. C. WHITTINGTON, S. WRAY;
NINDS, NIH, Bethesda, MD

Abstract: Recent evidence indicates that during embryonic development, neural crest and ectodermal cells contribute to the olfactory placode and give rise to olfactory sensory neurons, gonadotropin-releasing hormone (GnRH) cells, and olfactory ensheathing cells. However the mechanisms by which these initial neuronal fates are established and regulated in the olfactory placode have yet to be examined. The present work seeks to identify the gene regulatory network that governs embryonic olfactory neurogenesis. Sox proteins have been shown to play important regulatory roles in neurogenesis in the central nervous system and olfactory placode. Sox2 cooperates with cofactors to regulate stem cell renewal and differentiation during development,

and is a component of the molecular pathway utilized in nasal placode induction. Sox21, a Sox2 target and binding partner, has been implicated in regulating differentiation, and has recently been shown to control the progression of neuronal differentiation in the central nervous system based on its level of expression. Although these Sox proteins appear to have roles in controlling neuronal differentiation, their coordinated functions in the olfactory placode have not been explored. To determine whether Sox21 may have a role in regulating olfactory neurogenesis, the spatiotemporal expression of Sox21 is being analyzed in the developing mouse. RT-PCR and immunocytochemistry data confirmed Sox21 expression in the neurogenic regions of the nasal pits at E10.5-E11.5. At these ages, the olfactory placode consists of a multitude of cell populations, including neural stem cells, neuronal progenitors, neuronal precursors and neurons. To determine which cells express Sox21, sections were immunostained with markers identifying cells in these different stages of neurogenesis. Sox21 was expressed in progenitor and mitotic cells, and was absent in neuronal precursors, immature neurons, and GnRH cells. Thus, the expression pattern of Sox21 is consistent with it having a regulatory role in the developing olfactory placode. To understand the function of Sox21, its expression will be manipulated using in vivo and in vitro methods, and progression of neurogenesis in the olfactory placode followed. This work will delineate neurogenesis in the olfactory placode, and define the regulatory network involved in a cell's decision to stay as a progenitor cell or differentiate.

Title: RETROSPECT: A strategy to timestamp the transcriptome of neural progenitors to identify fate determining genes

Authors: *T. J. PETROS, J. DIMIDSCHSTEIN, G. FISHELL;
New York Univ., New York, NY

Abstract: A fundamental impediment to furthering our understanding of brain development is the ability to track changes in gene expression in specific neuronal populations over time. GABAergic interneurons provide an ideal and particularly relevant context for exploring methods to overcome these issues. Interneurons are an extremely heterogenous population of cells that arise from two transient structures in the ventral telencephalon, the medial and caudal ganglionic eminences (MGE & CGE), and migrate tangentially to occupy numerous forebrain structures. However, the genetic programs that regulate these fate decisions and maturation into distinct interneuronal subclasses remain largely unknown. The lack of early markers that distinguish different interneuron subgroups within the MGE and CGE, combined with the inability to relate gene expression in progenitor populations with the mature interneurons they give rise to, has greatly hindered progress in this area. The technique of DNA adenine methyltransferase identification (DamID) represents one extremely promising avenue to overcome these challenges. We aim to 'timestamp' the transcriptome of MGE interneuron progenitors as they undergo fate decisions embryonically while retaining the capacity to identify their interneuron subclass in the mature brain. The creation of a spatially and temporally inducible Dam protein fused to RNA polymerase will allow us to methylate actively transcribed genes within differentiating MGE progenitors for the retrospective identification of fate determination genes in mature interneuron populations. Of note, this strategy is applicable for transcriptomes in any cell type, particularly ones in which mature markers of specific cell types are not present during earlier developmental timepoints.

Title: A tracer system for lifelong neural stem cell fate with lentivirus.

Authors: *S. ISHIDA[1], A. TANAKA[1], T. FUCHIGAMI[1], Y. FUKAZAWA[2], S. HITOSHI[1];
[1]Shiga Univ. of Med. Sci., Otsu, Japan; [2]Univ. of Fukui, Yoshida-gun, Japan

Abstract: In mammalian brains, each neural stem cell (NSC) progeny divides several times as a neural progenitor, differentiates into a post-mitotic cell, and migrates into a specific region. It is controversial if cells derived from NSCs in the perinatal period migrate to a single or multiple region(s) and when cells become fated to migrate to specific sites. To answer these questions, we have focused on cell lineage of lifelong NSCs in the perinatal mice's brains, and established a system to trace the lifelong NSC lineage with lentivirus.
At embryonic day (E) 16 or postnatal day (P) 0, mice's brains were infected intraventricularly with lentivirus that expresses GFP and the mice were sacrificed at P30. Tissues were collected from cortex (Ctx), olfactory bulb (OB), and subependymal zone. Neurosphere assay was conducted with cells from the subependymal and GFP positive neurospheres were collected after passaging twice or more, which we regarded as cells generated from lifelong NSC. DNA was extracted from Ctx, OB, and the neurospheres. After a lentivirus integration site in genomic DNA of each neurosphere line was identified by an inverse PCR technique, PCR was done with DNA extracted from Ctx and OB as templates and primers corresponding to this lentivirus integration site. Then, electrophoretic pattern was analyzed to trace cell lineage from lifelong NSC. Our analysis with this system indicated that (1) major portion of NSC lines did not produce cells migrating to any of Ctx or OB, thus these cell lines were thought to be quiescent, (2) minor portion of the cell lines promoted cells migrating to exclusively wither of Ctx or OB, thus we did not identify a cell lineage migrating to two regions, and (3) among lifelong NSCs of the perinatal brain, symmetric and expansive division was rare.

Title: Phosphofructokinase-1 negatively regulates neurogenesis from neural atem cells

Authors: *D.-Y. ZHU, F.-Y. ZHANG, X.-D. QIAN, C. QIN, Y.-H. LIN, H.-Y. WU, L. CHANG, C.-X. LUO;
Nanjing Med. Univ., Nanjing, China

Abstract: Neural stem cells (NSCs), present in both the developing and adult nervous system, could be an ideal therapeutic tool for neurodegenerative disorders, if they differentiate into the optimal types and numbers of neurons. Phosphofructokinase-1 (PFK-1) is a rate-limiting enzyme in glycolysis by phosphorylating fructose-6-phosphate to form fructose-1, 6-bisphosphate, and has been implicated in the functions of astrocytes and neurons. Here, using loss- and gain-of-function approaches, we showed that PFK-1 negatively regulates neurogenesis by mediating the proliferation of neural progenitors and the neuronal fate commitment of NSCs. Using in vitro assays, we found that PFK-1 knockdown enhanced, and PFK-1 overexpression inhibited the neuronal differentiation of NSCs, which was consistent with the findings from NSCs subjected to 5 h of hypoxia. Meanwhile, the neurogenesis induced by PFK-1 knockdown was attributed to the increased proliferation of neural progenitors and the commitment of NSCs to the neuronal lineage. Similarly, in vivo knockdown of PFK-1 also increased neurogenesis in the dentate gyrus of the hippocampus. Finally, we demonstrated that the neurogenesis mediated by PFK-1 was likely achieved by targeting mammalian achaete-scute homologue-1 (Mash 1), neuronal differentiation factor (NeuroD), and sex-determining region Y (SRY)-related HMG box 2 (Sox2). All together, our results reveal PFK-1 as an important regulator of neurogenesis.

Title: Calcium dynamics in neural stem cells after chronic ethanol exposure and withdrawal

Authors: *A. H. MAHNKE[1,2], R. C. MIRANDA[1,2];
[1]Neurosci. and Exptl. Therapeut., [2]Women's Hlth. in Neurosci. Program, Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Ethanol is a known teratogen and *in utero* exposure can lead to a spectrum of neurodevelopmental disorders known collectively as Fetal Alcohol Spectrum Disorders. The end of the first trimester to the beginning of the second trimester is a particularly sensitive time to ethanol exposure, since during this time stem cells rapidly divide to produce most of the adult neurons. Previously, we showed that ethanol exposure during this period alters the programming of murine neural stem cells to favor premature maturation rather than renewal. Here, we further examined how ethanol exposure at sub-binge, binge, and chronic drinking levels (60mg/dL, 120mg/dL, and 320mg/dL) affects active cellular dynamics of gestational day 12.5 murine neural stem cells in neurosphere cultures. Cultures were chronically treated with ethanol for 5 days and then imaged, or allowed to withdraw from ethanol for two days before imaging. After treatment, cells were loaded with a calcium indicator dye, Fluo-4 AM, and imaged on a confocal microscope. Fluo-4 fluorescence allowed for the visualization of calcium dynamics in individual cells and showed that cells within an individual neurosphere are heterogeneous with respect to calcium dynamics. Some cells maintain steady calcium levels, while other cells exhibit dynamic calcium activity. Preliminary data suggest that these dynamics can be altered by both ethanol exposure and withdrawal. Notably, the mid-range, 120mg/dL dose was particularly effective at altering calcium dynamics in the neurosphere, increasing the number of cells exhibiting calcium oscillations as well as increasing overall frequency and amplitude of calcium spikes. After the withdrawal period, 120mg/dL treatment appears to have a lasting influence on calcium dynamics, with previously exposed cells showing an increased amplitude of calcium signal. These data firstly indicate the emergence of significant and surprising cell-to-cell variability in calcium activity among daughter fetal neural progenitors within a neurosphere niche that originate from a common stem cell. Moreover, these data also show that ethanol exposure continues to perturb cellular dynamics, even after ethanol is withdrawn, which may contribute to prolonged alterations to calcium-dependent intracellular signaling pathways that control neural stem cell growth and maturation.

Abstract: Melatonin, an endogenous neurohormone mainly secreted by pineal gland in the brain, has several biological functions including antioxidative and neuroprotective activity. Additionally, melatonin is able to enhance embryonic brain cells proliferation and differentiation. However, its potential effect on neuronal differentiation has never been investigated in amniotic fluid mesenchymal stem cells (AF-MSCs). In the present study, we isolated stem cells from amniotic fluid, characterized mesenchymal stem cell marker antigens and then examined the cytotoxic, proliferative and differentiative effects of melatonin in AF-MSCs. After cells expansion in culture medium for 6-8 passages, the melatonin-induced neuronal differentiation in AF-MSCs was investigated using alpha-MEM with or without melatonin. Melatonin at 0-1,000 nM were not caused cytotoxicity and not increased proliferation in the cells. Western blot analysis showed increase in neuronal protein (βIII-tubulin, TH, and Nurr1) expression with dose-dependent effect in melatonin-treated cells whereas GFAP expression was suppressed by melatonin. Flow cytometry analysis demonstrated that melatonin increased nerve cell adhesion molecule (NCAM) and TH expression and changed differential expression patterns of mesenchymal stem cell antigens (CD29, CD73, CD90, CD105, CD34 and CD45). These results suggest that melatonin is able to potentiate amniotic fluid stem cells differentiation into neuronal cells observing by increase in neuronal protein markers and decrease in surface marker antigens of mesenchymal stem cells.

Title: RNA-binding protein MARF1 regulates embryonic neurogenesis.

Authors: *Y. KANEMITSU[1], M. FUJITANI[2], Y. FUJITA[1], T. YAMASHITA[1];
[1]Mol. Neurosci., Grad. Sch. of Medicine, Osaka Univ., Suita-shi, Osaka, Japan; [2]Hyogo Col. of Med., Nishinomiya-shi, Hyogo, Japan

Abstract: Autism is a disorder of brain development characterized by impaired social interaction and communication. The latest child autopsy studies suggest the abnormality of neuronal fate specification during pregnancy. Microduplication in Chromosome 16p13.11 is one of known risk factors of autism. We hypothesize that one or several candidate genes in 16p.13.11 locus could be responsible for neurogenesis and pathophysiology of autism. After expression screening by *in situ* hybridization in mouse developing brain, we examined the function of RNA binding protein Meiosis Arrest Female 1 (MARF1). It has been already reported that oocyte form of MARF1 (oMARF1) suppresses the target molecules via its own RNase activity, and is indispensable for oogenic process. However, the function of another isoform, somatic form of MARF1 (sMARF1) is still obscure. Here we report the expression pattern and function of sMARF1 in developing mouse brain. sMARF1 protein is highly expressed in embryonic brain tissue and more in matured differentiated neurons than cortical pogenitors. The overexpression of sMARF1 in neuronal precursor cells which is derived from embryonic day-12.5 cortices, increases the number of Tuj1-positive differentiated neurons, while the knockdown of sMARF1 increases the number of Ki67-positive proliferating cell *in vitro*. The knockdown of sMARF1 *in vivo* by *in utero* electroporation increases the ratio of proliferating cell and Pax6-positive radial glia in subventricular zone. Moreover, we show that sMARF1 promotes neuronal differentiation in vitro via RNase activity domain. Thus, our findings suggest that sMARF1 regulates neuronal differentiation in developing brain through RNase activity.

Title: A complex of the ubiquitin ligase TRIM32 and the deubiquitinase USP7 balances the level of c-Myc ubiquitination and thereby determines neural stem cell fate specification

Authors: *S. NICKLAS[1], A.-L. HILLJE[1,2], S. OKAWA[3], I.-M. RUDOLPH[2], F. COLLMANN[2], A. DEL SOL[3], J. C. SCHWAMBORN[1,2];

Abstract: Stem cells are able to self-renew and to undergo differentiation. The balance between stem cell maintenance and differentiation has been proposed to depend on antagonizing ubiquitination and deubiquitination reactions of key stem cell transcription factors. Based on this hypothesis, the stability of such stem cell transcription factors is controlled by one or more pairs of E3 ubiquitin ligases and deubiquitinating enzymes. Accordingly, increased ubiquitination of the stem cell transcription factor results in its proteasomal degradation, thereby inducing cellular differentiation, whereas increased deubiquitination stabilizes the stem cell transcription factor leading to maintenance of the stem cell fate. In neural stem cells, one of the key stem cell transcription factors is c-Myc. Previously, we have shown that c-Myc is ubiquitinated by the E3 ligase TRIM32 during embryonic and adult neurogenesis, thereby targeting c-Myc for proteasomal degradation and inducing neuronal differentiation. Consistent with its role in inducing neuronal differentiation, we have shown that TRIM32 becomes upregulated during adult neurogenesis, as neural stem cells progress towards a more differentiated fate. This upregulation is accompanied by a subcellular translocation of TRIM32 from the cytoplasm of neuroblasts within the rostral migratory stream to the nucleus of olfactory bulb neurons. However, we observed that a subpopulation of proliferative type C cells in the subventricular zone already contain nuclear TRIM32. As these cells do not undergo neuronal differentiation, despite containing TRIM32 in the nucleus where it can ubiquitinate c-Myc, we hypothesize that antagonizing factors, specifically deubiquitinating enzymes, are present in these particular cells. Here, we show by using a mass spectrometry approach that TRIM32 associates with various deubiquitinating enzymes, including USP7. This particular deubiquitinating enzyme is of special interest, since it has been implicated in neural stem cell maintenance before. USP7 and TRIM32 were found to exhibit a dynamic and partially overlapping expression pattern during neuronal differentiation both *in vitro* and *in vivo*. Most importantly, we are able to demonstrate for the first time that USP7 deubiquitinates c-Myc, thereby antagonizing TRIM32 function. Thus, we provide a potential mechanism by which stem cell fate is determined in neural stem cells, namely through the balanced ubiquitination and deubiquitination of c-Myc by TRIM32 and USP7.

Title: Effects of ionizing radiation on neuronal stem cells during differentiation

Authors: K. RAU, B. ROTH, *B. LAUBE;
TU Darmstadt, Darmstadt, Germany

Abstract: In the developing and adult brain the exact cellular proliferation, migration, and differentiation mechanisms of neural stem cells (NSCs) are of prime importance. Ionizing radiation (IR) affects neurogenesis in the dentate gyrus of the hippocampus, which may explain learning deficits observed in patients treated with radiotherapy. NSCs are characterized by the ability of self-renewal and to differentiate to neurons, astrocytes and oligodendrocytes. Increasing evidence suggests that the activity of receptors and ion channels is intimately related to the control of proliferation and differentiation into defined cell types. Here, we have studied the physiology of early differentiation and network formation in neuronal cultures derived from the murine neural stem cell line J1 in a 2D differentiation protocol. Upon differentiation, the J1 cells show a loss in the stem cell marker nestin and a specific expression of certain differentiation markers and synaptic proteins like GFAP, MAP2 and PSD95, synaptophysin, respectively. Based on this differentiation protocol, we selectively irradiated (up to 0,5 Gy) individual differentiation stages and investigated the effects of IR on differentiation events like synaptogenesis, migration or neuronal functionality. Since potassium channels regulate cell behaviors such as proliferation and migration through both canonical ion permeation-dependent and noncanonical ion permeation-independent functions, we initially assessed the properties and composition of potassium channels expressed in different developmental stages upon radiation. By using whole-cell patch-clamp recording and immonohistochemistry, we measured the current responses of irradiated and unirradiated J1 NSCs in self renewal state and determined the potassium conductance of undifferentiated and differentiated J1 cells. We can show that IR increase the conductance of potassium channels, indicating that IR has lasting effects on the bioelectronical settings of NSCs. Thus, we can show that even low dose radiation of neural stem cells leads to significant variations in its electrophysiological homeostasis and the biophysical properties (like potassium conductance) of NSCs. In conclusion, NSCs could be successfully differentiated into functioning neural networks with differential developmental patterns upon radiation that may lead to subtle deficits in neuronal function.

Title: miRNA-pseudogene interactions as a regulator of neural stem cell pluripotency and a target for ethanol teratogenesis

Authors: ***N. SALEM**, S. BALARAMAN, R. HOLGATE, E. RAYMOND, R. C. MIRANDA; Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Fetal alcohol exposure is a leading non-genetic cause of neurodevelopmental disability. Neural stem cells (NSCs) that give rise to most neurons of the adult brain during the first and second trimester are particularly vulnerable. We previously found that ethanol exposure did not result in NSC death, but rather, the loss of NSCs due to premature maturation. Moreover, we found that a class of small non-protein-coding regulatory microRNAs (miRNAs) was decreased following ethanol exposure. We recently found that the loss of miRNAs result in expression of a network of genes that support premature NSC maturation. However, the question that remains is whether ethanol also specifically prevents NSC renewal by interfering with miRNA-regulated processes. To address this question, we assessed the regulation of the homeobox transcription factor, Oct4/POU5F1, which is important for maintaining stem cell renewal and pluripotency. The Oct4 family includes a number of transcribed non-protein-coding pseudogenes. We hypothesized that these pseudogenes serve as miRNA sponges. Immuno-precipitation studies with the miRNA binding protein, Ago-2, showed that one Oct4 pseudogene, Oct4PS9, bound miRNAs in both the nucleus and cytoplasm of NSCs, supporting its role as a miRNA sponge. RNA-capture analysis also showed that Oct4PS9 specifically associated with miRNAs. Our preliminary data shows that Oct4PS9 preferentially associates with miR-21, an ethanol-regulated miRNA which also localizes to both nucleus and cytoplasm of NSCs. These data suggest that Oct4PS9 may regulate miR-21 availability to the cytoplasmic RISC complex in addition to epigenetic pathways in the nucleus. Ethanol exposure resulted in an increase in expression of Oct4PS9 transcripts, but resulted in decreased expression of Oct4 protein. Pseudogene-miRNA interactions may protect pluripotency factors and consequently regulate

NSC renewal. These data advance a novel mechanism for ethanol teratology in that ethanol exposure may disrupt long non-coding RNA (lncRNA)-mediated regulatory mechanisms resulting in dysregulation of miRNA-function in fetal NSCs.

Title: Neural differentiation of cultured human neuroblasts is associated with transcriptomic poly(A) tail length modulation

Authors: *D. J. KILTSCHEWSKIJ[1,2], T. BEILHARZ[3], M. J. CAIRNS[1,2,4];
[1]Mol. Neurobio., The Univ. of Newcastle, Callaghan, Australia; [2]Priority Res. Ctr. for Brain and Mental Hlth. Res., Hunter Med. Res. Inst., New Lambton, Australia; [3]Dept. of Biochem. and Mol. Biol., Monash Univ., Melbourne, Australia; [4]Schizophrenia Res. Inst., Sydney, Australia

Abstract: Differentiation of complex cell types involves multiple layers of posttranscriptional regulation to establish the appropriate patterns and timing of intracellular protein synthesis. One important dimension of this system is modulation of mRNA 3′ poly(A) tail length as this *cis*-acting structure is critical for mRNA stability and translation. Cleavage of this tail reduces both transcript cytoplasmic stability and potential for translation, and is therefore thought to be an important intermediate in gene repression by microRNA (miRNA) and the RNA-induced silencing complex. In the current study, we sought to characterize genome-wide changes in mRNA poly(A) tail length in retinoic acid differentiated SH-SY5Y cells and explore its relationships to steady-state mRNA levels. SH-SY5Y cells were subject to a 14 day sequential *all-trans* retinoic acid and brain-derived neurotrophic factor treatment regimen to obtain near-pure cultures of neuron-like cells. Transcriptomic and poly(A) tail changes were investigated and compared via high-throughput deep sequencing using conventional RNA-Seq and a novel high-throughput library preparation for genome-wide analysis of mRNA poly(A) tail length, termed PAT-Seq. After genome alignment, read-count and poly(A) tail length attribution, we identified differentiation-associated change in poly(A) tail length in over 1,700 mRNAs whereby a strong bias towards lengthening was observed. In addition, a striking correlation between mRNA expression and poly(A) tail length ($R^2 = 0.3064$, $p < 0.0001$) was discovered, lending support to existing research suggesting increased poly(A) tail length confers mRNA stability.

Differentiation-associated changes in poly(A) tail length also exhibited significant enrichment in neurogenesis and cell cycle gene ontologies, which was also observed in 5,600 differentially expressed genes ($p < 0.05$). These analyses provide compelling support for the role of poly(A) tail length dynamics in the posttranscriptional regulation of mRNA during neural development. We suspect that factors involved in the modulation of mRNA stability and translation also have significant role in the pathogenesis of disease.

Title: CCP1 is a positive regulator of Notch signaling pathway in the regulation of neural stem cells

Authors: *J. KIM, D. HAN, S.-H. BYUN, M. KWON, K. YOON;
Sungkyunkwan Univ., SUWON-SI, Korea, Republic of

Abstract: In the developing central nervous system, it has been widely known that Notch signaling preserves progenitor pools, inhibits neurogenesis, and drives astrocyte differentiation. CCP1 is known as a chloride channel protein containing membrane spanning regions. *In situ* RNA analysis indicates that CCP1 is mainly transcribed in the ventricular and sub-ventricular zone (VZ and SVZ) in E14.5 embryonic mouse brain. In this study, we assessed the role of CCP1 in the mammalian brain development. We first found that Notch intracellular domain increased transcription of CCP1. Interestingly, CCP1 also synergistically increased transactivational ability of Notch. We used a retroviral vector system to investigate the effects of CCP1 expression on the properties of neural stem cells *in vivo* as well as *in vitro*. CCP1 induced efficient neurosphere formation, a high level of neural stem cell proliferation, and localization of neural progenitor population in the VZ and SVZ of developing mouse brain. Taken together, our data indicate that CCP1 is a novel Notch target gene and also a regulator in the canonical Notch signaling pathway.

Abstract: Objective: Cell-cell communication among neural progenitor cells (NPCs) is essential for proper self-organization of the nervous system, a topic of great interest in regenerative medicine. Graph theory and network analysis have been used to study the functional connectivity of mature neuronal circuits but not developing networks. In developing networks, different modes of cell-cell communication dominate than in mature neuronal networks, and proximity of cell bodies plays a key role in neural cell fate. The objective of this study is to quantitatively describe the spatial organization of progenitor cell bodies at different stages of neuronal differentiation in order to uncover the role of cell-cell communication during neural network formation.
Methods: hESC-derived neural progenitor cells were stimulated to differentiate through withdrawal of bFGF from culture medium and imaged continuously for up to 14 days. Time-lapse image sequences were processed using custom-written algorithms, and spatial proximity of cell bodies was used to create graph representations of NPC spatial topology. 16 graph-based metrics describing features such as connectivity, information flow and motif counts were evaluated in NPC graphs in order to quantify the spatial organization of cells at different time points. Functional maturation of NPCs was analyzed using whole-cell patch clamp electrophysiology and immunochemistry.
Results: Statistical measures of information flow in NPC spatial graphs revealed a shift from topologies with high global efficiency to high local efficiency, around the time mature neuronal phenotypes appeared in culture. Trends in information flow are intuitively explained by corresponding trends in graph connectivity. Our results support the view that network-wide signaling in immature progenitor cells gives way to more structured, hierarchical communication in mature neural networks. We also demonstrate that the evaluation of recurring motif patterns in NPC graphs reveals unique geometric arrangements of cells in neural rosette-like structures at early stages of differentiation.
Conclusions: Our method introduces a tangible means to test theories about spatially-dependent

forms of neural cell communication. Our results point to spatial re-organization of progenitor cells during electrical maturation, insights which help further our understanding of the design principles involved in the development of functional neural networks. Applications of this work can help pave the way for systematic modulation of neural cell self-organization for therapeutic purposes, eg. in treating repercussions of brain injury or stroke.

Title: Purinergic signalling in a latent stem cell niche of the rat spinal cord

Authors: ***N. MARICHAL**, G. FABBIANI, O. TRUJILLO-CENOZ, R. E. RUSSO, 11600; Neurofisiología Celular y Mol., Inst. De Investigaciones Biológicas Clemente E, Montevideo, Uruguay

Abstract: The ependyma of the spinal cord harbours stem cells which are activated by traumatic spinal cord injury. Progenitor-like cells in the central canal (CC) are organized in spatial domains with cells on the lateral aspects combining characteristics of ependymocytes and radial glia (RG), whereas in the dorsal and ventral poles they have the morphological phenotype of RG and display complex electrophysiological phenotypes. The mechanisms regulating the behaviour of these progenitors remain unknown. Because ATP is massively released after spinal cord injury we hypothesized that purinergic signalling may be important in this spinal stem cell niche.We combined immunohistochemistry, in vitro patch-clamp whole-cell recordings and Ca^{2+} imaging to explore the effects of purinergic agonists on ependymal progenitor-like cells in the neonatal (P1-P6) rat spinal cord. Prolonged focal application of a high concentration of ATP (1 mM) induced a slow inward current. Equimolar concentrations of BzATP generated larger currents that reversed close to 0 mV, had a linear current-voltage relationship and were blocked by brilliant blue G, suggesting the presence of functional P2X7 receptors. Immunohistochemistry showed that P2X7 receptors were expressed around the CC and the processes of RG. BzATP

also generated Ca^{2+} waves in RG that were triggered by Ca^{2+} influx and propagated via Ca^{2+} release from internal stores through activation of ryanodine receptors. Taken together, we showed that progenitor-like cells in the ependyma of the rat spinal cord have functional ionotropic P2X7 receptors. We speculate that the intracellular Ca^{2+} signalling triggered by P2X7 receptor activation may be an epigenetic mechanism to modulate the behaviour of progenitors in response to ATP released after injury.

Title: Regulation of neural stem cell division modes in the developing zebrafish brain

Authors: ***X. ZHAO**[1,2], R. CHOI[2], S. GUO[2];
[1]Neurosci. Center, U.Helsinki, Helsinki, Finland; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Asymmetric cell division (ACD) is a conserved and fundamental process in neurogenesis for generating cellular diversity across both invertebrates and vertebrates. As the principal neural stem cells (NSCs), radial glia progenitors (RGP) undergo ACD to generate self-renewing and differentiating daughter cells in the developing central nervous system. Until now, the cellular and molecular mechanisms of ACD and subsequent daughter fate choice is not well understood in vertebrates. By using zebrafish, we have identified that the cortical polarity regulator Partitioning defective protein-3 (Par-3) plays a crucial role in the establishment of ACD through localizing the ubiquitin E3 ligase Mindbomb (Mib), which activates Notch by ubiquitinating the Notch ligand unequally in the apical daughter. Using immunocytochemistry, in vivo imaging, and other molecular genetic and biochemical methods, we are elucidating the nature of Mib asymmetry and the underlying mechanisms that orchestrate such asymmetry.

Title: *Drosophila* type II neuroblasts undergo temporal patterning

Authors: *B. MARK, M. H. SYED, C. DOE;
Biol., Univ. of Oregon, Eugene, OR

Abstract: The steroid hormone Ecdysone regulates *Drosophila* Type II Neuroblast temporal patterning.
How a small population of stem cells can give rise to neuronal diversity remains a fundamental question in developmental neuroscience. One mechanism by which stem cells have been shown to expand neural diversity is via temporal patterning programs. Stem cells change their expression of various transcription factors over time, conveying a unique transcriptional profile to progeny born in each window. Traditionally, these temporal patterning programs have been shown to be primarily cell intrinsic. Here we show that the insect steroid hormone ecdysone serves as an extrinsic cue that governs the temporal patterning program of *Drosophila* type II neuroblasts, a central brain stem cell with a transit amplifying division pattern similar to that of vertebrate outer subventricular zone progenitors. Ecdysone acts via its receptor EcR, a nuclear receptor which regulates transcription of a host of developmentally relevant genes. The ecdysone receptor EcR-B1 isoform is temporally expressed in type II neuroblasts beginning at early L3 larval stages and persists for the remainder of larval life. Ecdysone and its receptor EcR-B1 act together in order to induce the transition between two identity factors Chinmo and Broad-Complex, as well as inducing the expression of other transcription factors including E93, offering both a novel mechanism by which neuroblasts regulate temporal patterning, as well as a novel mechanism by which steroid hormones regulate development.

Title: Bag3 is involved in neuronal differentiation

Authors: *S. L. NORI[1], V. NICOLIN[3], F. FLORENZANO[4], A. SANTORO[2];
[2]Dept of Medicine, Surgery and Dentistry, Scuola Medica Salernitana, [1]UNIVERSITY OF SALERNO, Baronissi, Italy; [3]Clin. Dept. of Medical, Surgical and Hlth. Sci., Univ. of Trieste, Trieste, Italy; [4]Confocal microscopy unit, Natl. Res. Council, European Brain Res. Inst., Rome, Italy

Abstract: BAG3 belongs to the family of co-chaperones interacting with the heat shock protein HSP70 through the structural domain known as BAG domain. BAG3 mediates the retrograde transport of both misfolded proteins to the microtubule organizer center (MTOC) and autophagic vacuoles to perinuclear region, facilitating the clearance of aggregated-prone proteins in several cell types. Some studies reported a BAG3 transient expression in rat cerebral cortex and hippocampus and a persistent expression in the rostral migratory stream and subventricular zone of the lateral ventricle. However, few data are reported on subcellular localization of BAG3 in neurons. From this point of view, we recently detected a molecular weight variant of BAG3 (40 kDA) in synaptosomes and evidenced that BAG3 mRNA is present in synaptosomal polysomes of rat brain. The objective of the present study was to provide further insights on the expression and subcellular distribution of BAG3 in neurons. We studied BAG3 expression in NGF-induced neurite outgrowth in PC12 cells, by using confocal and transmission electron (TE) microscopy and then performing morphometric analysis. Results showed that after NGF-induced neurite outgrowth, BAG3 localized mainly in the neuritic domain compared to cell body, while in control cells it appeared confined to the cytoplasm near the nuclear membrane. Interestingly this phenomenon was associated only to a slight increase in the total BAG3 immunofluorescence suggesting a change in its distribution rather than an increase in protein expression during neuronal differentiation. This observation was corroborated by TE microscopy analysis of NGF-treated PC12 cells showing that BAG3 was confined mainly in synaptic vesicles of the axon. Moreover, we also investigated BAG3 expression in the developing (E18) and adult cerebral cortex. Preliminary results indicate that BAG3 was intensely expressed in cellular processes and some migrating cells in the developing cortex, while in the adult cortex, only a low immunoreactivity was found in the majority of neuronal cell bodies and glial cells. Altogether

these data suggest that BAG3 could be involved in neuronal differentiation acting during the whole process.

Title: Promoting neuronal differentiation and neurite guidance of human neural progenitors using electrospun PCL fibrous scaffolds

Authors: ***M. C. ZALIS**[1], S. JOHANSSON[1], F. JOHANSSON[2], U. E. JOHANSSON[3]; [2]Dept. Biology, Unit of Functional Zoology, Bio-interface Group, [3]Inst. Clin. Sci. in Lund, Dept. Ophthalmology, [1]Lund Univ., Lund, Sweden

Abstract: Transplanted neural cells show great potential to replace neurons in damage or disease where neurons are lost. However, limited long-term survival and functional outcome are yet major hurdles to overcome. Therefore, we hypothesized that the use of supporting artificial scaffolds may increase survival, neuronal differentiation and, neurite extension and guidance of neural progenitors. Here we initially studied the potential use of electrospun fibrous scaffolds for supporting the culture of human neural progenitors in vitro.
We fabricated biodegradable polycaprolactone (PCL) fibrous substrates, consisting of either randomly- and aligned oriented sub-micron fibers (fiber diameter: 550-700 nm). Human neural progenitor cells (HNPC), mitogen-expanded multipotent cell line, were cultured for 10 days on nanofibers and 2D (flat) glass surfaces. Survival, neurogenic potential, neurite extension and nuclei orientation, were studied using alamar blue assay, immunohistochemistry, and compared

to flat controls. Fluorescent- and scanning electron microscopy were used.
Excellent survival of HNPCs was found at both nanofiber scaffolds, closely comparable to flat surfaces controls. Morphological formation was strongly influenced by culture substrates, with significantly more multipolar morphologies found at random fibers and flat controls. At aligned fibers, a trend toward nuclei orientation in parallel with fiber orientation, more bipolar morphologies and longer neurites extended along the fibers were found. Significant increase in neuronal differentiation (MAP-2-positive cells) was found on nanofibers scaffolds compared to flat surfaces. In parallel, lower numbers of cells expressing markers of immature/glial cells, i.e. nestin-, S100b- and GFAP were found at both fibrous substrates.
In summary, PCL nanofiber scaffolds indicate biocompatibility, promote neuronal maturation of the HNPCs and influence neuronal morphological formation. The fact that neurons extended long neurites, a requirement for successful neuronal cell transplantation, and which can be guided by fiber orientation support the proposal of using scaffolds that can be tailor-made for advancing cell transplantation as a therapy.

Title: Effect of histamine H_1 receptor inhibition in rat embryo cortical and mesencephalic neuroepithelia: in the search for its functional role during fetal neurogenesis *In vivo*

Authors: *B. M. VALADEZ[1], N. F. DÍAZ[2], J. A. G. ARIAS MONTAÑO[3], A. MOLINA HERNÁNDEZ[2];
[1]Physiology, Biophysic and Neurosciences, Ctr. For Res. and Advanced Studies of the IP, Ciudad DE Mexico, Mexico; [2]Natl. Inst. of Perinatology, Ciudad de Mexico, Mexico; [3]Physiology, Biophysic and Neurosciences, Ctr. For Res. and Advanced Studies of the IPN, Ciudad DE Mexico, Mexico

Abstract: Histamine H_1 receptors (H_1Rs) are expressed in the rat neural tube from embryo day 14 (E14) to E20. Histamine reaches its highest level during the neurogenic peak (E14), and *in vivo* and *in vitro* experiments indicate its participation in neuronal differentiation through H_1R

activation. Histamine exerts differential affects on cerebral cortex and ventral mesencephalic neuroepithelia neural stem cells, promoting phenotype differentiation in cortex deep layers whereas in ventral mesencephalon reduces the tyrosine hydroxylase (TH) phenotype *in vitro* without affecting total immature neurons. In this study E12 and E14 rat embryos were used to study H_1R expression by RT-PCR, its membranal location by radioligand binding and its tissue distribution by immunocytochemistry. Because histamine has been proposed to participate in neuron commitment of neural stem cells, the main cell population at E12, the H_1R antagonist clorpheniramine was intraperitoneally injected at E12 and the deep layer cortical (FOXP2, Tbr1 and SOX5) and ventral mesencephalic (TH, lmx1b and PITX3) phenotypes were evaluated at E14 and E16 by immunohistochemistry. Our results show H_1R expression in both neuroepithelia at E12 and E14, its presence in total forebrain/midbrain membranes with a higher density at E12 and its location in the ventricular zone. H_1R inhibition negatively affects the cortical and mesencephalic markers at E14 and E16. These results indicate that the H_1R is expressed by neural stem cells in the cortical and ventral mesencephalic neuroepithelia with a likely membranal location, and that receptor blockade alters cortical and mesencephalic development, suggesting an important role of histamine and H_1Rs during brain development.

Title: The effect of decreased miR-31 expression on spinal cord stem cell transcriptomes

Authors: C.-F. WANG[1,3], P.-F. LI[2,3], F. TIAN[1,3], *R.-X. ZHANG[4];
[1]Lab. Animal Res. Ctr., [2]Exptl. Ctr., Shanxi Med. Univ., Taiyuan, China; [3]Shanxi Key Lab. of Animal and Animal Model of Human Dis., Taiyuan, China; [4]Ctr. Integrative Med., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Spinal cord injury (SCI) often results in severe and permanent neurological deficits. Recent studies have shown that neural stem cell (NSC) replacement is effective in treating SCI.

However, one obstacle of this strategy is the low efficiency of NSC differentiation. Our previous study showed that the expression of miR-31 is significantly higher in spinal cord stem cells (SCSCs) isolated from embryonic day 14 (E14) spinal cord ependymal layer compared to motor neurons (MNs), indicating that miR-31 may play an important role in maintaining SCSCs in an undifferentiated state. In the present study, we characterize the RNA transcript profiles (transcriptomes) of SCSCs from E14 mice treated with small interfering RNA (siRNA) to lower the expression of miR-31. Total RNA was extracted from siRNA treated and non-siRNA treated E14 SCSCs (control) using TRIzol Reagent, and then sequenced on an Illumina HiSeq2500. Gene expression was analyzed with Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG). We found that 1295 genes were significantly differentially expressed. Among those genes, 549 were up-regulated and 746 genes were down-regulated in the SCSCs transfected with siRNA compared to control SCSCs. The further bioinformatics analysis using the GO classification shows that the molecular function of the differentially expressed genes mainly corresponds to channel regulator activity, receptor regulator, and chemoattractant activity, and the affected biological processes mainly are locomotion, biological adhesion, biological phase, hormone secretion and cell aggregation. The KEGG enrichment analysis showed that the pathways of differentially expressed genes mainly participate in focal adhesion, MAPK signaling, cytokine-cytokine receptor interaction, and neuroactive ligand-receptor interaction. Theses pathways are more related to neurons than stem cells. Our results demonstrate that down-regulation of the miR-31 expression can induce the differentiation of SCSCs, and that miR-31 plays an important role in the differentiation of SCSCs.

Title: Ets factors regulate gliogenesis in perinatal development and glioma

Authors: ***H. PARK**[1,2], R. LEVY[2], M. DUTRA-CLARKE[2], A. A. AKHTAR[2], G. B. KIM[2], M. DANIELPOUR[2], J. J. BREUNIG[2];
[1]Regenerative Med. Inst., [2]Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: We have previously demonstrated that disruption of the Nf1-Ras pathway in the VZ compartment at multiple signaling nodes uniformly results in rapid NSC depletion, progenitor hyperproliferation, and gliogenic lineage restriction. Abrogation of Ets subfamily activity, which

is upregulated downstream of Ras, rescues these phenotypes and blocks glioma initiation. Thus, the Nf1-Ras-Ets axis might be one of the select molecular pathways that is a hijacked for initiation and maintenance in glioma. Herein, we examine the cell autonomous role of Ets proteins during perinatal development. Expression analysis and inducible lineage tracing indicates that Etv5 is enriched in glial subtypes. Using a novel genetic technology to independently misexpress several Etv5 variants (i.e. full-length, truncated, constitutively active) or loss-of-function elements (e.g. miR-E shRNA against Etv5), we observe phenotypes consistent with a putative role for Etv5 in cell fate determination of glia. Moreover, we present findings that the ability of Etv5 to block gliomagenesis can be generalized to other driver mutations. Thus, Ets proteins represent a key mechanism of glial cell fate determination in gliogenesis and glioma.

Title: Altering proteoglycans leads to unexpected changes in neural cells

Authors: ***C. MENCIO**, S. TILVE, C. AGBAEGBU, H. KATAGIRI, H. GELLER; NHLBI, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Proteoglycans (PGs) are important to a variety of neurological functions. From neural development to memory to regeneration and disease, both heparan sulfate (HS) and chondroitin sulfate proteoglycans (CSPGs) play a number of promoting and inhibitory roles. While research is clear that these macromolecules are involved, their actual role of action remains relatively unclear. This is in part due to the lack of tools with which to study them and our incomplete understanding of the tools that are currently available. One class of these such tools are xylosides. Xylosides are small molecules consisting of an aglycone attached to a xylose residue which serve as a competitor for glycosaminoglycan (GAG) chain biosynthetic machinery. Used in research since the 1970s, treatment with these molecules leads to the inhibition of endogenous PGs and the production of primed GAGs, or GAG chains built on the xyloside and as such lack a core protein. Primed GAGs are pushed out of the cell and can be found in the extracellular space.

Much of the previous research has focused on high concentration treatment (≥ 1mM) by xyloside and largely bypassed any role primed GAGs may play in experimental outcomes. We have found that low concentration (≤ 1μM) xyloside (LCX) treatment will also alter the GAG profile of and PG production by astrocytes, neuro2A cells, and primary neurons. Reduction in CSPGs was seen in LCX samples at 72h after treatment, much later than observed in samples treated with higher concentrations of xyloside which showed significant reduction at 24 and 48h. Additionally, LCX treatment caused unexpected changes in cell behavior and morphology. LCX-treated neuronal cells demonstrate enlarged growth cones with microtubule looping that were absent in cells that were exposed to both vehicle and 1mM xyloside treatment. This research serves as a first step to fully explore the potential of xylosides as a research tool and possible therapeutic for injury and disorders of the nervous system.

Abstract: During the development of the mammalian cerebral cortex radial glia cells (RGCs) produce different layer-specific subtypes of excitatory pyramidal neurons. At the population level, these cells are generated in an inside-out pattern that is highly correlated with their birthdate. Classical models of cortical development propose that this phenomenon is due to the progressive restriction of RGCs to generate progressively more superficial layer neurons over the time, and experiments both in vitro and in vivo are consistent with this idea. However, recent studies have also suggested the existence of pools of RGCs in the rodent cortex with restricted potential to generate specific classes of pyramidal cells. In this study, we combine retroviral

lineage tracing and Mosaic Analysis with Double Markers (MADM) techniques with Cre/LoxP mouse genetics to trace the progenies of individual RGCs in the mouse developing cerebral cortex. By unbiasedly analysing the outcome of dozens of clones, we have obtained information about the relative contribution of different classes of RGCs to cortical development. Our results indicate that the most abundant progenitor cells in the rodent cortex have the potential to generate pyramidal cells for all cortical layers, but the diversity of RGCs or their potential is larger than previously recognised. This diversity of neural progenitors may play a prominent role in orchestrating the complex laminar organisation of the mammalian cerebral cortex.

Title: Whole genome single cell sequencing confirms the presence of mosaic aneuploidy throughout cortical development

Authors: *S. E. ROHRBACK[1], J. CHUN[2];
[1]Biomed. Sci., Univ. of California San Diego, La Jolla, CA; [2]Mol. and Cell. Neurosci., The Scripps Res. Inst., San Diego, CA

Abstract: Contrary to popular belief, not every cell in the body contains identical DNA. This phenomenon of genomic mosaicism was first identified as a driving force behind cancer, but has more recently been found to be enriched in the brain. In particular, aneuploidy has been shown to be enriched in cerebral cortical cells, most dramatically in neural progenitor cells (NPCs) during embryonic development. Despite being confirmed by several independent groups using cytogenetic methodologies, there is controversy regarding the rates and persistence of aneuploidy in the brain. To assess this discrepancy, we used a customized single cell sequencing and bioinformatics approach to obtain an unbiased, genome-wide assessment of the copy number states in a variety of sample preparations. Three novel insights have been gained from our work. First, during the development of our custom bioinformatic pipeline, we found that several

commonly used quality control measurements are biased towards excluding hypoploid cells from analysis**.** Eliminating their use increased the accuracy of aneuploidy rate assessments in control populations**.** Second, we developed a strategy to sequence the individual mouse metaphase spreads, which are the gold standard for determining cellular ploidy. This approach confirmed that single cell sequencing accurately identifies the occurrence of mosaic aneuploidy. Finally, we applied our single cell sequencing method on over 400 interphase nuclei collected throughout cortical development, and have confirmed that aneuploidy is both present in interphase NPCs and can persist in adult neurons. This pipeline is being utilized to gain further insights into neuronal aneuploidies during and beyond cortical development.

Title: Mechanisms that balance neuronal subtype production in the developing neocortex

Authors: *K.-I. TOMA, C. HANASHIMA;
RIKEN Ctr. For Developmental Biol., Kobe, Hyogo, Japan

Abstract: The cerebral cortex consists of diverse layer neurons that differ in their connectivity, morphology and molecular properties. These neurons are generated in a stereotypical temporal order during development, where neurons of deep-layer (DL) are generated first, followed by more superficial upper-layer (UL) neurons. While DL neurons establish long-range connections by sending axons to subcortical targets, UL neurons play central roles in higher order information processing by integrating bilateral cortical information. Despite their functional significance, the mechanisms by which laminar subtypes are generated at the correct timing and in appropriate numbers remain largely elusive.
Here, we employed a non-biased genetic ablation to eliminate early post-mitotic DL neurons in developing mouse neocortex. By using this method, we found that cortical progenitors produce DL neurons for a longer period to compensate for the loss of DL neurons, thereby maintaining the final ratio between DL and UL neurons. These results demonstrated that the mechanisms that adjust the number of DL and UL neurons required for proper circuit formation utilizes feedback signals propagated from DL neurons. We further explored the identity of this feedback signal

focusing on the molecular events that occurs during the switch in progenitor competence from DL neurons to UL neurons. Our results indicate that this feedback signaling controls the localization of UL neuron-specific transcription factors and determine the timing of neuronal differentiation. This feedback regulatory system confers the sequence of DL and UL neurogenesis, and scales the production of UL projection neurons based on the availability of their DL neuron counterparts during development and possibly evolution.

Title: Dmrt genes control the development of Cajal-Retzius cells derived from specific origins in the cerebral cortex

Authors: *T. KIKKAWA[1], N. SAKAYORI[2], H. YUUKI[1], N. OSUMI[1];
[1]Dept. of Developmental Neurosci., Tohoku Univ. Sch. of Med., Sendai, Miyagi, Japan; [2]Dept. of Mol. Genet., Inst. of Biomed. Sci., Fukushima, Japan

Abstract: For the development of the central nervous system, a large variety of neuronal cell types are needed to be generated at defined times and locations. Cajal-Retzius (CR) cells are the first neurons generated during corticogenesis and are essential pioneer neurons that control neuronal migration in the cortex. CR cells are derived from specific regions within the cortex, i.e., the pallial septum (PS) in the rostromedial cortex, and the pallial-subpallial boundary (PSB) and cortical hem (CH) in the caudomedial cortex. However, the molecular mechanism underlying the generation of CR cell subtypes in distinct CR cell origins is poorly understood. We have previously shown that *Dmrta1* (*double-sex* and *mab-3* related transcription factor like family A1) is expressed in neural stem/progenitor cells in the neocortex and regulates proneural genes (Kikkawa et al., 2013). In this study, we found that Dmrta1 was expressed in the PS, PSB, and a part of the CH, whereas Dmrt3 was strongly expressed in the CH. To reveal functions of *Dmrta1* and *Dmrt3* in the production of CR cells from distinct origins, we observed CR cells in

Dmrta1 knockout (*Dmrta1*$^{-/-}$) (Kikkawa et al., unpublished) and *Dmrt3* knockout (*Dmrt3*$^{-/-}$) mice (Konno et al., 2012). We found that *Dmrt3* ablation decreased the number of p73-positive CR cells derived from the PS and CH compared with wild type (WT) mice, suggesting an abnormal medial-cortical structure of *Dmrt3*$^{-/-}$ and *Dmrta1*$^{-/-}$ *Dmrt3*$^{-/-}$ mice. On the other hand, *Dmrta1*$^{-/-}$ mice shows the reduction of p73-positive CR cells derived from the PS. There was no significance difference of the number of Calretinin-positive/p73-negative CR cells derived from the PSB. These results suggest that Dmrt members are differentially involved in the development of CR cells according to their original cortical regions.

Title: Temporal dynamics of laminar subtype neuron differentiation in developing mouse neocortex

Authors: *P. HOU, C. NISHIYAMA, C. HANASHIMA;
RIKEN Ctr. For Developmental Biol., Kobe-Shi, Japan

Abstract: The cerebral cortex holds a remarkable capacity to integrate multimodal sensory information and generate coordinated outputs that underlies higher cognitive functions. While the localization of neocortical areas responsible for modality-specific information processing has been mapped over a century ago, how each area is assembled to serve its unique function has remained largely elusive. To address this, we established a highly reproducible tracing system to label cohorts of neurons generated at distinct developmental timing utilizing the *Neurog2*-driven Cre recombinase. Upon tamoxifen administration, we specifically marked layer subtype neurons using various fluorescent reporter lines in vitro and in vivo. Based on this approach, we monitored the dynamics of neurons generated at different corticogenesis period. We further applied this system in culture to assess the capacity of neuronal differentiation of these cortical cells in vitro. These results indicated that laminar subtype identity are determined soon after the

cell cycle exit, providing a useful platform to assess the mechanisms underlying neuronal specification in cortical establishment.

Title: Challenging interneurons in novel environments reveals roles for both intrinsic and environmental mechanisms that sculpt their maturation

Authors: *G. QUATTROCOLO, G. J. FISHELL, T. J. PETROS;
Neurosci., NYU, New York, NY

Abstract: The majority of interneurons derive from two different embryonic structures: the Medial Ganglionic Eminence (MGE) and the Caudal Ganglionic Eminence (CGE). Distinct subtypes of interneurons originate from each structure, with Parvalbumin- and Somatostatin-expressing interneurons deriving from the MGE, and Reelin- and VIP-positive interneurons deriving from the CGE. Postmitotic interneurons are partially fate determined, and they go on to populate numerous regions within the telencephalon. Recent clonal analysis (Mayer et al., 2015; Harwell et al., 2015) has showed that the same progenitor cell in the MGE can give rise to interneurons located in different structures, such as the cortex, hippocampus or striatum. In addition, it was shown that both Parvalbumin- and Somatostatin-expressing interneurons can derive from the same progenitors. These data seems to exclude the presence of different progenitors pools giving rise to cortical versus hippocampal interneurons. However, little is known regarding the mechanisms guiding the interneurons maturation and their integration in distinct neuronal networks. Which aspects are intrinsically encoded and which ones are dependent on environmental cues? To address this question we isolated the cortex and the hippocampus of Nkx2.1-Cre;Ai9 mice at P0-P2, sorted the fluorescent cells and transplanted them either homotopically (cortex-to-cortex) or heterotopically (cortex-to-hippocampus, cortex-to-striatum) to P0-P2 wild type mice. A month after transplantation we analyzed the molecular,

electrophysiological and morphological profile of the transplanted interneurons. The data suggest that: 1) the heterotopic environment can sculpt the maturation of the transplanted interneurons as they integrate in the network, and 2) different interneuronal features are inherited from the donor environment. Our findings shed light on the mechanisms regulating the interneuron development and neuronal circuit formations.

Title: Ctip1 controls area-specific subtype ratios and subsequent differentiation in sensory cortex

Authors: *L. F. CUSTO GREIG[1], M. B. WOODWORTH[2], J. D. MACKLIS[2];
[1]Harvard Dept. of Stem Cell and Regenerative Biol., Cambridge, MA; [2]SCRB, Harvard Univ., Cambridge, MA

Abstract: The molecular linkage between neocortical projection neuron subtype and area development, which enables the establishment of functional areas by projection neuron populations appropriate for specific sensory and motor functions, is poorly understood. Here, we report that Ctip1 controls precision of neocortical development by regulating both subtype identity and area identity in neocortical projection neurons. Ctip1 is expressed by postmitotic callosal and corticothalamic projection neurons, but is excluded over embryonic development from corticospinal motor neurons, which instead express its close relative, Ctip2. Loss of Ctip1 function results in a striking bias in favor of subcerebral projection neuron development in sensory cortex at the expense of corticothalamic and deep-layer callosal development, while misexpression of Ctip1 in vivo represses subcerebral gene expression and projections.In parallel,

Ctip1 functions in primary sensory areas to repress motor and activate sensory gene expression programs, enabling establishment of sharp molecular boundaries defining functional areas. In Ctip1 mutants, abnormal gene expression leads to aberrantly motorized corticocortical and corticofugal output connectivity. Ctip1 critically regulates differentiation of layer IV neurons, and selective loss of Ctip1 in cortex deprives thalamocortical axons of their receptive "sensory field" in layer IV, which normally provides a tangentially and radially defined compartment of dedicated synaptic territory. Therefore, although thalamocortical axons invade appropriate cortical regions, they are unable to organize into properly configured sensory maps.Together, these data identify Ctip1 as a critical control that couples subtype and area specification, enabling specific functional areas to organize precise ratios of appropriate output projections.

Title: Clonally related forebrain interneurons disperse broadly across both functional areas and structural boundaries

Authors: *C. MAYER[1,2], X. J. JAGLIN[2], R. C. BANDLER[2], C. STREICHER[3], C. L. CEPKO[4], S. HIPPENMEYER[3], G. FISHELL[2];

Abstract: The medial ganglionic eminence (MGE) gives rise to the majority of mouse forebrain interneurons. Here, we examine the lineage relationship among MGE derived interneurons using a replication-defective retroviral library containing a highly diverse set of DNA barcodes. Recovering the barcodes from the mature progeny of infected progenitor cells enabled us to

unambiguously determine their respective lineal relationship. We found that clonal dispersion occurs across large areas of the brain and is not restricted by anatomical divisions. As such, sibling interneurons can populate the cortex, hippocampus striatum, and globus pallidus. The majority of interneurons appeared to be generated from asymmetric divisions of MGE progenitor cells, followed by symmetric divisions within the subventricular zone. Altogether, our findings uncover that lineage relationships do not appear to determine interneuron allocation to particular regions. As such, it is likely that clonally related interneurons have considerable flexibility as to the particular forebrain circuits to which they can contribute.

Title: Projection neuron class specification occurs post-mitotically in the subplate during human corticogenesis.

Authors: ***M. Z. OZAIR**[1], C. KIRST[2], B. VAN DER BERG[4], A. H. BRIVANLOU[3];
[1]Brivanlou lab, Rockefeller Univ., New York, NY; [2]Ctr. for Studies in Physics and Biol., [3]Brivanlou lab, The Rockefeller Univ., New York, NY; [4]Fac. of Sci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The six-layered neocortex is unique to the mammalian lineage and has undergone significant expansion in primates. Classic studies of mouse and primate corticogenesis have established the inside-out nature of layer formation during development, while more recent studies have highlighted several developmental adaptations exclusive to primates. These adaptations together enable production of large numbers of projection neurons (PNs) that are required to populate the primordium of the primate neocortex, namely, the cortical plate. There are various classes of PNs on the basis of their projection hodology. While recent work has emphasized the role of post-mitotic regulatory programs in specification of PN classes, how these programs are executed and whether they are cell autonomous or under the influence of

signaling pathways is currently unknown. The subplate (SP) is a transient zone underneath the cortical plate that is also greatly enlarged in primates and is known to be essential for formation of cortical circuits. The human SP has been shown to be uniquely enriched in genes that lie near human accelerated conserved noncoding sequences. However, the significance of SP enlargement and its contribution to early corticogenesis remain unknown. Using a combination of in vivo human fetal brain observations, novel genetic and computational tools for analysis, and in vitro modeling of corticogenesis, we show that the SP is a major contributor to cortical lamination and projection neuron class-specification. Our results establish that SP neurons represent a novel ground state upon which post-mitotic transcriptional refinement takes place and culminates in the major classes of PNs that populate the six layers. Furthermore, we provide direct evidence that the human SP derives from post-mitotic preplate neurons. We also demonstrate that the SP is the exclusive contributor to layers V-VI in parts of the developing cortex. In addition, our *in vitro* and *in vivo* experiments provides clues to signaling pathways that regulates these post-mitotic programs and in turn specify SP neurons to various PN classes. The relative ratios of PN classes are thought to be altered in psychiatric and neurodevelopmental disorders such as schizophrenia, autism, and intellectual disability. By establishing a link between SP fate and PN class specification, our work provides a potential link between SP and developmental disorders. Overall, these findings have strong implications for understanding human corticogenesis, neurodevelopmental diseases, disease modeling, as well as stem cell-based therapies.

Title: Non-canonical Wnt signaling regulates the ratio of somatostatin- and parvalbumin-expressing cortical interneurons

Authors: ***M. MCKENZIE**[1,2], L. COBBS[1], G. FISHELL[1], E. AU[2];
[1]Smilow Neurosci., NYU Sch. of Med., New York, NY; [2]Pathology and Cell Biol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Cortical GABAergic interneurons exhibit remarkable diversity in their intrinsic firing properties, subtype marker expression, layer organization, synaptic connectivity and morphology. The mechanisms underlying the generation of this diversity are largely unknown. We have identified a novel rostral-caudal Wnt gradient within the medial ganglionic eminence (MGE) that delineates the specification of the two main interneuron subtype classes. Caudally-situated MGE progenitors receive high levels of Wnt signaling and give rise to somatostatin (SST)-expressing cortical interneurons. Parvalbumin-expressing basket cells, by contrast, originate mostly from the rostral MGE where Wnt signaling is attenuated. Interestingly, canonical Wnt signaling through b-catenin is not required for this process. Wnt signals transmitted via nuclear translocation of the intracellular domain of the non-canonical receptor Ryk, however, are sufficient to drive interneuron progenitors to a SST fate. Inhibition of Ryk signaling by a function blocking antibody conversely decreases the production of SST positive interneurons. Graded Ryk gain of function experiments performed in mouse ES-derived cortical interneurons reveal a dose-dependent effect, suggesting Ryk signaling acts in a gradient.

Title: Transcriptome analysis of the developmental dynamics of Cajal-Retzius neurons in the embryonic mouse neocortex.

Authors: *J. LI, L. SUN, X. YU, S. QI, X. PENG, Q. SHEN;
Tsinghua Univ., Beijing, China

Abstract: Cajal-Retzius (CR) cells, among the earliest-born neuronal population of the developing neocortex, are crucial for brain development. They are involved in regulating subsequent neuronal migration and laminar patterning of the cerebral cortex. Previously we identified Ebf2 as a molecular marker for cortical neurogenesis and CR neurons during neural development. Here, we used a transgenic mouse line that expresses EGFP in Ebf2-expressing cells to purify Ebf2+ cell population by FACS at different embryonic stages. Gene expression profiles of Ebf2+ and Ebf2- cell population were analyzed by next generation RNA-seq. Bioinformatics analysis revealed differentially expressed genes in Ebf2-GFP+ cells and Ebf2-

GFP- cells and temporal gene expression dynamics during early embryonic CR neuron development. We found that many known CR neuron-specific genes, such as Reelin and p73, are enriched in Ebf2+ cell population, consistent with their identity being CR neurons. Based on the dynamic gene expression pattern at different stages, CR neuron-enriched genes can be clustered into different groups, reflecting that specific sets of genes may regulate different aspects of CR neuron differentiation. We also identified a number of lncRNAs that are enriched in CR neurons, confirmed by in vitro and in vivo data. In addition, we found that the upstream regulatory regions of these lncRNAs were associated with active histone modifications by ChIP studies, indicating epigenetic regulation of CR gene expression. Overall, our work has identified genes that are related to early neurogenesis, particularly CR neuron identity, and will help understand the molecular mechanisms governing the developmental function of CR neurons.

Title: Distinct layer six neuron subtypes employ Foxp2 and Met during cortical development

Authors: *R. J. KAST[1], H.-H. WU[2], P. LEVITT[2];
[1]Saban Res. Institute, Children's Hosp. Los Angeles, Los Angeles, CA; [2]Saban Res. Institute, Children's Hosp. Los Angeles, Keck Sch. of Medicine, USC, Los Angeles, CA

Abstract: The extraordinary cellular diversity of the six layered cerebral cortex is critical for the highest levels of perception, cognition and motor control. To better understand how these functions emerge during development, it will be critical to determine how neuronal diversity is generated within each cortical layer and how individual cell types reach functional maturity. Toward this end, here we map the developmental expression of two important neurodevelopmental genes, Foxp2 and Met, onto discrete and largely non-overlapping cell types in layer 6. The majority of layer 6 excitatory projection neurons fall into 2 categories: corticothalamic and corticocortical neurons. Through neuroanatomical tracing and molecular profiling experiments, here we find that the transcription factor Foxp2 is enriched in

corticothalamic neurons and the receptor tyrosine kinase Met is selectively expressed by corticocortical neurons in layer 6. This information is particularly relevant given evidence implicating these genes in related, yet distinct disorders of higher cognitive function. Moreover, each of these genes has been associated with aspects of neural development that distinguish these two cell types. Ongoing experiments involving conditional mouse genetics seek to determine how Foxp2 and Met influence the development of these important layer 6 cortical circuit components.

Title: Approaches to the quantification of polyploid neurons in rat cortex

Authors: *J. SIGL-GLÖCKNER[1], M. BRECHT[2];
[1]AG Brecht, Bernstein Ctr. For Computat. Neurosci., Berlin, Germany; [2]Humboldt University/ BCCN Berlin, Berlin, Germany

Abstract: Principal cell diversity is a central issue in the neurobiology of the cerebral cortex. We address this issue by examining DNA content of cells in rat sensory cortex. Using fluorescence microscopy, we have previously shown that soma and nuclear size and patterns of DAPI-(DNA)-fluorescence vary between groups of cells in rat cortex. Layer 4 cells and non-neural cells are of small and homogenous size, while layer 5 exhibits a remarkable size diversity of somata and nuclei and contains some very large neurons. We also measured integrated DAPI-(DNA)-fluorescence and counted chromocenters, spots of densely packed heterochromatic DNA. In comparison to layer 4 neurons and non-neural cells, integrated DAPI-(DNA)-fluorescence and chromocenter counts of layer 5 neurons were greater and more widely distributed. These results suggested that some very large neurons in layer 5 are polyploid, owning more than two homologous copies of each chromosome. Moreover these supposedly polyploid neurons were differently distributed across cortical sensory areas. To better understand whether polyploidy is a

novel generator of neuronal diversity in the cortex, we recently focused on methods to directly quantify DNA content. On the one hand, we apply flow cytometry to more rigidly measure fluorescent staining of DNA in the nucleus. Combining DAPI-(DNA)-staining with immunohistochemistry, we are able to differentially measure DNA content of live neural and non-neural nuclei. Similar to previous reports[1], preliminary results revealed that 3-5% of cortical neurons appear to be tetraploid, containing 4 sets of homologous chromosomes. However, flow cytometry requires the homogenization of brain tissue and therefore curtails any insight into the phenotype and location of supposedly tetraploid neurons. Therefore we currently focus on approaches to directly quantify chromosomes of identified cells in brain sections. First, antibody staining is used to distinguish different cell types. Second, chromosomes are labelled using fluorescent in situ hybridization of telomeres with a peptide nucleic acid probe. Finally fluorescent telomere spots are imaged using confocal microscopy and counted, whereby supposedly tetraploid neurons will have twice as many telomeres. However, since hybridization requires excessive digestion, the integrity of the tissue is often harmed preventing complete hybridization. Once these challenges are overcome, we aim to combine size measurements, chromocenter counts, flow cytometry and in situ hybridization to gain a better understanding of how polyploid neurons contribute to cell diversity in the normal vertebrate brain. Title: Distinct progenitor lineages contribute to neuronal diversity in layer 4 of the barrel cortex

Authors: *T. GUILLAMON-VIVANCOS[1,2], M. MEDALLA[2], W. A. TYLER[2], T. F. HAYDAR[2], J. I. LUEBKE[2];
[1]Boston Univ., Boston, MA; [2]Boston Univ. Sch. of Med., Boston, MA

Abstract: Distinct neocortical areas differ in regard to neuronal diversity, but how this diversity is achieved during development is still poorly understood. Radial Glial Cells (RGCs), the neural

stem cells of the developing cortex, divide to generate neurons directly or give rise to intermediate progenitor cells (IPCs), which also generate new neurons. Our overall hypothesis is that distinct streams of neurogenesis underlie neuronal diversity in the neocortex. Indeed our group recently reported that neurons exhibit distinct morphological and electrophysiological properties in layer 3 of the mouse frontal cortex depending on their precursor type of origin. Using a novel genetic fate-mapping technique we labeled Tbr2-expressing progenitors and their neuronal progeny as well as those derived from precursor that do not express Tbr2 with red and green fluorescent proteins respectively. Using this strategy, we fate-mapped neurons in layer 4 of the barrel cortex via in utero electroporation at E13.5. At postnatal day 21, we used whole-cell patch clamp recordings to assess the electrophysiological properties of these neurons and then subsequently assessed their morphology using high-resolution confocal microscopy. We found that both Tbr2 and non-Tbr2 progenitors generated both pyramidal and stellate neurons. Our preliminary results also suggest that non-Tbr2 neurons have higher rheobase and lower firing rates than Tbr2 neurons, consistent with our previous findings in the frontal cortex.
In addition, we studied whether neurons derived from distinct precursor streams are distributed differentially across the depth and distinct compartments of the barrel field. Interestingly, non-Tbr2 neurons were localized at more superficial (closer to the pia) levels within layer 4 than Tbr2 neurons. Further, the non- Tbr2 neurons were preferentially localized in the center of the barrel, the compartment that receives input from the barrel field, while the Tbr2-derived neurons were more frequently located in the septum.
This study contributes to a better understanding of how different streams of neurogenesis contribute to adult neuronal diversity and provides specific insight on the development of the barrel cortex, a commonly used system to model neocortical microcircuitry.

Title: Connexin 43 blockade increases extracellular potassium without causing seizures in the mouse neocortex

Authors: *P. BAZZIGALUPPI[1], B. STEFANOVIC[2], I. WEISSPAPIR[1], L. LEYBAERT[3], P. CARLEN[1];
[1]Fundamental Neurobio., Univ. Hlth. Network, Toronto, ON, Canada; [2]Physical Sci., Sunnybrook Res. Inst., Toronto, ON, Canada; [3]Dept. of Basic Med. Sci., Ghent, Belgium

Abstract: Extracellular potassium concentration, $[K^+]_o$, is a major determinant of neuronal excitability. In the healthy brain $[K^+]_o$, levels are tightly controlled. During seizures, $[K^+]_o$ increases up to 15mM and is thought to cause seizures due to its depolarizing effect. Although astrocytes have been suggested to play a key role in the redistribution of excess K^+ through Connexin43 (Cx43)-based Gap Junctional (GJ) coupling, the relation between this highly dynamic regulatory process and seizure generation is still unknown. Here we examined the role of astrocytic Cx43-Gjs and hemi-channels in $[K^+]_o$ regulation *in vivo*, contrasting the effects of selective blockers *vs.* broad-spectrum neuronal and astrocytic GJ blocker, Carbenoxolone (CBX). $[K^+]_o$ was measured by a K^+-sensitive microelectrode and neuronal excitability estimated by local field potential (LFP) responses to forepaw stimulation and changes in the power of resting state neuronal activity. Starting at the control $[K^+]_o$ level of 1.61 ± 0.3 mM, cortical microinjection of CBX increased $[K^+]_o$ to 11 ± 3 mM, whereas the selective Cx43-Gjs GAP27 increased it from 1.9 ± 0.7 to 9 ± 1 mM. At these elevated $[K^+]_o$ levels, no seizure activity was observed. Cx43 hemi-channel blockage by the selective peptide TAT-GAP19 increased $[K^+]_o$ by only ~1 mM. Microinjection of 4-AP increased $[K^+]_o$ to levels comparable to those achieved with CBX or GAP27 administration and induced spontaneous and recurring seizures. On the other hand, external application of increased $[K^+]_o$ to over 12 mM did not trigger seizures. These findings are the first *in vivo* demonstration that astrocytic GJs are major determinants of $[K^+]_o$, but that their blockade alone does not trigger seizures in the neocortex.

Title: Single-cell analyses reveal neural progenitor fate specification during cerebral cortex development

Authors: *J. LIU[1], X. WU[2], L. YANG[2], C. BUN[1], Q. LU[1];
[1]Developmental & Stem Cell Biol, [2]Dept. of Mol. and Cell. Biol, City of Hope, Duarte, CA

Abstract: During cerebral cortex development, neural stem cells/progenitors first expand the progenitor cell pool, and then undergo differentiation, generating neurons and glia sequentially. How such developmental transitions of neural progenitor cells are regulated is not well understood. One major obstacle is the high heterogeneity of neural progenitors, such as in the developing cerebral cortex of mouse, containing radial glia cells (RGCs), intermediate progenitor cells (IPCs) or basal progenitors, astrocyte progenitors and oligodendrocyte progenitors, and etc. These progenitors coexist and were surrounded by numerous new-born or mature neurons, making study on progenitor fate transition very difficult. In the current study, we combined dual-reporter neural progenitor sorting with single-cell transcriptome deep sequencing (RNA-seq). From 3 developmental stages, we acquired the global transcriptomes of 107 purified neural progenitors: 36 at starting of neurogenesis (embryonic day E12.5); 36 at peak of neurogenesis (E15.5); and 35 at starting of gliogenesis (E18.5). At the same time, we captured and sequenced 20 IPCs at E15.5 through Tbr2 (Eomes)-GFP/Dcx-mRFP sorting. Unsupervised hierarchical clustering analyses for all the 127 cells classified them into different groups, which can be recognized by cell-type specific markers. At E12.5, 75% of cells were RGCs in cell cycle, and others were new-born and maturing IPCs. At E15.5, 7 out of 36 cells were cycling RGCs, while a big group of neurogenic progenitors and IPCs account for the majority. At E18.5, isolated progenitor cell population consisted with RGCs, IPCs, astrocyte progenitors, as well as interneuron progenitors. Surprisingly, the group of neurogenic progenitors at E15.5 was more closely related to the group of astrocyte progenitors at E18.5 than to new-born or maturing IPCs, based on clustering analyses. Furthermore, principle component analysis (PCA) revealed two distinct differentiation paths of RGCs: one path reflecting neuronal differentiation of RGCs via IPCs, and the other path delineating commitment of RGCs for becoming neurogenic or gliogenic (astrocytic) progenitors. Our data thus indicated there are two types of RGCs, each of which appeared to follow a distinct progressive restriction scheme of fate specification during cortical development. We will further present our most recent findings with this respect.

Title: Prdm16 transcriptional activity in radial glial cells controls cortical neurogenesis

Authors: *J. BAIZABAL CARBALLO, M. TURRERO, N. GÓMEZ, O. OLUKOYA, C. HARWELL;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Radial glial cells (RGCs) are the origin of cell diversity in the mature cerebral cortex. RGCs establish the organization of different cortical layers by progressively generating specific subtypes of excitatory neurons. At the onset of neurogenesis, early RGCs divide asymmetrically to produce neurons directly. As neurogenesis continues, RGCs transition to give rise to intermediate progenitors, which divide symmetrically to produce pairs of neurons through a process of indirect neurogenesis. At present, the molecular mechanisms whereby specific transcriptional programs control the pattern of neurogenesis by cortical RGCs are not well understood. The family of PRDM (Positive Regulatory domain-containing) genes has important functions in controlling stem cell renewal and differentiation in multiple tissues. In particular, Prdm16 is part of the evolutionary conserved gene network that is expressed in both mouse and human RGCs. Interestingly, mutations mapping within Prdm16 genomic region in human chromosome 1 are linked to abnormal development of the cerebral cortex and intellectual disability. Furthermore, previous evidence has suggested a role of Prdm16 in progenitor survival and proliferation in the mouse brain. Yet, the gross brain defects and perinatal lethality observed in Prdm16 loss of function mice has precluded a more detailed analysis. Here, we generated cerebral cortex-specific mutant mice to investigate the role of Prdm16 in cortical development. Absence of Prdm16 during embryonic neurogenesis increased cell cycle exit of RGCs. This process resulted in a significant reduction of proliferating intermediate neuronal progenitors at the subventricular zone of mutant cortices. Accordingly, quantification of the size of clonal radial units using in vivo retroviral labeling demonstrated that Prdm16 mutant RGCs produce smaller clones in comparison to controls. Our data suggest that Prdm16 maintains the undifferentiated state by inhibiting direct neurogenesis, favoring the production of intermediate progenitors and indirect neurogenesis. Currently, we are investigating the molecular mechanisms by which Prdm16 transcriptional program in RGCs controls neurogenesis in the cerebral cortex.

Title: HMGNs affect alternative isoform regulation of mRNA in prefrontal cortex, hippocampus and embryonic stem cells.

Authors: *P. LISOWSKI[1], S. ZHANG[2], T. DENG[2], T. FURUSAWA[2], M. BUSTIN[2];
[1]iPS Cell Based Dis. Modeling Group, Max-Delbrück-Center For Mol. Med. (MDC), Berlin, Germany; [2]Protein Section, Lab. of Metabolism, Ctr. for Cancer Research, Natl. Cancer Institute, Natl. Inst. of Hlth., Bethesda, MD

Abstract: High mobility group N (HMGN) family members are nucleosome-binding proteins that affect chromatin structure. HMGN variants are expressed in most brain regions; however, their effect on the fidelity of cellular transcription profile and on neurological functions is not known. Here, we study the role of HMGN family in the modulation of transcriptome in hippocampus, prefrontal cortex, embryonic stem cells (ESCs), mouse embryonic fibroblasts (MEFs), and B cells of genetically altered mice and cell lines that either lack, or overexpress functional HMGN variants. Transcription profiles of wild-type, HMGN1/HMGN2 double knockout, and HMGN1 overexpressing mice and cell lines were analyzed by paired-end, RNA-seq using Illumina GAIIx. The sequence reads were analyzed with Cufflinks/Cuffdiff followed by Mixture of Isoforms (MISO) - a probabilistic framework towards detection of alternatively spliced genes, differentially regulated isoforms and exons across samples. To discover alternative isoform regulation of mRNA we estimated differential transcript usage (DTU), differential transcript expression (DTE), alternative 3 and 5' splice sites (A3SS, A5SS) usage, mutually excluded exons (MXE), retained introns (RI), and skipped exons (SE). We identified that the loss or overexpression of HMGNs in adult brain and ESCs result in alternative 3' and/or 5' splice sites usage of genes involved in transcription regulation such as tRNA methyltransferase 1 (TRMT1) in prefrontal cortex or HOXA1 encoding DNA-binding transcription factor regulating gene expression patterns responsible for morphogenesis, differentiation, as well as placement of hindbrain segments in the proper location along the anterior-posterior axis during development. Thus, epigenetic factors such as HMGNs could affect the proper functioning of central nervous system by modulating the transcriptional profiles in stem cells as well as in cortical and hippocampal neurons. This study posits a role of HMGNs

in nervous system development, and provides a basis for further hypotheses on the role of HMGNs in alternative isoforms regulation of mRNA.

Title: Mechanisms of cell fate refinement in the embryonic cortex are deregulated by lack of Mecp2

Authors: *C. COBOLLI GIGLI[1], L. SCARAMUZZA[1], C. KILSTRUP-NIELSEN[2], N. LANDSBERGER[1,3], F. BEDOGNI[1];
[1]Dept. of Neurosci., San Raffaele Hosp., Milano, Italy; [2]Univ. of Insubria, Varese, Italy; [3]Univ. of Milan, Milano, Italy

Abstract: During development, neurons progressively restrict their fate repressing the expression of specific genes while differentiating. This process vastly relies on transcription and is therefore subject to epigenetic control. The Methyl-CpG binding protein 2 (MeCP2) is an epigenetic factor that, binding methylated DNA, participates to chromatin folding and transcriptional regulation. Mutations of *MECP2* leads to Rett syndrome (RTT), a devastating condition whose pathogenetic mechanisms are not yet completely understood but most likely originate from developmental derangements. We hypothesised that lack of this epigenetic factor may alter proper cellular maturation due to misinterpretation of the DNA methylation signature characterizing each cell type throughout its development. To evaluate this hypothesis, we analyzed the developing *Mecp2* null cerebral cortex. Interestingly, at the embryonic day 15.5 (E15.5) the transcriptional identity of proliferating cortical progenitors is increased in null cortices compared to wt. Since proper cortical development is ensured by a tightly regulated progression through cell cycle phases, we tested whether dynamics of neurogenesis were deregulated in null samples. Interestingly, rather than altering cell cycle progression, lack of Mecp2 affects the expression of markers that are typical of cells transitioning from one stage to the next one.This suggests that null cells, switching from one cellular type to the next one, retain parts of the previous identity, possibly due to the lack of control over transcription normally

exerted by Mecp2. Given proper proliferation dynamics of cortical progenitors are crucial for the subsequent development of newborn neurons, it is possible to infer that the known maturation delay affecting the developing Mecp2 null cortex could be generated by derangements in the control of cell fate refinement.

Title: The role of Fezf2 in regulating postnatal ventricular zone stem cell fate

Authors: *A. A. AKHTAR, M. DUTRA-CLARKE, G. KIM, R. LEVY, S. SAVINOFF, M. DANIELPOUR, J. BREUNIG;
RMI, Cedars Sinai Med. Ctr. Regenerative Med. Inst., West Hollywood, CA

Abstract: The transcription factor Fezf2 has been identified as a critical determinant of layer 5 corticofugal projection neurons. This class of neurons includes corticospinal motor neurons that are lost in degenerative motor neuron disorders such as amyotrophic lateral sclerosis (ALS). Previous work has explored the ability of Fezf2 to reprogram cells to a corticofugal phenotype within a very spatial and temporal window of early development. Interestingly, Fezf2 is expressed by a large majority of dorsal ventricular zone (VZ) stem and progenitor cells. We have developed an electroporation-based method for stably expressing Fezf2 in neural stem cells lining the lateral ventricle. Increasing expression of Fezf2 in these cells reduces astrogliogenesis and olfactory bulb (OB) neurogenesis. To avoid acute OB neurogenesis alterations, we developed an inducible and reversible, 3rd generation, doxycycline(Dox)-regulated genetic system for expressing Fezf2. When our expression vector is induced by Dox in cultures of mouse neural stem cells or astrocytes, Fezf2 causes morphological conversion into neuron-like cells despite the presence of growth factors and serum. When Fezf2 expression is induced postnatally in the olfactory bulb, we see changes in nuclear size, increased ER81 expression, and evidence of ectopic axonal growth from the olfactory bulb. Using this new technology, we are exploring the ability of Fezf2 to reprogram heterogeneous populations of stem, progenitor and terminally differentiated cells to corticofugal subtypes in postnatal and adult mice.

Title: Birth time-dependent specification of pyramidal neuron laminar and projection types through intermediate progenitors

Authors: *J. M. LEVINE[1,2], D. HUILGOL[1], M. HE[3], Z. J. HUANG[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Mstp, Stony Brook Univ., Stony Brook, NY; [3]Inst. of Brain Sci., Fudan Univ., Shanghai, China

Abstract: Pyramidal neurons (PyNs) comprise the majority of cortical neurons and underlie nearly all aspects of cognitive operations. The progenitor cells that give rise to neocortical PyNs mainly include radial glial cells (RGCs) and intermediate progenitor cells (IPCs) located in the embryonic cerebral ventricle wall. RGCs divide asymmetrically to generate neurons either directly or indirectly through IPCs, which divide symmetrically to produce pairs of PyNs. It remains unclear how progenitor types (e.g. RGCs, IPCs), their lineage progression, and timing of neurogenesis contribute to the specification of diverse PyN subtypes defined by axon projection, connectivity, and physiology. In particular, the role of IPCs in the generation of PyNs is poorly understood. The T-domain transcription factor (Tbr2) is specifically expressed in cortical IPCs. We have generated an inducible *Tbr2-CreER* mouse driver, which allows comprehensive lineage tracing from IPCs and have developed a novel genetic method to fate-map neurons according to their lineage and precise birth time. We have used the *Tbr2-CreER* driver and Cre-dependent reporter mice to fate map IPCs throughout embryogenesis. In addition to assessing the laminar position of PyN subtypes, axon projections are analyzed with a novel method utilizing viral labeling of fate-mapped PyNs. Using retrograde virus along with our genetic driver and reporter lines allows us to restrict cell labeling by progenitor type, birth date, and projection target. With this method, we can further elucidate the PyN subtypes born from IPCs throughout neurogenesis,

using axon projection as more descriptive definition of cell type than laminar location. Fate mapping experiments revealed that IPCs sequentially gave rise to PyNs with distinct laminar patterns spanning multiple nonconsecutive layers with only a trend towards an inside-out sequence. This suggests that IPCs do not generate PyNs in a strictly inside-out manner. Rather, temporal cohorts of multiple fate-restricted IPCs simultaneously, as well as sequentially, generate PyN subtypes defined by their axon projection and laminar location. Ongoing experiments include an investigation of the PyNs that are generated by direct neurogenesis from RGCs, in contrast to those that are generated by IPCs, and the development of a novel genetic birth-dating strategy utilizing the Tis21 gene that is expressed in progenitors as they undergo neurogenic division. These findings begin to link progenitor type and their time of neurogenesis to the specification of PyN subtypes.

Title: Role of intermediate progenitors in the specification of cortical pyramidal neurons

Authors: *D. HUILGOL[1], J. M. LEVINE[1], M. HE[1,2], P. WU[1], Z. J. HUANG[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Inst. of Brain Sci., Fudan Univ., Shanghai, China

Abstract: The neocortex covers the anterior-most portion of the mammalian brain and is involved in a range of cognitive functions. It consists of multiple layers with distinct neuronal types, of which pyramidal or projection neurons (PyNs) constitute ~80% of cortical neurons. PyNs mediate multiple information processing streams and all the major cortical output channels, and are diverse in terms of their laminar location, gene expression, connectivity and physiology. However, the developmental origins of this diversity are poorly understood. PyNs arise from mainly two types of progenitors: the radial glial cells (RGCs) and the intermediate

progenitor cells (IPCs). It is unclear how these progenitors, their lineage progression and timing of neurogenesis contribute to specification of diverse PyN identities, for example defined by their projection targets. In particular, the role of IPCs is not understood. We have generated an inducible knock-in mouse driver for Tbr2 (*Tbr2*-creER), a T-domain transcription factor which is specifically expressed by the IPCs and is necessary for their identity. This allowed us to perform comprehensive lineage tracing for PyNs born from IPCs. Cortical neurogenesis is known to follow an inside-out sequence of layer formation, such that neuronal birth timing relates to its laminar identity. Fate mapping at different embryonic ages using a reporter bred with *Tbr2*-creER line reveals that PyN generation does not follow the expected inside-out pattern of sequential laminar generation. We observed that PyNs produced at specific time points span multiple non-consecutive layers suggesting the simultaneous presence of multiple fate-restricted IPCs at these ages. Analysis of the progenitors in terms of their location in the germinal zone, their morphology and markers revealed that they are indeed IPCs. We hypothesize that PyNs are born based on their projection targets, which follow a broad but not a strict inside-out sequence of birth order. To achieve high resolution fate mapping, we have performed clonal analysis from Tbr2(+) progenitors using MADM (Mosaic Analysis with Double Markers) and Brainbow mice. Pairs of PyNs produced at different developmental time points are similar in morphology and laminar positions. We are currently utilizing different clearing techniques to analyze and compare the projections of PyNs born from a single IPC. Ongoing experiments also include axon tracing by using viral labeling methods to characterize PyN subtypes beyond their laminar positions.

Title: Endogenous and hemorrhage-derived lysophosphatidic acid (LPA) signaling alters mitotic spindle orientation and subsequent cell fates of neuroprogenitor cells in the mammalian cerebral cortex

Authors: *Y. C. YUNG, W. MCDONALD, J. CHUN;
Mol. and Cell. Neurosci., The Scripps Res. Inst., LA Jolla, CA

Abstract: Mitotic spindle and cleavage plane orientation are critical factors influencing symmetric vs asymmetric cell division during cortical development. Their intracellular molecular pathways and associated fate determinants have been progressively characterized. However, soluble, extracellular signals affecting cleavage plane are now being revealed, including recent studies in semaphorin signaling. Here we report that lysophosphatidic acid (LPA), an extracellular lipid signaling molecule present in cerebrospinal fluid, shifts cleavage planes through different G protein-coupled LPA receptor subtypes and downstream pathways. Dual genetic removal of LPA_1 and LPA_2 produced changes in cleavage orientation. In addition, perturbation of endogenous LPA levels via *ex vivo* cortical hemisphere cultures or *in vivo* fetal cerebral cortical injections resulted in altered apical adherens junctions, cell polarity, apico-basal mitotic spindle orientation, and subsequent altered neural fates compared with controls. Exposure to either blood plasma or serum - known significant sources of LPA - consistent with hemorrhage also produced similar changes. Genetic removal of both LPA_1 and LPA_2 receptors abrogated LPA, plasma, or serum-induced changes, yet also resulted in unstimulated cleavage plane orientation alterations comparable to wild-type controls, indicating normal influences on cleavage plane through endogenous LPA actions on its receptors. These data identify LPA as a soluble, extracellular signal acting through two cognate LPA receptors to influence neuroprogenitor cell fate under basal development and neuropathological conditions that elevate LPA, including hemorrhage and hypoxia. These pathological stimuli alter brain development which contribute to diseases such as hydrocephalus and likely other hemorrhage-related neurodevelopmental disorders.

Title: Morphological analyses of radial glial cells in the developing mouse neocortex

Authors: ***M. SHIN**[1], A. KITAZAWA[2], Y. MATSUNAGA[1], K. HAYASHI[1], K.-I. KUBO[1], K. NAKAJIMA[1];

Abstract: During mammalian neocortical development, excitatory neurons are generated directly or indirectly from specialized progenitors called radial glial cells (RGCs), located in the ventricular zone (VZ). Newly born neurons migrate toward the outermost superficial region of the cortical plate by passing through their predecessors. In the course of this 'inside-out' manner of neuronal alignment, radial fibers extended from RGCs to the pial surface play as a scaffold for migrating neurons, resulting in their columnar configuration which might contribute to the development of functional units in the future. To establish neuronal arrangement successfully, radial fibers are required to maintain their long thin structure properly for providing for migrating neurons.Reeling glycoprotein, which is secreted by Cajal-Retzius cells in the marginal zone, is known to be one of the key molecules for establishing the 'inside-out' neuronal layers, since Reelin-deficient mice, called *reeler*, show roughly inverted neuronal layers. Although much about the molecular and functional basis of Reelin singling has been elucidated in the context of neuronal migration, little is known about the effects of Reelin on the RGCs. Several lines of evidence in mammalian neocortical development have found that Reelin can affect morphology of radial fibers, however, the biological role of Reelin on RGCs still remains to be elucidated.To investigate whether structure of RGCs is disrupted in the *reeler* mutant mice, we electroplated a GFP-expression plasmid into E14-16 heterozygous and homozygous *reeler* embryonic cortices to visualize radial fibers with GFP. To examine the fiber morphology in detail, we quantitively analysed the fibers after imaging at high resolution. Fibers in the *reeler* mutant had occupied approximately 6μm more in width when transversing the entire cerebral wall, compared to those in the control mice. 3D imaging was also carried out to reveal differences of radial fibers between normal and *reeler* mutant mice.

Craig Venter Inst., Rockville, MD; [4]Pathology, UCSD, San Diego, CA

Abstract: The human cerebral cortex is a remarkably complex structure comprised of billions of cells. However, despite many years of research focused on classifying cell types using morphological, electrophysiological, and gene expression data, a thorough understanding of the complete range of cell types that populate the human cerebral cortex is lacking. Here we investigated the potential of using RNA-seq on single nuclei isolated from adult human neocortex to generate transcriptomic signatures and derive cell type classifications. Single nucleus RNA-seq was used to capture the transcriptomes of >1000 individual nuclei isolated from adult human postmortem brain samples. We focused our analyses on two specific layers within distinct cortical regions, layer 1 of middle temporal gyrus and layer 5 of frontoinsular cortex, in order to access a diversity of inhibitory and excitatory neuron types of high biological interest. Layer 1 of middle temporal gyrus contains several anatomically and physiologically distinct classes of GABAergic interneurons, including neurogliaform cells. Layer 5 of frontoinsular cortex contains a variety of excitatory and inhibitory cell types, as well as a high concentration of von Economo neurons, a type of projection neuron described in relatively few species and particularly enriched in select regions of human cortex. Neuronal nuclei were specifically labeled using an antibody against NeuN, and individual neuronal (NeuN-positive) and non-neuronal (NeuN-negative) nuclei were captured using fluorescence-activated cell sorting. cDNA libraries from individual nuclei were constructed using a modified Smart-seq2 protocol and sequenced on a HiSeq instrument at a depth of >1 million reads/sample. Our results indicate that single nucleus RNA-seq successfully discriminates major cell types in the adult cortex, including excitatory and inhibitory neuronal types and glial cell types. Furthermore, iterative clustering revealed multiple subtypes of inhibitory and excitatory neurons in our target regions of interest. These results demonstrate the utility of single nucleus RNA-seq for characterizing the diversity of cell types in the adult human neocortex and provide insight into the biochemical and functional differences between cell types.

Title: CRISPR/Cas9-induced disruption of gene expression in mouse embryonic brain and single neural stem cells *In vivo*

Authors: ***N. KALEBIC**, E. TAVERNA, S. TAVANO, F. K. WONG, D. SUCHOLD, S. WINKLER, M. SAROV, W. B. HUTTNER;
MPI-CBG, Dresden, Germany

Abstract: *In vivo* manipulation of gene expression is a major way of studying the function of individual genes in their physiological context. Here we applied the CRISPR/Cas9 system to disrupt gene expression in neural stem cells in the developing mammalian brain *in vivo*.
As a proof-of-principle we first targeted GFP in a knock-in mouse line, where GFP is expressed in a subset of neural progenitor cells during embryonic cortical development. We electroporated embryonic brains *in utero* with a single plasmid encoding Cas9, guide RNA (gRNA) and a fluorescent marker, and obtained nearly complete (90%) disruption of GFP expression two days after targeting. Considering that changes in cell fate during cortical development typically occur within a single progenitor cell cycle, electroporation of the Cas9/gRNA plasmid has a potential drawback that any genome editing can only occur after Cas9 and the gRNA have been produced. To overcome this limitation, we directly electroporated recombinant Cas9/gRNA complex and achieved near-maximal efficiency of disruption of GFP expression already 24 hours after electroporation. Strong disruption of GFP expression within a single cell cycle was detected after microinjecting the Cas9/gRNA complex into single neural stem cells in organotypic slice cultures, an approach that enabled us to trace the fate of individual cells upon genome editing.

Finally, we applied these approaches to disrupt the expression of *Eomes*, a gene fundamental for neocortical neurogenesis. This resulted in a reduction in basal progenitors, a major pool of neural progenitors in the developing cortex, and an increase in neuronal differentiation. Sequencing analysis revealed no detectable indels in the four major off-target sites, suggesting that the observed neurodevelopmental phenotype was indeed caused by selective disruption of the *Eomes* locus.
Thus, we successfully applied the CRISPR/Cas9 system to achieve rapid, efficient and enduring disruption of gene expression followed by fate tracing of immediate daughter cells during mammalian brain development *in vivo*.

Title: Roles of differential sulfation in Fgf8/Erk signaling during mouse forebrain development.

Authors: *W. CHAN, D. PRICE, T. PRATT;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Heparan sulfate proteoglycans (HSPGs) are cell surface/secreted molecules expressed by all cells. HSPGs consist of linear heparan sulfate (HS) carbohydrate side-chains attached to a core protein and are involved in regulating key signalling pathways in the developing mammalian brain via sugar-protein interactions. HS has an enormous variety of structures due to postsynthetic modification. HS hypothesis states that the specificity for the interaction between the HSPGs and particular signalling pathways is encoded by differential HS sulfation. Hs2st and Hs6st1 are enzymes involved in generating different HS structures by sulfating the 2-O or 6-O carbon molecule of the sugar backbone respectively. Loss of either Hs2st or Hs6st1 function has profound, but distinct, consequences for forebrain development confirming their importance. The distinct effects differential sulfation have on forebrain development suggests that specific HS structures drive distinct developmental programmes via the regulation of signaling pathways

supporting the HS code hypothesis. Fibroblast growth factor (Fgf) is a family of signaling molecules crucial for forebrain development. Fgf8 is a secreted morphogen where it functions to pattern the forebrain via regulated gradient formation. Fgf8 protein levels and the interpretation of the Fgf8 protein gradient are important for Fgf8 signaling. HS has been previously shown to be involved in these processes however, the role differential sulfation plays in these processes and particularly, the molecular mechanism(s) behind this has not been clearly resolved. Fgf8 signaling has been widely studied and its signaling mechanism well characterised. Yet, the conventional model of its signaling mechanism could not fully explain the observations preliminary to this work where *Hs2st* and *Hs6st1* mutants have disrupted Fgf8/Erk signaling, presenting a gap in our current understanding of Fgf8/Erk signaling. We developed an *ex vivo* assay to probe the formation of Fgf8 gradient over time and the regulation of Fgf8 gradient formation and signaling by differential HS sulfation. Our data shows that specific HS sulfation regulates Fgf8 distribution and its interpretation in distinct ways supporting the HS code hypothesis. Our *ex vivo* data allowed us to formulate predictions about the regulation of the Fgf8 gradient and its interpretation *in vivo*. Testing these predictions *in vivo* enabled us to model the regulation of the Fgf8 gradient and its interpretation by differential sulfation during forebrain development. This provides us with further insight into the role of HS in the complex but precise regulation of mouse forebrain development.

Abstract: Striatal medium-sized spiny neurons (MSNs), composed of striatonigral and striatopallidal neurons, are derived from the lateral ganglionic eminence (LGE). We previously have shown that, in Sp9 mutant mice, LGE striatopallidal MSN progenitors have reduced proliferation. Moreover, most striatopallidal MSN progenitor cells fail to differentiate into

mature striatopallidal neurons, and die cell-autonomously through Bax-dependent apoptosis. On the other hand, development of striatonigral MSNs is largely unaffected. In the present study, we found that in the striatum of Sp8 and Sp9 double conditional mutant mice, none of striatopallidal MSNs was produced. This was due to cell cycle arrest of striatopallidal MSN progenitors, which further induced these progenitors undergoing apoptosis in the LGE SVZ, but not in the striatum. Once again, development of striatonigral neurons appears normal. Diverse molecular mechanisms underlying these phonotypes are currently under study.

Title: Nkx2.9 programs mesodiencephalic dopaminergic neurons early in development

Authors: ***W. M. KOUWENHOVEN**[1,2], L. VON OERTHEL[1], C. WAGEMANS[1], I. HOUWERS[1], J. TIAN[2], M. GRUPPILO[2], J. LOCKER[2], M. P. SMIDT[1];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Nkx2.9 (or Nkx2.8 in most other species, except for mouse) is a member of the NK homeobox family and resembles Nkx2.2 based on homology and on its expression pattern in the central nervous system. However, while Nkx2.2 is required for the development of serotonergic neurons, the role of Nkx2.9 in the mid-hindbrain region is still ill-defined. In a recent paper from our group we investigated the role of homeobox transcription factor Engrailed 1 (En1) in mid-hindbrain development, and designated Nkx2.9 as a possible transcriptional target of En1 (Veenvliet et al., 2013). In the current work we elaborate on this finding by determining whether mesodiencephalic dopaminergic (mdDA) neurons require Nkx2.9 during their molecular development. Here, we describe for the first time that Nkx2.9 contributes significantly to the molecular programming of mdDA neurons. Lineage-tracing reveals that a large majority of mdDA neurons encounter Nkx2.9 expression during early embryonic development. Furthermore,

we demonstrate using next generation RNA-Seq and *in situ* hybridization on Nkx2.9-ablated animals, that Nkx2.9 influences the expression of the dopamine transporter (Dat) in mdDA neurons.

Title: α7 nicotinic acetylcholine receptors mediate nicotine-induced neurite outgrowth of rat superior cervical ganglia cells

Authors: *S. TAKATORI[1], H. HINO[2], F. TAKAYAMA[2], Y. KITAMURA[3], T. SENDO[3], H. KAWASAKI[4];
[1]Matsuyama Univ., Matsuyama, Japan; [2]Dept. of Clin. Pharmaceut. Sciences, Grad. Sch. of Medicine, Dent. and Pharmaceut. Sciences, Okayama Univ., Okayama, Japan; [3]Dept. of Pharmacy, Okayama Univ. Hosp., Okayama, Japan; [4]Dept. of Clin. Pharmacy, Col. of Pharmaceut. Sciences, Matsuyama Univ., Matsuyama, Japan

Abstract: ***Background****:* The previous *in vivo* study demonstrated that nicotine facilitates only reinnervation of sympathetic adrenergic nerves injured by topical phenol-application in the rat mesenteric artery, and markedly increased levels of nerve growth factor (NGF) contents and the expression of NGF receptor TrkA in superior cervical ganglia (SCG), which were inhibited by the pretreatment of nicotinic acetylcholine receptor (nAChR) antagonist hexamethonium (Takatori S *et al*., Eur J Pharmacol, 748: 1-9, 2015.). To clarify possible mechanisms, the present study was further investigated the effect of nicotine on neurite outgrowth of primary cultured-SCG cells *in vitro*. ***Methods****:* SCG cells isolated from Wistar neonate rats were primarily cultured for 5 days. Numbers of neurite outgrowth from cell body were measured in the presence of nicotine (10-3000 μM), acetylcholine (ACh) (10-3000 μM), or NGF (10-100 ng/mL). Hexamethonium (100 μM) or α-bungarotoxin (100 nM) was incubated with nicotine for 5 days. ***Results****:* Nicotine (10-1000 μM) concentration-dependently increased neurite outgrowth numbers from tyrosine hydroxylase-immunopositive SCG cells, while high concentration of 3000 μM did not increase the numbers. The nicotine-induced increase in neurite numbers was dependent on

the exposure time (8-24 hr/day) of nicotine. Combined incubation with nicotine and hexamethonium or α-bungarotoxin did not increase neurite outgrowth of SCG cells. ACh at 10-1000 μM had no effect on the neurite numbers, but high concentration of 3000 μM markedly increased them. NGF also markedly increased neurite outgrowth numbers of SCG cells. Combined incubation with nicotine (10-1000 μM) and NGF (10 ng/mL) resulted in an additive increase in NGF-induced neurite numbers. ***Conclusion****:* These results suggest that nicotine has a neurotrophic effect on sympathetic ganglia cells via activation of α7 nAChR. (This study was supported by Smoking Research Foundation).

Title: TRPM8 as a candidate channel to regulate temperature-dependent changes in spinal neuron differentiation

Authors: *K. A. SPENCER[1,2], L. N. BORODINSKY[1,2];
[1]Shriners Hosp. For Children Northern CA, Sacramento, CA; [2]Physiol. and Membrane Biol., Univ. of California Davis, Davis, CA

Abstract: Developmental rate of ectotherms, including frogs, is dependent on the temperature of the environment. However, it is unknown how environmental temperature influences nervous

system development. Neuronal differentiation in the spinal cord is dependent on spontaneous Ca^{2+} activity. We hypothesize that factors in the environment may affect neuronal specification by modulating this spontaneous Ca^{2+} activity. In this study, we investigate the role of temperature in spinal neuron differentiation in *Xenopus laevis*.
Data show that growing tadpoles at cold temperature (14.5°C) results in larger animals that are about 10% longer and have an overall number of cells in the spinal cord 15 and 25% higher compared to warmer temperature-grown tadpoles (22.5 and 26.5, respectively). Strikingly, the number of motor neurons is 100% higher in cold temperature-grown tadpoles. In addition, the distance between sensory axon bundles projecting in the axial skeletal muscle is significantly longer in tadpoles grown at 14.5°C than those grown at 26.5°C. Further analysis of morphological features of both sensory and motor neurons in embryos grown at different temperatures is underway.
To investigate the mechanisms underlying these temperature-driven changes in neuron specialization, I assessed the effect of TRPM8, a cold sensitive channel, on spontaneous Ca^{2+} spike activity. I first evaluated the expression of TRPM8 by RT-PCR and immunostaining and find that TRPM8 is present in the embryonic spinal cord. Blocking TRPM8 activity with 10 μM AMTB, reverses the cold-temperature-induced increase in Ca^{2+} spike frequency in ventral spinal neurons. Additional experiments will further explore whether a TRPM8-mediated increase in Ca^{2+} spike frequency at low temperatures influences motor neuron differentiation.
Altogether these results demonstrate that temperature regulates spinal cord development in *Xenopus laevis*, and suggest this may work through TRPM8. The findings indicate that the environment intervenes in the differentiation program of developing neurons.

Eye Institute, Natl. Inst. of Hlth., Bethesda, MD; [4]Genet., [5]Systems Biol., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Background and Objective Retinal ganglion cells (RGCs) are the only output neurons that collectively transmit visual information from the retina to different regions in the brain. In the mouse retina, some 20 to 30 subtypes of RGCs have been described based on morphology and/or function. However, the genetic regulatory mechanism controlling RGC subtype specification and differentiation remains vaguely understood, in part because of the difficulty in experimentally tracing a specific RGC subtype lineage through development. Here we describe experiments demonstrating that T-box transcription factor T-brain 1 (Tbr1) is expressed in approximately 11% of mouse RGCs. By using genetically-directed sparse labeling and dye-filling on individual RGC, we have uncovered two separate RGC subtypes expressing Tbr1. Methods To conduct sparse-labeling and dye-filling in Tbr1-expressing RGCs, we generated $Tbr1^{CreERT2/+}$:$Pou4f1^{cKO\text{-}AP}$ and $Tbr1^{CreERT2/+}$:Ai9 mouse lines, respectively. Tamoxifen was injected intraperitoneally into these mice for five consecutive days to activate Cre recombinase, and hence turn on $Pou4f1^{cKO\text{-}AP}$ or Ai9 reporter lines. We then performed flat-mount alkaline phosphatase (AP) staining on the retinas from tamoxifen-injected $Tbr1^{CreERT2/+}$: $Pou4f1^{cKO\text{-}AP}$ mice to reveal the RGC subtypes expressing Tbr1. Furthermore, we conducted neurobiotin-filling in individual Ai9/tdtomato-marked Tbr1+ RGCs in tamoxifen-injected $Tbr1^{CreERT2/+}$:Ai9 mice to systematically examine the detailed dendritic morphologies of Tbr1-expressing RGCs. Results and Conclusions With both mouse lines, we provide evidence for two morphologically distinct RGC subtypes within Tbr1+ RGCs, including the JAM-B RGC, an upward motion-detecting RGC subtype, and a RGC subtype which stratifies in the OFF layer of the inner plexiform layer. These mouse lines provide a unique opportunity to investigate the differentiation, growth, the central projection and physiology of these RGC types, and to understand the genetic regulatory mechanisms that control the development of these RGCs.

Title: Pioneering connections from brain to retina, which might be a unique human specialisation

Authors: *I. BYSTRON[1], C. BLAKEMORE[2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Sch. of Advanced Study, Inst. of Philosophy, London, United Kingdom

Abstract: Although the proliferative zones of retina and ventral diencephalon derive from the same region of the embryonic prosencephalon, they generate very different classes and distributions of neurons. We are interested in the relationship between cell production and migration in the human retina and neighboring diencephalon.
Human embryos from Carnegie stages (CS) 10-19 (29-44 days post-conception) were obtained according to national guidelines in Russia and from the Human Developmental Biology Resource UK. Different components of the neural stem cell niche in the diencephalon, optic stalk and presumptive retina were reconstructed by rapid, interactive, high-resolution volume rendering of multichannel 3D confocal data sets from a Zeiss LSM 710 confocal microscope. We observed a previously unreported early neuronal population with a very unusual pattern of migration. Typically, in the mammalian forebrain (including the retina), neurons born locally in the ventricular zone (VZ) of the neuroepithelium migrate radially and accumulate under the pial surface. However, the majority of first-born neurons in human embryonic hypothalamus (at CS 12) appear to migrate tangentially along the surface of the ventral diencephalon lining the third ventricle, towards the optic vesicle. By CS13-14 these precocious cells, which we call Meitar neurons, invade the neural and pigmental retina. The leading processes of Meitar neurons arrive in the dorso-central vitreal surface of the retinal epithelium at CS16, followed at CS17 by the appearance of the first locally generated ganglion cells at the same location. The leading and trailing processes of Meitar neurons, with multiple varicosities, are easily distinguishable from the smooth GAP-43-positive axons of ganglion cells. The axons of the first ganglion cells follow the processes of the pioneering Meitar neurons into the optic head, then run through the optic

stalk, invading the basal diencephalon at late CS 18.The non-axonal processes of Meitar cells might not only constitute a guidance scaffold for subsequent axonal navigation but also provide a route for molecular communication between brain and optic cup, conceivably playing a part in orchestrating local neurogenesis. In rodents, cats and monkeys, the first axons to enter the optic stalk are from ganglion cells, and before their appearance, the wall of the stalk, like the retina, is composed of undifferentiated neuroepithelium. In ferrets, transient retinopetal axons from the diencephalon enter the optic stalk but do not invade the retina. No cell type comparable to Meitar neurons has been reported in any other mammalian species.

Title: Cyclin d2 controls the generation of a subpopulation of retinal ganglion cells in the ciliary margin zone of the ventral mammalian retina

Authors: *F. MARCUCCI[1], V. MURCIA-BELMONTE[2], E. HERRERA[2], C. MASON[1]; [1]Pathology, Columbia Univ., New York, NY; [2]Inst. de Neurociencias de Alicante, Alicante, Spain

Abstract: The retina of lower vertebrates and chick grows continuously through life by integrating new neurons from a population of proliferating progenitors located at the ciliary margin zone (CMZ). It is unknown whether the mouse CMZ niche provides the neural retina with retinal cells. By performing live imaging in a transgenic mouse line that expresses eGFP in the CMZ and peripheral neural retina, we observed that some cells located in the CMZ move laterally to populate the zone where differentiated retinal ganglion cells (RGC) reside. In

addition, we observed that Cyclin D2, a protein that regulates cell cycle progression, is highly expressed in the proximal CMZ of the ventral retina. Cyclin D2 is required for proliferation and generation of RGCs, in particular, the ipsilaterally projecting RGCs (iRGCs). Interestingly, in the retina of albino mice, which have fewer iRGCs than pigmented retinas, the number of Cyclin D2-positive cells is reduced. Together, these results support the idea that in mammals, the developing CMZ could act as a neurogenic area, giving rise to subsets of RGCs ultimately located in the peripheral neural retina, and that the proper generation of those RGCs depends on the activity of Cyclin D2.

Title: FOXP2 modifies the chromatin landscape of developing neurons

Authors: *S. L. HICKEY, S. BERTO, G. KONOPKA;
Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: FOXP2 is among the few genes implicated in heritable forms of verbal dyspraxia. Because FOXP2 is a transcription factor expressed in the brain during development, its role in regulating developmental pathways that might be important for speech and language has been of particular interest. By analyzing FOXP2 whole genome binding and gene regulation in human neural progenitors (hNPs), we have found evidence that FOXP2 may actively modify the chromatin landscape. We hypothesize that by modifying the chromatin landscape of neural progenitors FOXP2 turns off cellular programs that maintain an undifferentiated state while turning on programs that drive a cell towards a neuronal fate. To further understand the role of FOXP2 in chromatin modification during neural differentiation, we identified areas of nucleosomal depletion using an assay for transposase-accessible chromatin using sequencing (ATAC-seq) in proliferating and differentiating hNPs with and without FOXP2. Using this approach, we found that cells expressing FOXP2 have open chromatin near genes involved in neuron differentiation, and closed chromatin at genes involved in development. Moreover, many of the identified accessible sites are only present in differentiating cells expressing FOXP2,

suggesting that FOXP2 may act as a pioneer factor. Together, these data examine epigenetic regulation by FOXP2 in human neural progenitors over development, a novel role for FOXP2 outside of its previously studied function as a canonical transcription factor.

Title: Turn-over and function of H3K79 methylation in post-mitotic neuronal development

Authors: *H. V. HEESBEEN;
Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Neuronal progenitors that become post-mitotic still need to follow a long developmental path to finally turn into mature neurons. During this time-window, gene-activity remains heavily regulated, partly by the modification of histones. The roles of histone modificiations in post-mitotic neuronal precursors, when new histones are only introduced by active turnover and not by chromatin duplication, may thus depend on the balance between methylation versus histone turn-over and demethylation. In this study we have focused on Dot1, a methyltransferase that may play a substantial role in the fine-tuning of gene-regulation by facilitating methylation of lysine 79 on histone 3 (H3K79), which levels correlate with transcription. In addition, H3K79 methylation has been proposed to be conservative and no demethylating enzyme has been found thus far. Here, we have investigated the turnover of H3K79 methylation in post-mitotic neurons and sequentially investigated the set of transcripts under regulation of Dot1 activity, the only H3K79 methyltransferase. Herefore we have used mouse models of dopaminergic post-mitotic development and investigated the speed of H3K79 methylation loss in the absence of Dot1. Our data indicates a high turnover of H3K79 methylation. Furthermore, we have found a level-dependent specificity in gene-regulation by Dot1 in post-mitotic dopamine neurons. Finally, loss of Dot function did not affect all dopaminergic neuronal subtypes equally but especially lead to the reduction of substantia nigra dopamine neurons.

Title: Embryonic development of neurons selectively vulnerable in Parkinson's disease

Authors: *M. A. OLIVEIRA, R. BALLING, R. M. T. FLEMING;
Luxembourg Ctr. For Systems Biomedicine (LCSB),, Esch-Sur-Alzette, Luxembourg

Abstract: A specific set of brainstem nuclei have been proposed to be susceptible to degeneration by histopathological analysis of subjects with suggested prodromal or established early Parkinson's disease. We hypothesise that neuronal vulnerability reflects a shared cellular and molecular phenotypic characteristics that confer selective vulnerability to degeneration. Neuronal cellular and molecular phenotypic specification is mainly the cumulative result of a transcriptional regulatory program active during the development of the nervous system. By manual curation of the developmental biology literature, we comprehensively reconstructed an anatomically resolved cellular developmental lineage of the adult neurons in five brainstem nuclei that are selectively vulnerable to degeneration in early Parkinson's disease. We formed a synthesis of the transcription factors that are required to be active, or required to be inactive, in each of these five brainstem nuclei. Certain transcription factors, e.g., Ascl1 and Lmx1b, seem to required for specification of many neuronal populations that are susceptible to degeneration in early Parkinson's disease. Systematic in vivo assessment of fate determining transcription factors should be completed for all neuronal populations susceptible to degeneration in early Parkinson's disease.

Title: An ancient neurotrophin receptor code, investigating somatosensory neuron diversification in larval zebrafish

Authors: P. GAU, A. CURTRIGHT, D. RAIBLE, *A. K. DHAKA;
Biol. Structure, The Univ. of Washington, Seattle, WA

Abstract: Zebrafish have different survival requirements than terrestrial vertebrates. Within days post fertilization (dpf) zebrafish larvae are fully functioning animals that must survive in a hostile environment while they develop into mature fish. As we have reported previously the presence of nociceptive ion channels in all early born TG neurons suggests that nociceptors are the first lineage of somatosensory neurons to develop in fish. This is distinct from terrestrial vertebrates that develop *in ovo* or *in utero* where mechanoceptors and proprioceptors arise during early stages of neurogenesis followed by the formation of nociceptors, suggesting that in zebrafish nociceptors take precedence in larval survival. Notably the expression profile of nociceptive ion channels in zebrafish is consistent with profiles observed in terrestrial vertebrates. These observations argue that fish have substantially different somatosensory requirements than terrestrial vertebrates yet the coding of nociceptor lineages remains largely conserved. During terrestrial vertebrate embryonic development, progenitors differentiate into distinct subclasses that are marked by the unique expression of neurotrophin receptors that are instructive for their survival and specification. Nociceptors, which process pain information, express TrkA; mechanorecepetors which process light touch information, express TrkB and proprioceptors, which measure muscle tension and provide information about limb position, express TrkC. In this study we explore the development of somatosensory neuron populations in larval zebrafish by characterizing the neurotrophin receptor code of sensory neuron populations and investigating genetic programs that shapes somatosensory neuron diversification.

Title: Lmx1b influences the subset specification of mesodiencephalic dopaminergic neurons

Authors: *I. WEVER, P. LARGO BARRIENTOS, M. P. SMIDT;
Mol. Neurosci., Swammerdam Inst. For Life Sci., Amsterdam, Netherlands

Abstract: The Lim Homeobox transcription factor 1 beta (Lmx1b) has been identified as one of the transcription factors that play an important role during the development of mesodiencephalic dopaminergic (mdDA) neurons. During early development, Lmx1b is essential for induction and maintenance of the Isthmic Organizer (IsO), and genetic ablation of this factor results in the disruption of the inductive activity from the IsO and loss of properly differentiated mdDA neurons.
To study the downstream genetic targets of Lmx1b without affecting the IsO, we generated a conditional model in which Lmx1b was selectively deleted in the Pitx3 expression domain from embryonic day (E)11.5 onward. In accordance with literature, no significant changes could be observed in general dopamine (DA) marks, like Th, Pitx3, Vmat2 and En1 at E14.5 and the animals were born at expected Mendelian frequency, were fertile and survived to adulthood. Next to examining the general DA marks, we also investigated several subset marks. The mdDA system can be roughly divided into two groups, namely the substantia nigra Pars Compacta (SNc) and the ventral tegmental area (VTA). Although the two groups originate from the same progenitor pool, they are molecularly different and are differentially depending on transcription factors for their proper development. The rostrolateral group, destined to become the SNc, requires both Pitx3 and En1 to induce the DA phenotype and is closely marked by Ahd2. While the caudal group, destined to become the VTA, is mainly dependent on En1 for the induction of the DA phenotype and is marked by Cck. When looking at these two subgroups at E14.5, we observed a significant up-regulation of the rostrolateral mark Ahd2, while Cck expression is unaffected. When examining other subset marks, like Dat and Calb1, no clear differences were observed, suggesting that Lmx1b might only be important for the regulation of Ahd2. Further studies showed that over-expression of LMX1B in MN9D cells leads to a down-regulation of Ahd2, while expression levels of other factors, like Th and Pitx3, remain unaltered. In addition, we found that Lmx1b can bind to a FLAT element in the Ahd2 gene, suggesting that Lmx1b might influence Ahd2 expression directly by binding to this element.

Title: Transcriptional control of the specification of spinal CSF-contacting Neurons

Authors: D. J. DI BELLA[1], A. L. CARCAGNO[1], M. B. PARDI[2], M. SARTORETTI[1], L. BRUM[1], A. MARÍN-BURGIN[2], *G. M. LANUZA[1];
[1]Inst. Leloir, Buenos Aires, Argentina; [2]IBIOBA, Buenos Aires, Argentina

Abstract: The generation of precise neuronal types in the right time and quantity, is essential for building a functioning nervous system. In the last 20 years, we have reached a huge understanding of the genetic mechanisms that control neuron specification during embryonic development, in which extrinsic cues are translated into positional coordinates that determine neuronal identity. However, the temporal contribution to neuronal diversity has been less explored. We have recently identified a neurogenic event in the amniote spinal cord that takes place simultaneously with glial specification, during advanced developmental stages previously considered non-neurogenic. CerebroSpinal Fluid contacting Neurons (CSF-cN), widely conserved in chordates, are located at the interface between the central nervous system and the CSF and are generated from late ventral progenitors. The genetic mechanisms that allow the differentiation of this class of neurons at gliogenic stages are unknown. In this work, we identified that the transcription factors Ascl1, Gata3 and Gata2 are sequentially expressed in mouse CSF-cN and control their specification. Through expression analysis and mouse genetics, we described that Gata3 and Gata2 are postmitotically expressed in CSF-cN, where they control the acquisition of this neuronal identity. Loss of function experiments showed that Gata3 and Gata2 play distinct roles in different CSF-cN subsets. Meanwhile, the proneural protein Ascl1 is expressed in late ventral proliferating progenitors that give rise to CSF-cN and is exclusively necessary for their differentiation in amniotes. By temporal dissection of Ascl1 activity, we found that this transcription factor is an essential component of late CSF-cN neurogenesis, acting at the time of their specification. Finally, fate mapping experiments in the absence of Ascl1 demonstrated that it confers neurogenic potential to late ventral progenitors, which would otherwise become ependymal cells. We conclude that the sequencial action of Ascl1-Gata3/2 directs the late specification of CSF-cN in amniotes. Ascl1 acts governing the onset of neuronal differentiation in the gliogenic neural tube and Gata3/2 control CSF-cN identity.

Title: Identification of STAM1 as a novel effector of ventral projection of spinal motor neurons

Authors: ***S. LEE**, H. NAM;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: During spinal cord development, motor neuron (MN) axons exit the spinal cord ventrally, although the molecular basis for this process remains poorly understood. STAM1 and Hrs form a complex involved with endosomal targeting of cargo proteins, including the chemokine receptor CXCR4. Interestingly, the absence of CXCR4 signaling in spinal MNs is known to enforce improper extension of the axons into the dorsal side of the spinal cord. Here we report that the MN-specific Isl1-Lhx3 complex directly transactivates the *Stam1* gene and STAM1 functions in determining the ventral spinal MN axonal projections. STAM1 is co-expressed with Hrs in embryonic spinal MNs, and knock-down of STAM1 in the developing chick spinal cord results in down-regulation of the expression of CXCR4, accompanied by dorsally projecting motor axons. Interestingly, overexpression of STAM1 or CXCR4 also results in dorsal projection of motor axons, suggesting that proper CXCR4 protein level is critical for the ventral motor axon trajectory. Our results reveal a critical regulatory axis for the ventral axonal trajectory of developing spinal MNs, consisting of the Isl1-Lhx3 complex, STAM1 and CXCR4.

Title: The mechanistic basis by which the Bone Morphogenetic Proteins direct sensory interneuron identity in the dorsal spinal cord

Authors: *M. ANDREWS, L. DEL CASTILLO, D. SIVALINGAM, S. J. BUTLER; Neurobio., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Inductive signaling by the Bone Morphogenetic Protein (BMP) family is reiteratively required to direct stem and progenitor cells towards different cellular fates throughout embryonic development. This family of growth factors is thus a critical reagent used in many stem cell replacement therapies. As part of the effort to develop stem cell-based approaches to rebuild damaged or diseased spinal cords, we are studying how the BMPs direct neuronal identity in the embryonic spinal cord. The roof plate (RP), at the dorsal midline of the spinal cord, expresses many BMPs and the collective activity of these BMPs is required to specify different populations of sensory interneurons (INs) in the adjacent dorsal spinal cord. Surprisingly, the mode by which the BMPs direct IN identity remains unresolved, and there is no established protocol to derive these classes of spinal sensory INs in vitro. Previous studies have suggested that the BMPs act as concentration-dependent morphogens to direct neural identity, largely by analogy with the Sonic hedgehog gradient that patterns the ventral spinal cord. However, it is unclear how multiple BMPs would cooperate to establish a single morphogen gradient. Moreover, our recent studies have suggested that different BMPs have distinct effects on the induction of particular IN fates. Using both in vitro and in vivo methods, we are assessing the extent to which the different BMPs act in a concentration dependent manner, or have signal-specific activities in directing cellular identity. Additionally, we are evaluating how the canonical BMP second messengers, the Smad proteins, translate the activities of the different BMPs into the specification of particular neural identities. Through these studies, we will better understand the mechanism by which the BMPs direct IN identity during development while also developing a stem cell differentiation protocol as a first step towards the restoration of sensory circuitry after spinal damage.

Title: Hox proteins generate neuronal diversity by regulating the transcriptional output of a single terminal selector gene

Authors: *P. KRATSIOS[1], S. YEN KERK[2], O. HOBERT[2];
[1]Neurobio., Univ. of Chicago, Chicago, IL; [2]Columbia Univ., New York, NY

Abstract: Understanding how the expression of neuron class-specific genes is established during development is of key importance to the problem of neuronal diversity. Exploiting the molecular diversity of distinct motor neuron (MN) classes in *C.elegans*, we show that the conserved COE-type terminal selector UNC-3 is required for MN diversity by directly regulating the expression of MN class-specific terminal identity genes. We further find that Hox proteins cooperate with UNC-3 and remarkably employ two distinct, region-based strategies to generate MN diversity. In the *C.elegans* ventral nerve cord, the more anteriorly expressed *Hox* genes, *lin-39*/Scr/Dfd and *mab-5* (Antennapedia-type), act as UNC-3 coactivators and directly regulate the expression of MN class-specific genes. Conversely, the posterior *Hox* gene *egl-5/Abd-B* represses *lin-39* and *mab-5 expression*, thereby diversifying posteriorly located MNs. Intriguingly, *Hox* and *unc-3* orthologs are coexpressed in mouse MNs along the spinal cord, suggesting that this intersectional, region-based regulatory principle may be conserved across phylogeny.

Title: Effects of response learning on medium spiny neurons and astrocytes in the dorsal striatum

Authors: *B. A. BRIONES[1,2], E. GOULD[1,2];
[1]Psychology, [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: In the rodent, the dorsolateral striatum (DLS) is required for motor-response learning (Packard & Knowlton, 2002). Despite strong evidence linking the DLS with response learning, little is known about whether the region is structurally plastic in response to engagement in response learning tasks. Such information would fill in the gaps in our knowledge of how the striatum responds to experience and may provide clues about the mechanisms underlying response learning. To investigate this question, we used DiI labeling to analyze dendritic spines, primary sites of excitatory synapses, on medium spiny neurons. Our preliminary results suggest that response learning increases dendritic spine density and head width in the DLS and produces greater immediate early gene expression in the DLS compared to the dorsomedial striatum, a region implicated in spatial-place learning. Next, since it is becoming increasingly clear that neurons work in concert with nonneuronal cells to mediate synaptic function and plasticity (Barres, 2008), we examined whether morphological differences exist in GFAP-labeled astrocytes after dorsal striatum dependent behavior and found that GFAP-labeled astrocyte number and size was greater in response learning animals compared to controls. Future studies will seek to understand the functional consequences and region-specificity of these differences as well as the potential role of astrocytes and astrocyte-neuron interactions in response learning.

Title: Genetic analysis of KA and V2b neuron specification in zebrafish spinal cord

Authors: *S. BANERJEE[1], L. ANDRZEJCZUK[1], S. J. ENGLAND[1], A. PRENDERGAST[2], L. DESBAN[2], S. HARVEY[3], H. WILLIAMS[3], R. KETTLEBOROUGH[3], C. WYART[2], K. E. LEWIS[1];

[1]Syracuse Univ., Syracuse, NY; [2]INSTITUT DU CERVEAU ET DE LA MOELLE EPINIERE, Paris, France; [3]Wellcome Trust Sanger Inst., Cambridge, United Kingdom

Abstract: Coordinated motor behavior is critically dependent on neural circuits that form within the ventral spinal cord. Three types of GABAergic interneurons that are important components of these circuits are V2b interneurons and two classes of Kolmer Aghdur (KA) CSF contacting neurons (KA' and KA'' cells). These three types of neurons originate from three distinct progenitor domains in the ventral spinal cord. Although recent research has identified some physiological functions and behavioral roles of these interneurons, little is known about how these cells are functionally specified during development. V2b and KA neurons express post-mitotic transcription factors Gata2, Gata3 and Tal1. Using mutants for each of these genes we have shown that these three transcription factors have unique roles in determining the GABAergic identity and regulating the expression of several other transcription factor genes in V2b and KA neurons. Interestingly, we found that even though Gata2, Gata3 and Tal1 are expressed in all three cell types, the phenotypes of each of the three mutants affect different subsets of KA and V2b cells.
To identify additional genes that may be involved in specifying functional properties of KA neurons, we have isolated pure populations of these cells using FACS and performed RNAseq analyses. We have identified 293 genes that are enriched in KA neurons compared to a pan neuronal population. We are analyzing these genes by expression (*in situ* hybridization) and functional (loss of function mutant) studies. Together, data from these studies will provide a more comprehensive understanding of the development of V2b and KA/CSF contacting neurons.

Title: Investigation of dopaminergic neuron lineage marker expression from human nato3 overexpression in the developing chick embryo

Authors: *D. DOYLE, J. KOELSCH, N. HUISINGH, M. TAYLOR;
Grand Valley State Univ., Allendale, MI

Abstract: In Parkinson's disease, the loss of mesencephalic dopaminergic neurons within the pars compacta region of the substantia nigra could be ameliorated with cell replacement therapy. There is no clear answer as to how Nato3, a basic helix-loop-helix transcription factor expressed in the floorplate of the developing midbrain, affects the generation of dopaminergic neurons in the developing nervous system. Previous studies in our lab have investigated the effects of an overexpression of Nato3 from *Mus musculus* in the developing chick embryo. We found that overexpressing Nato3 sufficiently induces ectopic expression of the floor plate cell markers Shh and Foxa2 in the developing midbrain, as well as the immature dopamine neuron marker Lmx1b in the developing midbrain and spinal cord. Through the use of *in ovo* electroporation of a bicistronic EGFP reporter expression vector, and immunohistochemistry we are currently examining the effects of overexpression of Nato3 from *Homo sapiens* in the developing chick embryo. The results are expected to be similar to that obtained with Nato3 from *Mus musculus* based on 100% identity between the two protein sequences within the loop region of the transcription factor. The previous information obtained with Nato3 from *Mus musculus* provides evidence that Nato3 affects cells within a dopaminergic neuron lineage. Characterization of the effects of the overexpression of Nato3 from *Homo sapiens* could identify possible uses related to the development of dopaminergic neurons for cell therapy.

Title: Prostaglandin E2 promotes neurite outgrowth via EP2-cAMP signaling pathway in NSC-34 cells, a motor neuron-like cell line.

Authors: *H. NANGO, Y. KOSUGE, K. ISHIGE, Y. ITO;
Lab. of Pharmacol., Sch. of Pharmacy, Nihon Univ., Funabashi-Shi, Japan

Abstract: Prostaglandin E2 (PGE2), one of the major lipid mediators, exerts various biological effects by binding to 4 subtypes of E-prostanoid receptors (EP1-4). In addition, it is well known that PGE2 induces cell proliferation and differentiation in a number of different cells. However, the effects of PGE2 on cell proliferation and differentiation of motor neurons have not been clarified. The purpose of this study was to elucidate the mechanism of PGE2-induced differentiation of motor neurons using NSC-34 cells, a mouse motor neuron-like cell line.
We first examined whether exogenously applied PGE2 can suppress cell proliferation in undifferentiated NSC-34 cells using MTT reduction assay. Exposure of these cells to PGE2 (1-100 μM) for 48 h resulted in a reduction of MTT activity in a concentration-dependent manner. Immunoblotting studies showed that EP2 and EP3 were dominantly expressed in NSC-34 cells as well as motor neurons in mice. In order to clarify the subtype of EP receptors that contribute to effects of PGE2 in the cells, we investigated effects of two different types of EP agonists on cell proliferation in these cells. Treatment of these cells with butaprost (1-20 μM), an EP2-selective agonist, resulted in a concentration-dependent decrease of MTT reduction, and this effect was stronger than that that of PGE2. In contrast, sulprostone (1-30 μM), an EP1/3 agonist, had no effect. Next, we observed morphological transformation with phase-contrast microscope to evaluate the effects of PGE2 and these EP agonists on neurite outgrowth, and found that PGE2 and butaprost but not sulprostone promoted neurite outgrowth and increased the number of neurite-bearing cells. We also investigated the cytotoxic effects of PGE2 and butaprost on undifferentiated NSC-34 cells by propidium iodide (PI) fluorescent staining. Exposure of these cells to PGE2 and butaprost for 48 h did not increase the number of PI-positive cells. Dibutyryl-cAMP (1 mM), a cAMP analog, increased the number of neurite-bearing cells with no effect on cell proliferation in these cells.
In conclusion, the present study showed that PGE2 promotes neurite outgrowth and suppresses cell proliferation via EP2 subtype, and that cAMP-signaling pathway is involved in PGE2-induced differentiation of NSC-34 cells.

Title: Temporal transcription factor expression delineates lateral hypothalamic neurogenesis.

Authors: *H. R. TWIGG, C. L. JASONI;
Univ. of Otago, Dunedin, New Zealand

Abstract: There is clear evidence for a link between maternal obesity during pregnancy and the offspring's heightened risk for disease in later life, including obesity and the metabolic syndrome. This effect has been replicated in numerous rodent and primate models of maternal obesity. The hypothalamus is the key player in the neural regulation of body weight and energy homeostasis. Neurons of the hypothalamus receive endocrine signals from the body and begin to coordinate appropriate behavioural and physiological responses. Melanin-concentrating hormone (MCH)-producing neurons of the lateral hypothalamus (LH) are orexigenic, and contribute to body weight regulation by promoting feeding and consummative behaviours, amongst other homeostatic roles. We and others found an increase in expression of *pmch*, the mRNA encoding MCH, in offspring from obese rodent dams. However, whether this was due to an increase in the number of *pmch*-expressing cells, or an increase in the amount of *pmch* RNA expressed per cell was unclear. We have recently observed an increase in the number of MCH-expressing cells in offspring from obese dams. We hypothesise that this change in cell number occurs due to altered expression of developmental genes in the developing hypothalamus, such that hypothalamic progenitor cells produce increased numbers of differentiated MCH-expressing cells. To address this hypothesis, we first searched online resources to select transcription factors with putative binding sites at conserved regions of *pmch*, and which are known to be expressed in the developing hypothalamus. These transcription factors include *Dbx1,* which has a known role in MCH development, *Sim1,* and *FoxO1.* RNA was collected from the developing LHA from both wild-type mouse embryos, and embryos from obese mothers at gestational days (GD) 11.5, 14.5, 16.5 and 18.5, and transcription factor expression was assessed using quantitative PCR (qPCR). *FoxO1* showed stable expression across normal development. *Sim1* showed low levels of expression at GD11.5 but gradually increased to peak at GD18.5. *Dbx1* showed low levels of expression at GD11.5, peaked dramatically with a 16-fold increase at GD14.5, dropping again to GD11.5 levels by GD18.5. Maternal obesity during pregnancy affected the normal expression profile of these genes in the fetal hypothalamus. Perturbation to the expression profiles of transcription factors required for normal LH and MCH cell development, influenced by maternal obesity, may therefore contribute to an altered fate of hypothalamic progenitors, and thus to an increase in orexigenic MCH neurons.

Abstract: The establishment of neuronal polarity is vital for neuronal migration, the wiring of neuronal circuits, and synaptic connectivity; the disruption of these processes leads to various neurodevelopmental disorders such as autism spectrum disorder, mental retardation, and schizophrenia. Well-orchestrated extracellular and intracellular signaling cascades shape neuronal polarization, and actin cytoskeleton reorganization is of particular importance. Here, we investigated the function of Coronin 2B, a member of an evolutionarily conserved actin-binding protein family, during neuronal polarization. Coronin 2B was enriched in the mouse nervous system, specifically in the cerebral cortex and hippocampus. In early differentiating cultured hippocampal neurons, Coronin 2B was concentrated at neurite tips and co-localized with F-actin. Silencing Coronin 2B expression in hippocampal neurons by shRNA significantly reduced the number of MAP2-positive dendrites, while overexpression increased the number of MAP2-positive dendrites, accompanied by the loss of tau-positive axons. These findings strongly suggest that Coronin 2B is a key regulator of neuronal polarization. Further understanding of the roles of Coronin 2B in the establishment of neuronal polarity may provide clues on its functions in central nervous system development.

Abstract: The cellular production, distribution and migration dictates the architectonic organization of brain, which includes both stratified (e.g. neocortex) and nuclear (e.g. thalamus, hypothalamus and brain stem) structures. In contrast to the well-studied stratified neocortex, little is known about the cellular production and organization in the nuclear structures. Using multiple driver lines including Gli1-CreER^{T2}, Axin2-CreER^{T2}, Neurog1-CreER^{T2} or Olig3-CreER^{T2} mice in combination with Mosaic Analysis with Double Markers (MADM)-based multicolor reporter system, we trace the ontogenetic clonal units arising from individual neuroepithelial cells (NEs) or intermediate progenitor cells (IPCs) to determine the cellular production and organization in the thalamus. Clonal analysis uncovers that Gli1- and Axin2-labeled NEs generate more progeny cells than Olig3-labeled population, suggesting Shh- and Wnt-responding populations of NEs with higher potency in proliferation. The clonally-related neurons generated by individual NEs are typically organized into radial columns, which specify a specific set of thalamic nuclei. There are no significant differences in cellular distribution and organization among Gli1-, Axin2- and Olig3-labeled clones. A majority of Neurog1-labeled clones contain 4 or fewer cells but they still populate different nuclei, indicating a late specification of nuclear fate. Taken together, our study reveals the NEs building the thalamus are heterogeneous in generating progeny cells but utilize uniform principles to organize sibling thalamic neurons.

Abstract: Vasoinhibins (Vi) are a family of peptides derived from the hormone prolactin that have been shown to act on endothelial cells inhibiting angiogenesis, vasodilation and vasopermeability. Furthermore, Vi can participate in the modulation of some functions of the central nervous system (CNS) such as stimulating vasopressin secretion and promoting anxiety and depression behaviors. The hippocampus has been implicated in these behaviors; thus, in the present study we explored whether Vi are generated in this structure and if they affect hippocampal neurons. Extracts from hippocampus were evaluated for the presence of Vi as well as for the intrinsic capacity of this tissue to cleave prolactin to generate Vi. To explore the actions of Vi on hippocampal neurons, primary fetal hippocampal neuron-enriched cultures were isolated from the brain of E16 mice and seeded on plates treated with poly-L-lysine. Hippocampal cultures were treated on the first day in vitro (DIV1) with increasing concentrations of Vi (5-20 nM) for up to 72 hours (DIV2-DIV4). Vi were found in the hippocampus, and incubation of prolactin with extracts from hippocampus resulted in the proteolysis of this hormone to yield Vi, both revealed by Western blot. Incubation of hippocampal neuron-enriched cultures with Vi reduced in a dose-dependent manner the cell number, as well as the metabolic activity, evaluated by microphotography image analysis and MTT assay, respectively. Altogether these findings show that Vi are produced locally in the hippocampus and are able to affect its neurons, suggesting a possible site for the reported actions of Vi on anxiety and depression.

Title: Genomically mosaic neurons of the adult mouse brain identified by DNA content variation (DCV)

Authors: *B. A. SIDDOWAY[1,2], S. ROHRBACK[2], C. SAUVEY[2], G. KAESER[2], A. CHEN[2], A. CERDA[2], M.-H. LEE[2], J. CHUN[2];

Abstract: Recent reports have determined that neurons from the same individual display substantial genomic variability among themselves and from germline. These newer studies confirm older work and hypotheses regarding the existence of genomically mosaic neurons in the brain. The physiological role of genomic mosaicism in neuronal populations remains unknown, however, genomic variability appears to be a standard feature of mature neurons in the normal brain and is consistently increased in sporadic Alzheimer's disease (SAD). Mosaic genomic differences among human neurons occur in many forms, including aneuploidies, copy number variations, repeat domain variability, LINE element insertions, single nucleotide variations, and global variability in DNA content (DNA content variation (**DCV**)) occurring both during and after neurodevelopment. It has been less clear whether DCV is present in the mouse brain. Here we report results from whole genome DNA content analysis in several mouse lines that indicate **DCV** exists and is enriched in neuronal subpopulations when compared across both brain regions and cell types. These results were validated by examining total DNA yield of flow sorted nuclei from each subgroup as well as via a semi-quantitative whole genome amplification approach. We have additionally developed and optimized single-cell sequencing methodology to examine mosaic genomic variation among individual neurons from adult mouse hippocampus. The presence of DCV and genomic variability in mouse neurons complements data from human brain and represents an animal model to investigate and characterize genomic mosaicism in the central nervous system.

Title: Neurog1 transcriptional activity is dependent on cellular context

Authors: ***C. SONG**, K. KWAN;
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: Loss of spiral ganglion neurons (SGNs) is a major cause of hearing loss. There are currently no available treatments for SGN loss. Understanding the role of key transcription factors that promote SGN differentiation will accelerate efforts for stem cell replacement therapies. Neurog1, a pro-neural transcription factor, is highly expressed in the neural-sensory-competent domain (NSD) of the developing inner ear. Neurog1 is required for generation of SGNs during otic neurogenesis. Repurposing Neurog1 activity is a potential way to promote SGN regeneration. We employ a immortalized multipotent otic progenitor (iMOP) cell line that can self-renew or differentiate into SGNs depending on various molecular cues. By overexpression or knockdown of Neurog1 in iMOP cells, we determined that Neurog1 promotes proliferation in the multipotent progenitors and confers neuronal fate during differentiation by promoting expression of different downstream targets. ChIP-seq experiments of active(H3K4me3) and repressive(H3K27me3) chromatin marks suggest that Neurog1 target genes may be transcriptionally regulated. In conclusion, our findings show that the function of Neurog1 is context dependent and can partly be attributed to the epigenetic status of its downstream targets.

Title: Both FGF2- and protein kinase C-mediated signaling determine differentiation of SH-SY5Y human neuroblastoma cells.

Authors: *L. A. DOKAS, S. J. WATSON, H. AKIL;
Univ. of Michigan, Ann Arbor, MI

Abstract: The SH-SY5Y cell line is an N-type neuroblastoma with catecholaminergic properties. These cells can be further differentiated by several mechanisms including the combination of a growth factor and a phorbol ester that activates protein kinase C (PKC). One of the most effective growth factors in this regard is FGF2. Given the phenotype of SH-SY5Y cells, differentiation with FGF2 and phorbol ester may model development from a neuroblastic stage to more mature neuronal morphology. We have previously reported that FGF2 and the phorbol ester, phorbol 12, 13-dibutyrate (PDB) each affect the morphology of differentiating cells: PDB produces lamellipodial profiles while FGF2 elongates cells and processes. In combination, highly networked cells result. In order to understand the signaling that underlies these changes, interactions between FGF2 and PKC are being characterized in undifferentiated and differentiated cells. Both FGF2 and PDB activate the extracellular stimulus-regulated kinase1/2 (ERK1/2) pathway, measured as phosphorylation of the activation domain of ERK1/2 at Thr202/Tyr204, with a considerable degree of crosstalk in undifferentiated cells. Although only the effect of FGF2 is blocked by the FGF receptor (FGFR)-selective inhibitor, PD 173074, the PKC inhibitor, GF 109203X, blocks both PDB- and FGF2-mediated ERK1/2 phosphorylation. One likely site of this crosstalk is at the level of raf since inhibition of MEK1/2, the protein kinase target of raf, affects ERK1/2 phosphorylation in response to either stimulus. Furthermore, ERK1/2 phosphorylation in response to FGF2 is lost in differentiated cells indicating that a change in FGFR sensitivity or coupling occurs during the process of differentiation. As a second means of characterizing involvement of PKC in SH-SY5Y cell differentiation, phosphorylation of two major substrate proteins, myristoylated alanine-rich C kinase substrate (MARCKS) and growth-associated protein-43 (GAP-43) have been compared. Both expression and phosphorylation of GAP-43 at Ser41 are increased in differentiated cells, principally in response

to PDB. MARCKS phosphorylation at Ser167/170 is also PDB-sensitive; however, in this case, co-exposure to FGF2 reduces levels of phospho-MARCKS. Since both MARCKS and GAP-43 are involved in actin-based remodeling of the neuronal cytoskeleton, differential regulation of their phosphorylated states by PKC and FGF2 could underlie the changes in cell morphology seen during differentiation of SH-SY5Y cells.

Title: Assessment of membrane fluidity changes during cellular development reveals time and cell type specificity

Authors: *P. NOUTSI[1], E. GRATTON[2], S. CHAIEB[3];
[1]Kaust/Biological & Envrn. Sci. & Eng., Thuwal, Saudi Arabia; [2]UCI, Irvine, CA; [3]KAUST, Thuwal, Saudi Arabia

Abstract: Cell membrane is made up of a complex structure of lipids and proteins that diffuse laterally giving rise to what we call membrane fluidity. During cellular development such as neuronal differentiation cell membranes undergo dramatic structural changes induced by proteins such as ARC and Cofilin among others in the case of synaptic modification. In this study we used the generalized polarization (GP) property of fluorescent probe Laurdan using two-photon microscopy to determine membrane fluidity as a function of time and for various cell lines. A low GP value corresponds to a higher fluidity and a higher GP value is associated with a more rigid membrane. Four different cell lines were monitored such as hN2, NIH3T3, HEK293 and L6 cells. Membrane fluidity was measured at 12h, 72h and 92 h. Our results show significant changes in membrane fluidity among all cell types at different time points. GP values tend to increase significantly within 92 h in hN2 cells and 72 h in NIH3T3 cells and at 92 h in HEK293 cells. L6 showed a marked decrease in membrane fluidity at 72 h and starts to increase at 92 h. As expected, NIH3T3 cells have more rigid membrane at earlier time points. On the other hand neurons tend to have the highest membrane fluidity at early time points emphasizing its

correlation with plasticity and the need for malleability during development. This study sheds light on the involvement of membrane fluidity during development in neurons and other cell lines

Title: Ethanol exposure induces Id gene expression in neural stem cells

Authors: ***A. TSENG**[1], N. SALEM[1], S. BURROWES[1], S. BALARAMAM[1], A. MAHNKE[1], S. EAVES[2], M. RAVEN[2], C. GARCIA[2], C. BEDDINGFIELD[2], R. MIRANDA[1];
[1]Mol. & Cell. Med., Texas A&M Hlth. Sci. Ctr., College Station, TX; [2]Texas A&M Univ., College Station, TX

Abstract: Prenatal alcohol exposure can result in a cluster of craniofacial, neuro-cognitive and growth deficits that are collectively termed Fetal Alcohol Spectrum Disorders (FASD). FASD is difficult to prevent and is the leading non-genetic cause of neurodevelopment disability worldwide. Neural stem cells (NSCs) are particularly vulnerable to alcohol (ethanol) exposure during the late first through the second trimester, when they are most extensively involved in neurogenesis. We previously found that ethanol induced premature depletion and aberrant maturation of NSCs. The mechanisms underlying aberrant NSC maturation are poorly understood. We hypothesized that the ID (Inhibitor of DNA binding) protein family was a potential mediator of ethanol induced NSC dysfunction. All four members of this highly conserved protein family regulate differentiation of NSCs during development and in the adult, by binding and inhibiting the activity of a number of basic helix-loop-helix transcription factors. We report mRNA transcripts of three out of the four ID protein family members are significantly decreased during neural differentiation, and furthermore, that ethanol increased expression of these transcripts in fetal NSCs. We further confirmed elevated protein expression of ID1 following ethanol exposure. Heuristic prediction of ID1 binding partners coupled with Gene Ontology (GO) analysis shows that ID1 targets are significantly enriched for determinants of

neural differentiation. Therefore, ethanol induced ID protein expression may underlie some of the aberrant neural phenotypes resulting from fetal alcohol exposure.

Title: Effects of different BMP receptor subunits on gene expression in neural progenitor cells

Authors: ***J. CHEN**[1], C.-Y. PENG[2], J. A. KESSLER[2];
[2]Neurol., [1]Northwestern Univ., Chicago, IL

Abstract: Bone morphogenetic protein (BMP) signaling regulates neural stem and progenitor cell (NPC) maturation. BMP receptors are heterotetramers composed of two BMP receptor II (BMPRII) subunits and two of either BMP receptor 1a (BMPR1a) or BMP receptor 1b (BMPR1b) subunits. Although BMPR1a and BMPR1b have similar signal transduction pathways, they exert different effects on NPC proliferation and differentiation. To examine the molecular mechanisms underlying these differences, we sequenced the RNA transcriptomes of wild-type, $BMPRII^{fx/fx}$, $BMPR1a^{fx/fx}$, and BMPR1b-/- cultured postnatal subventricular zone neurospheres treated either with BMP4 or with the BMP inhibitor, noggin. Although BMPR1a and BMPR1b have overlapping downstream signaling pathways and targets, RNA deep sequencing showed many differences in the genes they regulate. After 4 hours of BMP4 treatment, 5391 genes were significantly upregulated in wild-type neurospheres, 2183 genes in $BMPRII^{fx/fx}$ neurospheres, 1471 genes in $BMPR1a^{fx/fx}$ neurospheres, and 2737 in BMPR1b-/- neurospheres. When $BMPR1a^{fx/fx}$ and BMPR1b-/- gene lists are compared, $BMPR1a^{fx/fx}$ neurospheres have 260 genes uniquely regulated in response to BMP4 treatment, while BMPR1b-/- neurospheres have 1526 genes uniquely regulated. Using pathway analysis tools, we found that MAPK signaling, Wnt signaling, and heterotrimeric G-protein signaling are influenced by BMP4 treatment. Gene ontology analysis shows several processes differentially regulated by BMP4 treatment of $BMPR1a^{fx/fx}$ and BMPR1b-/- neurospheres, including Wnt signaling, synaptic signaling, and gliogenesis. These data support previous evidence that BMPR1a and BMPR1b activate different downstream signals in NPCs, as well as identify new BMP transcriptional targets for future study.

Abstract: Schizophrenia (SZ) is a major psychiatric disease with high heterogeneity of symptoms, one of them being cognitive deficit, which cannot be improved by available treatments. It has been suggested that impaired adult hippocampal neurogenesis (AHN) may contribute to the cognitive deficit observed in patients. Indeed, hippocampal volume reduction is a robust observation in postmortem brains of patients and some studies also found a reduction of neural progenitors. Moreover, several animal models for SZ, such as DISC1 deletion and maternal immune activation, also show decreased AHN. Several factors are known to modulate AHN, including the redox state, inflammation, as well as parvalbumin expressing fast-spiking interneurons (PVI), which are key players in SZ pathophysiology.
The aim of this study is to investigate whether the interaction between these 3 main factors may lead to impaired AHN.
We took advantage of a mouse model for redox dysregulation, the GCLM KO mice, that show SZ related phenotype. These mice have 70% decreased glutathione, an important antioxidant, and increased oxidative stress in the brain throughout life, as well as decreased PVI in the ventral, but not dorsal, hippocampus, which was related with impaired behavior related to this specific region (Steullet et al., 2010). We investigated the proliferation rate of hippocampal

progenitors and newborn neurons survival in the dorsal versus ventral hippocampus of adult GCLM KO and WT mice, using BrdU incorporation assays.
Preliminary data show a dysregulation in the proliferation and survival of newborn neurons in the GCLM KO dentate gyrus. These results suggest that the oxidative stress level in the dentate gyrus of the GCLM KO mice may affect AHN.
Further investigation will bring light on the mechanism underlying the involvement of redox and immune dysregulation, as well as PVI, on neurogenesis impairments in SZ.

Title: Age-related changes in growth factor expression in the human subependymal zone: Relationship to cell proliferation and neuronal differentiation

Authors: *C. WEISSLEDER[1], S. J. FUNG[1], M. W. WONG[1], G. BARRY[2], K. L. DOUBLE[3], G. M. HALLIDAY[1], M. J. WEBSTER[4], C. SHANNON WEICKERT[1];
[1]Neurosci. Res. Australia, Sydney, Australia; [2]Garvan Inst. of Med. Res., Sydney, Australia; [3]Brain and Mind Res. Inst., Sydney, Australia; [4]Stanley Med. Res. Inst., Bethesda, MD

Abstract: Background: Adult neurogenesis in the human subependymal zone (SEZ, also subventricular zone) adjacent to the lateral ventricles declines during normal human aging. However, it is unknown how expression of growth factors related to neurogenesis change in the SEZ throughout adulthood or how altered transcript levels may affect cell proliferation and neuronal differentiation.
Methods: In this study, we used quantitative polymerase chain reaction to measure mRNA expression of growth factors [epidermal growth factor (EGF), transforming growth factor alpha (TGFα), fibroblast growth factor 2 (FGF2)] and receptors [EGF receptor (EGFR), Erb-B2 receptor tyrosine kinase 4 (ErbB4), FGF receptor 1 (FGFR1)] in the human SEZ throughout adulthood (n=50, 21-103 years). We further performed correlation analysis between growth factor-related transcripts and expression of neurogenic (cell proliferation, neuronal

differentiation) and glial cell markers (astrocytes, microglia, oligodendrocytes).
Results: EGFR and FGF2 mRNAs increased with age, while TGFα, EGF, ErbB4 and FGFR1 mRNAs were unchanged during aging. Cell proliferation and immature neuron marker mRNAs were positively correlated with TGFα and ErbB4 expression. Astrocyte and microglial cell marker mRNAs showed a positive correlation with EGF, FGF2 and FGFR1 transcript levels, whereas EGFR expression positively correlated with oligodendrocyte marker mRNA.
Conclusion: Our findings indicate that EGF and FGF family members do not become limited with age and may modulate neurogenesis and gliogenesis in the human SEZ. Additional studies are required to anatomically map the expression of these factors to cell types and determine their regulatory role along with other important trophic factors involved in adult neurogenesis across the human lifespan.

Title: Akt-mTOR pathway interactions control postnatal neurogenesis

Authors: *A. FOSTER, J. MERCURIO, M. FINGER, N. W. HARTMAN;
Biol., Stockton Univ., Galloway, NJ

Abstract: The Akt pathway is important for cellular growth, proliferation and differentiation. Akt activation has been proposed to increase cellular differentiation and protein translation by activation of the mammalian target of rapamycin (mTOR) pathway. It is unclear whether Akt and mTOR play roles independent of each other in NSC development. NSCs in the subventricular zone (SVZ) continually generate new daughter cells that migrate to the olfactory bulb (OB), differentiating into neurons. Here, we show that a constitutively active form of Akt resulted in a threefold increase in the number of newly born neurons in the OB. In contrast to driving mTOR alone, Akt activation did not result in apparent aberrant migration in the SVZ or OB. Akt activation resulted in increased dendritic length and complexity; however, total dendritic length was not rescued via mTORC1 inhibition. Activation of the Akt pathway was also observed to push NSCs into cell cycle progression and differentiation. Blockade of downstream mTORC1 targets inhibited differentiation, but did not alter the number of

proliferative cells in the SVZ. These data suggest that Akt controls NSC differentiation via mTOR, but may exert proliferative effects on NSCs independently.

Title: The cytoplasmic FMRP interacting protein (CYFIP1) regulates neural stem cell proliferation and the maintenance of the neurogenic niche in the adult brain.

Authors: ***C. W. HABELA**[1], K.-J. YOON[1], G.-L. MING[2], H. SONG[2];
[1]Neurol., [2]Neurology, Inst. of Cell Engin. and the Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: The gene encoding cytoplasmic FMRP interacting protein (CYFIP1) is within the 15q11.2 copy number variants (CNVs), deletion and duplication of which have been linked to multiple neural developmental disorders including epilepsy, autism, intellectual disability and schizophrenia. There is increasing data to support it as an important protein in both normal and abnormal brain development. We previously showed that CYFIP1 is required for appropriate adherens junction formation in the neurogenic epithelium of the fetal brain of mice and loss of CYFIP1 function is associated with dysregulated embryonic cortical neurogenesis (Yoon et al. Cell Stem Cell 2014). However, it is not known whether CYFIP1 continues to facilitate the maintenance of the neurogenic niche and regulate neurogenesis in the postnatal period. The adult subventricular zone demonstrates continued postnatal neurogenesis in mammals. It is similar to the ventricular zone of development in that appropriate maintenance of its three dimensional structure is required for normal neurogenesis to occur. We hypothesized that CYFIP1 may continue to play a role in maintaining normal architecture in the SVZ neurogenic niche in the adult brain and that loss of its function would lead to dysregulation of neurogenesis here. We used both spatial and temporally controlled genetic knockdown of the *cyfip1* gene in a mouse model along with confocal microscopy to address this question. Loss of *cyfip1* in adult neural stem cells results in an increase in cell proliferation as well as loss of ependymal cells at the

ventricular surface. Our results suggest that CYFIP1 is required to maintain normal SVZ architecture throughout both pre- and post-natal development and can regulate neural stem cell behavior in the developing and mature brain. Dysregulation of CYFIP1 at either time-point may lead to neural dysfunction and its continued study is important for our understanding of neurologic disorders.

Title: Inhibition of adult neurogenesis impairs the normal balance between multiple gaba and glutamate receptors in various cortical and subcortical brain regions

Authors: *C. HEROLD[1], J. DEITERSEN[1], K. AMUNTS[1,2], K. ZILLES[2,3];
[1]Heinrich Heine Univ. Duesseldorf, C. & O. Vogt-Institute of Brain Res., Duesseldorf, Germany; [2]Inst. of Neurosci. and Med. INM-1, Res. Ctr. Juelich, Juelich, Germany; [3]Dept. of Psychiatry, Psychotherapy and Psychosomatics, RWTH Aachen University, and JARA – Translational Brain Med., Aachen, Germany

Abstract: Impaired adult neurogenesis has been linked to a number of neurological diseases that are often accompanied by cognitive dysfunctions. However, for a lot of these functions, performance depends on the optimal stimulation of neurotransmitter receptors in the hippocampal-fronto-striatal system. Thus modulating adult neurogenesis may have impact on these networks and result in changes at the level of signaling molecules. Here, we analyzed binding site densities for glutamatergic AMPA, NMDA, kainate and $mGluR_{2/3}$ receptors, GABAergic $GABA_A$ (including benzodiazepine binding sites), $GABA_B$, and dopaminergic $D_{1/5}$ and $D_{2/3}$ receptors using quantitative *in vitro* receptor autoradiography in numerous cortical regions and basal ganglia of mice treated with temozolomide (TMZ) to impair adult neurogenesis in comparison to a saline control group. In the HF of TMZ treated mice we detected increased $GABA_B$ receptor densities in the dentate gyrus (DG) and fields of the Cornu ammonis (CA1 and CA3). Additionally, we observed decreased AMPA receptor densities exclusively in the molecular layer of DG, while NMDA receptor densities dropped in the

subgranular and the molecular layer of DG and in all layers of CA1 to CA3. No changes were observed in the hilar region. The prelimbic area (PL), dorsal infralimbic area (ILAd), dorsal and ventral agranular cingulate area (AcAd, AcAv), frontal area 2 (FR2) and gustatory area (GU) showed increased $GABA_B$ receptor levels. $GABA_A$ receptor densities were increased in PL, ILA, AcAd, AcAv and medial orbital area (MO/DP). While kainate receptor densities were increased in the ventrolateral and lateral orbital area (vLO and LO) and in ILA, $mGluR_{2/3}$ receptors showed decreased levels in FR2, GU, vLO, LO, dorsal and ventral agranular insular area (AId and AIv), and claustrum (CLA). NMDA receptor densities dropped in GU, AId, AIv, vLO and CLA. In the basal ganglia increased $GABA_B$ receptor densities were detected in the Ncl. accumbens (ACB), while $GABA_A$ receptor densities increased in the globus pallidus (GP). Decreased levels of $mGluR_{2/3}$ receptors were detected in ACB, while NMDA receptors additionally decreased in caudate/putamen (CP). A slight decrease of $D_{2/3}$ receptors was observed in ACB core and CP. None of the analyzed areas showed changes for BZ binding sites or in $D_{1/5}$ receptor densities. To our knowledge, this is the first study that reports neurochemical changes in the hippocampal-frontal-striatal network after inhibition of adult neurogenesis. We demonstrated that the inhibition of adult neurogenesis leads to impairments of the normal balance of the expression of multiple transmitter receptors in various cortical and subcortical regions.

Abstract: During adult neurogenesis adult-born neurons undergo a drastic change in morphology from proliferating precursor cells of variable shape to post-mitotic neurons with axon and a complex dendritic tree. While it has been shown that remodeling of microtubules is essential for the formation of axon and dendrites, it is not yet understood how the composition and stability of microtubules is regulated to enable integration of the newborn cell into an already existing network.
We have previously identified the transcription factor Sox11 as a key regulator of neuronal differentiation and fate determination during adult hippocampal neurogenesis. To get insight into the regulatory network of Sox11 we performed transcriptome analyses of in vitro differentiating neural stem cells. Strikingly, following KO of the SoxC group proteins Sox11&4, expression of many tubulin isoforms was dysregulated along with a number of microtubule-associated proteins, among them Doublecortin (DCX), MAP2, Spastin, and Stathmin1 (Stmn). Importantly, further biochemical analyses as well as in vivo gain- and loss-of-function experiments confirmed that SoxC proteins can directly activate the promoters of a subset of neuronal cytoskeleton-related proteins.
Our results indicate that SoxC proteins constitute a central hub in the transcriptional network of genes regulating microtubule composition during neuronal development. Future work is directed at the question whether SoxC proteins also regulate cytoskeletal remodeling in the context of neuronal plasticity.

Title: D-serine modulates hippocampal neurogenesis through dual CREB recruitment on the promoters of NMDA subunits and neurogenic genes

Authors: *S. BARBATI, L. LEONE, S. FUSCO, K. GIRONI, M. D' ASCENZO, C. GRASSI; Univ. Cattolica, Med. Sch., Rome, Italy

Abstract: Adult hippocampal neurogenesis has a critical role in brain plasticity, learning and memory. The co-agonist of the glutamate N-methyl-D-aspartate (NMDA) receptor, D-serine, has been recently involved in the modulation of adult hippocampal neurogenesis but the underlying molecular mechanisms have not been fully identified. We found that administration of D-serine (100 μM) to cultured neural stem cells (NSCs) increased their proliferation (+35% BrdU-positive cells compared to control, $p<0.05$) and accelerated their neuronal differentiation (+115% DCX-positive cells compared to control, $p<0.05$). To identify the molecular mechanisms responsible for these effects we performed quantitative real time PCR (qRT-PCR) experiments on adult hippocampal NSCs cultured under both proliferating and differentiating conditions. Exogenous administration of D-serine to the culture medium significantly increased the expression of the pro-proliferative gene Hes1 (+217%, $p<0.05$) in undifferentiated NSCs and of the determination gene Mash1 whose expression was upregulated (+50%, $p<0.05$) and temporally anticipated compared to control NSCs. Furthermore, qRT-PCR experiments performed on differentiating NSC extracts revealed an accelerated expression pattern of NMDA receptor subunits in D-serine treated NSCs consisting in earlier and increased expression of the NR1, NR2A and NR2B subunits (+300%, +260% and +75% respectively, $p<0.05$) after 24 h of D-serine administration. Interestingly, immunofluorescence data showed that exposure to D-serine increased the activation of the transcription factor CREB (pCREB) both in proliferative (+60%) and in differentiative conditions (+65%). Moreover, chromatin immunoprecipitation experiment revealed the recruitment of pCREB on the promoters of Hes1 and NMDA subunits and its higher binding in presence of D-serine. Finally, whole-cell patch-clamp recordings displayed a significant increase in NMDA receptor-mediated currents in NSCs cultured for 24-72 hours with 100 μM D-serine, supporting our hypothesis that D-serine accelerates neuronal maturation of NSCs. Collectively, our results suggest that D-serine positively modulates proliferation and neuronal differentiation of hippocampal NSCs by epigenetic mechanisms leading to an accelerated pro-neuronal gene and NMDA receptor subunit expression.

Title: Histone H3 Lysine 27 demethylase UTX regulates postnatal hippocampal neurogenesis

Authors: G. TANG, Y. ZENG, H. DU, S. DAI, Q. TANG, Z.-Q. TENG, *C. LIU;
The State Key Lab. of Stem cell and Reproductive Biol., Inst. of Zoology, Chinese Acad. of Sci., Beijing City, China

Abstract: Neurogenesis exists in specific regions of postnatal and adult brains, which is tightly controlled by various epigenetic regulators. Understanding the epigenetic regulatory mechanisms of neurogenesis is necessary for developing new strategies for brain repair. The X chromosome-encoded histone demethylase UTX (also known as KDM6A) establishes transcriptionally permissive chromatin through removal of repressive trimethylation of histone H3 lysine 27 (H3K27me3). However, whether H3K27Me3 demethylation affects neurogenesis has remained largely unknown. To investigate this, we conditionally inactivated H3K27Me3 demethylases Utx in postnatal neural stem cells. We found that deletion of UTX in postnatal hippocampal neural stem cells promoted neurogenesis both in vivo and in vitro. Furthermore, we demonstrated that UTX mediates postnatal neurogenesis in hippocampus through its H3K27 demethylase activity. Loss of demethylase activity by conditional knock-out UTX in neural stem cells resulted in higher H3K27Me3 intensity. Finally, we found that UTX promotes H3K27Me3 removal at a specific subset of genes involved in neural stem cells proliferation and differentiation. Thus, we have identified a critical role for the enzymatic activity of UTX in modulating neural-specific gene expression during hippocampal neurogenesis. # Correspondence should be addressed to:tengzq@ioz.ac.cn, liuchm@ioz.ac.cn

Title: Functional rols of Rho-GTPase-activating proteins in adult neurogenesis

Authors: ***Y. SU**[1,2,3], A. K. FU[1,2,3], L. MIN[1,2,3], J. P. IP[1,2,3], N. Y. IP[1,2,3];

Abstract: Continuous generation of neurons in the subgranular zone of the dentate gyrus in the hippocampus occurs throughout life. Its dysfunction may lead to neurological disorders such as autism, epilepsy, and schizophrenia. Rho GTPase-activating proteins (Rho-GAP) are a family of regulatory proteins that bind to activated Rho GTPases, stimulating their GTPase activity. While Rho-GAPs regulate neuronal differentiation, neurite outgrowth, and migration during CNS development, whether they are important for the regulation of adult neurogenesis remains largely unknown. Here, we report the role of the Rho-GAP α2-chimaerin in adult neurogenesis. The results show that α2-chimaerin-knockout mice exhibited impaired adult hippocampal neurogenesis. This effect was mediated through the regulation of neural progenitor cell proliferation, but not differentiation or maturation. Conditional knockout of α2-chimaerin in nestin-positive cells shifted the division mode of neural progenitors from asymmetric to symmetric division. Moreover, deficiency of α2-chimaerin attenuated the dendritic development of adult-born neurons in the dentate gyrus. Our findings reveal the functional roles of Rho GTPase-activating proteins in adult neurogenesis and provide a possible target for drug development for the treatment of neurological disorders.

Title: A role for the signaling sphingolipid sphingosine-1-phosphate in the development of adult-born neurons

Authors: *A. DIANTONIO, C. YANG, J. WANG, Y. GU, S. GE;
Neurobio., Stony Brook Univ., Stony Brook, NY

Abstract: New neurons are continuously produced in the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus in adult mammals. In fact, up to 80% of dentate granule cells, the principal cells of the DG, are generated postnatally. Newborn neurons migrate within the DG, from the SGZ towards the molecular layer, where they eventually mature, form synapses, and integrate into existing circuits. There are many factors which influence neurogenesis, including the bioactive signaling sphingolipid sphingosine-1- phosphate (S1P). S1P acts as an extracellular ligand for the S1PR subfamily of G-protein- coupled receptors, and this signaling pathway affects cellular migration and neurite outgrowth. However, most of the studies on S1P's effects on neurogenesis have been conducted in vitro and focused on embryonic development. We are interested in the effects of S1P on the development of adult newborn neurons in vivo. Using RNA sequencing, we identified components of the S1P signaling pathway as potential factors involved in adult neurogenesis. To examine the potential of S1P to regulate adult neurogenesis, we quantified S1P levels in the DG via high-performance liquid chromatography-mass spectrometry and confirmed that the ligand was indeed present in this brain region in adult animals. Additionally, multiple behavioral treatments known to enhance neurogenesis led to decreased levels of S1P in the DG. We also used immunohistochemistry to determine that two of the five known S1PRs - specifically, S1P1 and S1P2 - are expressed in adult-born neurons. Using retroviral vectors to manipulate S1PR expression, we have found that cellular migration and dendritic arborization are affected by altered S1PR signaling.

Title: A mouse model for probing the significance of regulated intramembrane proteolysis of Neuregulin 1 in neural development

Authors: *A. JONE, P. RAJEBHOSALE, L. W. ROLE, D. A. TALMAG;
Neurobio. and Behavior, Stony Brook Univ., Centereach, NY

Abstract: Neuregulin 1 (Nrg1) is a family of versatile signaling proteins extensively involved in neural development and synaptic plasticity. One of the neuron-specific isoforms type III Nrg1 is critical for neuronal survival, neural fate determination, receptor trafficking, axon myelination, and synaptic transmission. Genetic deletion of Type III Nrg1 in mice results in deficits in synaptic plasticity and behavioral deficits involving working memory and sensorimotor gating. Upon ErbB4 binding or neuronal depolarization, Type III Nrg1 undergoes regulated intramembranous proteolysis (RIP), mediated in part by γ-secretase cleavage, to generate a carboxyl-terminal fragment. This soluble intracellular domain (ICD) of Type III Nrg1 is capable of translocating to the nucleus, where it possesses strong transcriptional transactivation properties. *In vitro*, the valine residue at position 321 is necessary for proper RIP of Type III Nrg1 and appropriate dendritic arborization. Interestingly, a single-nucleotide polymorphism that has been associated with psychosis and schizophrenia in a human population in Costa Rica results in the substitution of a leucine for this valine residue.
We generated a valine-321-leucine (V321L) mouse line and asked whether this point mutation affects Nrg1 RIP and disrupts developmental events *in vivo*. Through subcellular fractionation, we show that both full-length Nrg1 and the ICD fragment are enriched in the membrane fraction extracted from V321L homozygous mouse brain lysate compared to that of wild-type, suggesting that Nrg1 RIP is impaired by the V321L mutation. Because the ICD has been previously demonstrated to regulate neural stem cell proliferation and fate specification *in vitro*, we wondered whether neurogenesis is affected by disruptions in Nrg1 RIP *in vivo*. Ongoing studies are investigating the effect of this substitution on hippocampal neurogenesis in young adult mice. Preliminary results indicate that mice with the V321L mutation have reduced cell proliferation and generation of newborn neurons in the dentate gyrus compared to wild-type littermates.

Title: Conditional deletion of cannabinoid CB1 receptor alters neural precursor proliferation and affects neurogenesis-dependent behavior and synaptic plasticity

Authors: *T. ZIMMERMANN[1], M. MAROSO[2], S. LUDEWIG[3], I. SOLTESZ[2], M. KORTE[3], B. LUTZ[1], J. LESCHIK[1];
[1]Inst. of Physiological Chem., Univ. Med. Ctr. Mainz, Mainz, Germany; [2]Dept. of Neurosurg., Stanford Univ., Stanford, CA; [3]Zoological Institute, Div. Cell. Neurobio., TU Braunschweig, Braunschweig, Germany

Abstract: Adult born neurons in the subgranular zone (SGZ) of the dentate gyrus are continuously generated and incorporated in the hippocampal circuitry, yet the molecular mechanism of this process remain unclear. Adult neural stem cells contain a functional endocannabinoid system. Endocannabinoids are endogenous lipids, which can bind to the presynaptic cannabinoid 1 (CB1) receptor, thereby inhibit neurotransmitter release and activate different intracellular signaling cascades [1]. It has been shown that loss of CB1 receptor signaling inhibits neural precursor proliferation and decreases astroglial differentiation *in vitro* and *in vivo* [2]. However, it is not known, if this phenomenon is regulated through a direct or an indirect mechanism of CB1 receptor signaling.
To address this question, we generated the triple-transgenic nestin-CreERT2/R26R-YFP/CB1flox/flox mouse line. Tamoxifen (TAM) injections induced deletion of the CB1 receptor and expression of yellow fluorescent protein (YFP) specifically in adult nestin-expressing stem cells and their progeny. To assess which neurogenic stages were affected by elimination of CB1, YFP SGZ cells were assigned to categories based on expression of immunohistochemistry markers.
We found that neural stem cell-specific deletion of the CB1 receptor led to a reduced number of total YFP cells in the dentate gyrus four weeks after TAM injection and to a decrease in neural stem cell proliferation, as assessed by BrdU staining. Animals lacking a functional CB1 receptor in newborn neurons displayed a decrease in spatial memory function in the spatial object recognition test and an increase in behavioral despair in the forced swim test. Anxiety-like behavior in the light dark test and spontaneous activity in the open field were not affected. Field excitatory postsynaptic potentials (fEPSPs) were recorded in the CA1 region by stimulating Schaffer collateral axons of area CA3. TAM treated triple-transgenic Nestin-CreERT2/R26R-YFP/CB1flox/flox mice displayed a long-term potentiation (LTP) curve that is different to that of littermate controls.
The present study shows that the proliferation and survival of newborn neurons critically depends on the activation of the CB1 receptor, reflecting the importance of the functional connectivity and the involvement on the behavioral level.

Abstract: Age-related neurological disorders, including stroke and neurodegenerative diseases are becoming a major health care problem in many countries as average life expectancy is increasing. One appealing therapeutic strategy to treat neurological disorders would consist of recruiting endogenous neural precursor cells (NPCs) to replace the lost neurons. NPCs are present in two specific areas of the postnatal brain, the dentate gyrus (DG) of the hippocampus and the subventricular zone (SVZ) of the lateral ventricles. These NPCs give rise to neurons throughout life, a phenomenon termed postnatal neurogenesis. A prerequisite for the development of new therapeutic strategies involving postnatal NPCs is a better understanding of their molecular regulation. In this context, both extrinsic factors and intrinsic factors have been identified. For instance, the family of cell cycle regulators cyclin-dependent kinases (Cdks) are key regulators of postnatal neurogenesis since genetic invalidation of interphase Cdk2 or Cdk6 leads to a decrease of NPCs proliferation. Here, we investigated the role of Cdk1, an essential Cdk for M-phase in several tissues, in postnatal neurogenesis. Towards that purpose, we crossed mice bearing a conditional Cdk1 allele ($Cdk1^{lox}$) with mice expressing a tamoxifen-inducible form of the Cre-recombinase under the control of the Sox2 promoter (Sox2CreER), allowing us to specifically delete Cdk1 in Sox2+ NPCs in the postnatal brain. Following Cdk1 loss, our preliminary results show a acute decrease in the percentage of recombinated proliferating Sox2+ cells as well as a decrease in the absolute number of Sox2+ cells in the DG. Interestingly, we also observed an increased number of DCX+ progenitors cells and a long-term depletion of the pool of Sox2+ in the absence of Cdk1. The number of neurons seems to decrease in the same

time. Altogether, these data suggest a crucial role for Cdk1 in postnatal neurogenesis, but further investigations are required to identify its precise requirement in this process.

Title: Frizzled-1 regulates fate determination of neural progenitor cells in the adult hippocampus

Authors: ***L. VARELA-NALLAR**, S. B. ARREDONDO, M. D. MARDONES;
Ctr. Inv. Biomedicas, Univ. Andres Bello, Santiago, Chile

Abstract: The generation of new granule neurons in the adult hippocampus is controlled by the Wnt signaling pathway, which regulates different stages of neurogenesis including proliferation and differentiation of neural progenitor cells. We have determined that the Wnt receptor Frizzled-1 (FZD1) is expressed in neural stem cells (NSCs), transient-amplifying progenitors and immature neurons in the adult dentate gyrus. Here, we investigated the potential role of this receptor on proliferation and cell fate determination of progenitor cells. To knockdown the expression of FZD1 in proliferating cells in vivo, retroviruses expressing FZD1-targeting shRNA (shFZD1) or control shRNA (shC) were stereotaxically injected into the dentate gyrus of 2-month-old mice. FZD1 knockdown did not induce changes in proliferation of NSCs or neural progenitor cells as assessed by staining for Ki67 and specific markers. In agreement, no changes in the pool of tranduced NSCs and neural progenitors were observed between shC and shFZD1-injected mice 1 week after retroviral injection. However, there was a strong decrease in the percentage of FZD1-deficient cells expressing the immature neuronal marker doublecortin. Four weeks after retroviral injection there was a significant decrease in the percentage of shFZD1-transduced cells that became granule neurons, and concomitantly with this reduced generation of new neurons there was an increase in the percentage of FZD1-deficient cells that became astrocytes. In N2a cells and cultured adult hippocampal progenitors isolated from mouse brain, FZD1 knockdown reduced the canonical Wnt/β-catenin signaling pathway and the expression of Wnt target genes, including proneural transcription factors. Our results indicate that FZD1

receptor regulates cell fate commitment, and suggest that this effect is mediated by the activation of the canonical Wnt signaling pathway.

Title: Role of PTEN phosphorylation in brain development

Authors: ***J. LEDDEROSE**[1], S. GÖGEL[1], W. BINTIG[1], F. FURNARI[2], B. J. EICKHOLT[1]; [1]Charité Universitätsmedizin Berlin, Berlin, Germany; [2]Ludiwig Inst. for Cancer Res., UCSD, San Diego, CA

Abstract: Phosphatase and tensin homolog located on chromosome 10 (PTEN) was originally characterized as a tumor suppressor that can inhibit proliferation, migration, cell growth and apoptosis in a number of different cells. PTEN is also highly expressed in neurons and recent work indicates that de-regulation of PTEN affects important neuronal functions in the developing nervous system, which have been attributed to its role in controlling neurogenesis, neurite outgrowth, synaptogenesis, and synaptic plasticity. Human germline PTEN mutations or conditional deletions of PTEN in mice have provided insights into fundamental links between PTEN deregulation and neurological disorders such as macrocephaly, ataxia, seizures, mental retardation and autism. The regulation of PTEN activity and function crucially involves phosphorylation of a cluster of serine and threonine residues in the PTEN C-terminus. Within this cluster, PTEN can be phosphorylated at T366 by Glycogen Synthase Kinase 3 (GSK3), which has been suggested to regulate activity and PTEN protein turnover. Since PTEN antagonises and functions as a key upstream regulator of PI3K/GSK3 signalling, the fact that it is phosphorylated and regulated also by GSK3 itself, could indicate feedback regulation within this signalling cascade. Currently, little is known concerning neuronal functions of PTEN T366 phosphorylation. To determine the contribution of PTEN T366 to neuronal development and/or function, we analyzed mice in which this phosphorylation site was inactivated as a result of the introduction of a germline point mutation ($PTEN^{T366A}$). Whilst homozygous $PTEN^{T366A/T366A}$ mice, hereafter referred to as $PTEN^{T366A}$ mice, are viable and fertile, subtle differences in cortical lamination were observed. Thus, we will present our data that investigates cortical neurogenesis

and post-neurogenesis processes in different cortical layers of $PTEN^{T366A}$ mice, with an emphasis on the cell-type specificity and fine organization of dendritic arbors. Our results highlight specific roles of PTEN-T366 phosphorylation in generating anatomical and functional synaptic connections, possibly affecting sensory processing and higher cognitive function.

Title: Plexin-A1 is crucial for developmental neuronal death in cerebellum

Authors: *K. YUKAWA, T. ITO, M. HOSSAIN, T. NEGISHI, K. YOSHIDA;
Meijo Univ., Nagoya, Japan

Abstract: In the developing brain, microglia actively promotes apoptotic neuronal death. The microglial DAP12 immunoreceptor and CD11b integrin cooperatively induce neuronal apoptosis by controlling the production of superoxide ions. Our coimmunoprecipitation experiment has disclosed the association of DAP12 with the plexin-A1 semaphorin receptor and TREM2 in postnatal microglia. Thus, microglial plexin-A1 and DAP12 may cooperatively work to induce developmental neuronal death. We have reported that the interaction of Sema6D on dying neurons and microglial plexin-A1 is crucial for the execution of neuronal apoptosis in the developing hippocampus. To examine if plexin-A1 is also crucial for neuronal death in the developing cerebellum, we analyzed neuronal apoptosis, microglial distribution, semaphorin expression and superoxide ions production in wild-type (WT) and plexin-A1-deficient cerebella from postnatal day 1 (PND1) to postnatal day 14 (PND14). In the developing cerebellum, some of apoptotic neurons were localized in contact with microglia. There was a significant decrease of apoptotic cells in the plexin-A1-deficient cerebellum at postnatal day 3 and 4 (PND3 and 4) as compared with wild-type (WT). The generation of superoxide ions was mostly confined to Iba1-positive microglia. The superoxide ions-producing cells were significantly decreased in plexin-A1-deficient cerebella reflecting the dependency of superoxide ions generation on plexin-A1 signaling. The expression level of Sema6D, one of plexin-A1 ligands was significantly higher in cerebella at PND4 as compared with other developmental stages. Furthermore, activated caspase-3-positive neurons exhibited the increase of Sema6D expression in cerebella at PND4. Thus, Sema6D expressed by dying neurons may signal to microglia through the binding to

microglial plexin-A1, which facilitates the generation of superoxide ions and neuronal apoptosis in the developing cerebellum. Since activated caspase-3-positive neurons are distinct from calbindin-positive Purkinje cells, we are currently trying to identify the cell type which executes plexin-A1-dependent apoptosis in the cerebella at PND4.

[2]Deutsches Zentrum für Neurodegenerative Erkrankengen (DZNE), Dresden, Germany

Abstract: Resident neural stem cells (NSCs) of the subventricular zone (SVZ) and the dentate gyrus of the hippocampus (DG) generate new neurons, which integrate into existing circuits throughout life ("adult neurogenesis"). Though the broad scheme of adult neurogenesis is similar in both the neurogenic zones, there are important differences. Importantly, whereas wheel running is a potent pro-proliferative cue in the DG, it has no effect on SVZ neurogenesis. We hypothesized that a central metabolic pathway, which is uniquely regulated in the hippocampal NSCs, serves as the responsive checkpoint in response to the pro-neurogenic stimuli. A comparison of the expression profiles of Nestin-positive precursor cells from the two zones revealed redox regulation to be one such differentially regulated pathway. All the NSCs of the DG have high endogenous levels of reactive oxygen species (ROS), the readout of redox regulation, compared to the surrounding niche cells. All neurosphere-forming cells were found within a population with highest ROS content (top 16 %). Furthermore, neurosphere-forming frequency significantly correlated to the ROS content, as did the size of the spheres. ROS content also was a discriminating marker for the heterogeneous metabolic states of NSCs and allowed classifying them into subgroups, which differed in various cell biological properties. The

proportion of NSCs with the highest ROS content (termed ROS-Hi cluster) was significantly greater in the DG. The response to physical activity primarily occurred in this subgroup of NSCs. Reducing the subgroup of ROS-Hi NSCs did reduce constitutive neurogenesis but completely abolished the pro-neurogenic response of exercise

Title: Single cell transcriptome analysis of adult neurogenesis during aging

Authors: *Y. ZHU[1,2], D. JIMENEZ-CYRUS[3], D. BERG[1,2], M. BONAGUIDI[6], G.-L. MING[1,2,3,4,5], H. SONG[1,2,3,4];

Sch. of Med., Baltimore, MD; [6]Eli and Edythe Broad CIRM Ctr. for Regenerative Med. and Stem Cell Res., USC, Los Angeles, CA

Abstract: During aging, the regenerative capacity of stem cells in mammalian tissue declines. Specifically, the process of new neuron generation from neural stem cells (NSC) is progressively less efficient during aging. This is associated with a gradual increase in stem cell quiescence and a shift toward symmetric divisions and self-renewal. Characterizing the molecular dynamics that occur in individual stem cells over the lifespan is important not only to understand the biology of aging, but also to explore the potential of stem cells for regeneration. Traditionally, characterization of NSCs using marker-defined cell population studies inevitably included cells at different stages of fate determination and activation, making it difficult to dissect the age-related changes that affect the properties of NSCs at specific stages of neurogenesis. Here we utilized the high resolution and high throughput technology of single cell transcriptome analysis to comprehensively characterize the molecular states underlying fate determination in NSCs from young and aged mice. Using a line of mice expressing nuclear CFP under the control of a Nestin promoter (Nes-CFP), we isolated hippocampal Nes-CFP positive cells from two week-old, and one, two and four month-old mice and profiled the transcriptome. In older mice, we observed more NSCs exhibiting molecular signatures indicative of a quiescent state. In early neural progenitor cells, we detected higher levels of cell cycle gene expression, potentially to

compensate for the lower rates of stem cell activation. Gene network analysis indicates a key regulatory node that could orchestrate the quiescent nature of adult NSCs. Our work established a holistic road map of NSC gene expression dynamics during aging. Further work on functional characterization will validate and consolidate these findings.

Title: EAAC1 gene deletion reduces adult hippocampal neurogenesis after transient cerebral ischemia

Authors: *B. CHOI[1], S. WON[2], M. SOHN[3], S. SUH[1];
[1]Dept. of Physiol., Hallym University, Col. of Med., Chuncheon, Korea, Republic of; [2]Dept. of Neurol., Univ. of California San Francisco and Veterans Affairs Med. Ctr., San Francisco, CA; [3]Dept. of Nursing, Inha Univ., Incheon, Korea, Republic of

Abstract: The excitatory amino acid carrier-1 (*EAAC1*) is one of the most prevalent glutamate transporters expressed in neurons. *EAAC1* expression is detected in the dendrites and somata of all neurons in the hippocampus. Since extracellular glutamate clearance in the brain is predominantly performed by the glial glutamate transporters, such as GLAST and GLT-1, glutamate clearance by *EAAC1* is negligible in the brain. Instead, *EAAC1* predominantly performs cysteine transport, which is required for the glutathione synthesis, to boost neuronal antioxidant function. Our previous study showed that genetic deletion of *EAAC1* was found to exhibit increased susceptibility to neuronal oxidative stress after ischemia due to reduced antioxidative function. There are presently no studies investigating the role of *EAAC1* on hippocampal neurogenesis. Therefore, we have investigated the role of *EAAC1* on hippocampal neurogenesis using genetically modified young (3-5 month old) and aged (11-15 months old) mice after ischemia. Adult CD1 wild-type (WT) or *EAAC1*$^{-/-}$ mice were subjected to 30 minutes of bilateral common carotid artery occlusion. BrdU was intraperitoneally injected 2 times per day for 4 consecutive days starting 3 days after ischemia. Neurogenesis was evaluated using BrdU, Ki67 and doublecortin (DCX) immunostaining 7 or 30 days after ischemia. The number of BrdU,

Ki67 and DCX positive cells between WT and *EAAC1*$^{-/-}$ mice was similar at 1 week under the normal physiological conditions. However, *EAAC1*$^{-/-}$ mice showed a reduced survival rate of newly generated neurons 4 week later in both young and aged mice. The number of BrdU, Ki67 and DCX positive cells was increased 1 week after ischemia both in young and aged mice of either WT or *EAAC1*$^{-/-}$. However, the number of BrdU, Ki67 and DCX positive cells was significantly lower in young *EAAC1*$^{-/-}$ mice compared to young WT mice. In addition, *EAAC1*$^{-/-}$ mice showed reduced survival rate of newly generated neurons at 4 weeks after ischemia in both young and aged mice. Newly generated neuron survival was lower in *EAAC1*$^{-/-}$ mice than WT mice. The present study demonstrates that cysteine uptake by *EAAC1* is important for newly-generated neuron survival in the adult brain under physiological as well as pathological conditions. Therefore, this study suggests that *EAAC1* has an essential role for modulating hippocampal neurogenesis.

Title: Integration and functional role of different sub-populations of granule cells in the adult olfactory bulb.

Authors: *D. HARDY, S. MALVAUT, V. BRETON-PROVENCHER, A. SAGHATELYAN; CRIUSMQ, Québec, QC, Canada

Abstract: In the adult brain, the olfactory bulb is continuously supplied with new neurons that mostly differentiate into granule cells (GC). Different subtypes of adult-born GC have been identified based on immunohistochemical markers and localization in the granule cell layer, but their maturational profile, as well as their role in the bulbar network functioning and odor behaviour remain completely unclear. It is also unknown if structural and functional differences exist in the same sub-population of GC born during early postnatal life and in adulthood. Using viral injections, transgenic mice, confocal imaging, whole-cell patch-clamp recordings, pharmacogenetic and behavioral tests, we analyzed the structural and functional properties of different sub-populations of GC born during early postnatal period and adulthood with particular emphasis on calretinin-expressing newborn cells (CR+). Our morphological analysis performed at several time points after generation of early-born and adult-born neurons revealed that CR+ GC display similar maturational pattern as compared to CR- cells. Patch-clamp recordings from

early-born and adult-born CR+ GC showed similar frequency and amplitude of spontaneous inhibitory currents. In contrast, our results suggest that adult-born CR+ GC may receive less frequent excitatory inputs as compared to early-born CR+ neurons. Our analysis of early gene expression combined with anti-calretinin immunohistochemistry suggests that CR+ GC may be involved in the long-term odor associative memory. Altogether, our data highlight the role of CR+ GC in the OB and are important for understanding the role of specific sub-populations of interneurons in the bulbar network functioning and odor behavior.

Title: Let-7 regulates adult neurogenesis by activating autophagy

Authors: *R. PETRI, K. PIRCS, M. JÖNSSON, M. ÅKERBLOM, P. L. BRATTÅS, T. KLÜSSENDORF, J. JAKOBSSON;
Lund Univ., Lund, Sweden

Abstract: In the adult rodent brain, neural stem cells (NSCs) reside in the subventricular zone (SVZ) where they continuously give rise to neuroblasts that migrate along the rostral migratory stream (RMS) into the olfactory bulb (OB). There they differentiate into mature neurons and integrate into the existing neuronal circuitry.
Recently microRNAs (miRNAs) were shown to regulate important processes during adult neurogenesis such as cell fate specification and integration. miRNAs are small, non-coding, single stranded RNAs that regulate mRNA activity by associating with a protein called Argonaute2 (AGO2).
In this study, we injected lentiviral vectors encoding an AGO2-GFP fusion protein into the RMS. After eight weeks we dissected the OB, and conducted AGO2-RIPseq to isolate active miRNAs from new-born neurons. We identified several novel miRNAs that are enriched in new-born neurons and found that the let-7 family is the predominant miRNA in these cells. To study the role of let-7 in new-born neurons we inhibited let-7 function by injecting a miRNA-sponge construct (LV.let-7sp.GFP) into the RMS. As control we injected a vector encoding GFP

(LV.GFP). We immunohistochemically analysed OBs after 2, 4 and 8 weeks. In control animals, we found GFP-positive cells in all layers of the OB at any time examined. In LV.let-7sp.GFP injected animals, however, the cells reached the OB but failed to integrate into its different layers.
To identify potential let-7 targets in the OB that could be involved in the observed phenotype, we conducted further AGO2-RIP experiments followed by mRNA sequencing.
We found Slc7a5 to be highly enriched in RIP samples and to be a direct target of let-7. Slc7a5 is part of the amino acid sensing pathway, which has previously been shown to be regulated by let-7 to induce neuronal autophagy.
In line with this we found an accumulation of Sequestosome-1 (p62) in LV.let-7sp.GFP- injected animals, suggesting that loss of let-7 induces a block of autophagy in new-born neurons .
We then injected LV.let-7sp.GFP constructs alone or together with BECN and TFEB overexpressing lentiviral vectors, respectively, into the RMS. TFEB and BECN are both factors known to promote autophagy. After four weeks, we analysed OBs immunohistochemically for autophagic markers and confirmed a reinstatement of autophagy in co-injected animals. Moreover, significantly more GFP-positive cells were integrating into the different layers of the OB when autophagy was reinstated, compared to LV.let-7sp.GFP injected animals.
Taken together our study provides a novel and important link between miRNA regulation, autophagy and adult neurogenesis.

Title: XRN2 and PAPD4 provide an extra miRNA regulation level in neurons

Authors: *V. PASCHON[1], D. L. CAMPOS[2], F. F. CORREIA[2], N. D. R. NOGUEIRA[2], V. A. DA SILVA[2], A. H. KIHARA[2];
[2]Nucleo de Cognição e Sistemas Complexos, [1]Univ. Federal Do ABC, São Bernardo Do Campo, Brazil

Abstract: MiRNA is a hotspot in various fundamental processes, such as neurodevelopment, adaptation, and disease. These small non-coding RNAs are important regulators of gene expression at the post-transcriptional level, acting on the mRNA, decreasing the translation rate. The action of miRNAs on target genes depends on intracellular concentration, which in turn reflects the balance of biosynthesis and degradation. The aim of this project was to characterize the expression and distribution of genes involved in degradation and stability of miRNAs, XRN2 and PAPD4, during rat spinal cord development, neuronal activation by physics exercise and after injury. Quantitative results were determined using real-time PCR and western blotting, whose data were subjected to analysis of variance (ANOVA) followed by Tukey's test, with a significance level of 1-5%. Specific antibodies were used to determine the qualitative analyzes by immunofluorescence. For neunoal activation, rats were trainned following the protocol (Quirie, Hervieu et al. 2012). XRN2 and PAPD4 were highly expressed in the beginning of spinal cord development. PAPD4 was 527% higher in E21 in comparison with P60 ($P<0.05$) and XRN2 was 263% higher in E21 in comparison with P60 ($P<0.05$). Both gens showed distinct sub cellular localization by immunohistochemistry, accumulating in nuclei and cytoplasm during development or only in the nuclei of mature neurons. Combined analyzes using anti-XRN2 and -PAPD4 with anti-Ki67 and -glutamine synthetase (GS) revealed that miRNA regulating proteins were poorly expressed in progenitor cells as well as glial cells. Moreover, double-labeling experiments with choline acetyltransferase (ChAT), calretinin (CR) and calbindin (CB), specific spinal cord neuronal markers, showed that XRN2 and PAPD4 are expressed by motor neurons (ChAT-positive neurons) and inter neurons labeled with CR and CB. Those results indicate that XRN2 and PAPD4 provide an extra level of regulation for miRNA activity in immature and developed neurons comparing with glial cells. The neuronal activation by physical exercise did not change XRN2 labeling but increased the number of cells expressing PAPD4, while both protein levels were up-regulated. Finally, the spinal cord injury provides a large number of TUNEL-positive cells after 24-hours whatever fell off then accumulated XRN2 and PAPD4 showing potent anti-apoptotic roles. In summary, this work brings knowledge to increase the understanding in the field of miRNA regulation during development, neuronal function and after injury. Financial support: FAPESP.

Title: Calpain-1 deletion results in reduced survival of newborn cells in the adult mouse brain.

Authors: *J. SEINFELD, C. ABUYO, J. LE, X. BI, M. BAUDRY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Recent studies estimate that hundreds of new neurons are added to the adult human brain every day, and several reports have proposed that neurogenesis participates in cognition, including learning and memory. Previous studies have suggested that the calcium-dependent proteases, calpains, participate in cell division, migration and survival. In particular, our laboratory has established that one of the calpain isoforms in the brain, calpain-1, is necessary for the survival of newly born cerebellar granule cells (CGCs), as calpain-1 knock-out (KO) mice exhibit enhanced apoptosis during the postnatal period and decreased number of CGCs in adult cerebellum. In the present study we analyzed proliferation and survival of newly born cells in the dentate gyrus (DG), the subventricular zone (SVZ), the rostral migratory stream (RMS), and the olfactory bulbs (OB) in calpain-1 KO and wild-type (WT) mice. Cell proliferation was decreased in the DG of calpain-1 KO mice by 25%, as measured by Ki67 expression with immunohistochemistry (IHC). Survival of newly-generated cells in the OB was decreased by 47% in calpain-1 KO mice 30 days after bromodeoxyuridine (BrdU) administration (150 mg/kg per day for three days). On the other hand, comparable numbers of BrdU-positive cells were found in the RMS of calpain-1 KO and WT mice. These results are consistent with the hypothesis that calpain-1 is necessary for neuronal survival in mouse brain, not only during the postnatal period but also in adult brain. We are currently investigating the molecular mechanisms by which calpain-1 activation supports the survival of newly born cells in the brain. Preliminary results with primary cultures of fibroblasts derived from calpain-1 KO and WT mice suggest that calpain-1 also regulates migration. Further studies are needed to better define the roles of calpain-1 and calpain-2 in proliferation, migration and survival of newly-born neuronal precursor cells in the brain and the functional consequences of deletion/mutation of calpain-1.

Title: Role of neural stem cells in the sensory circumventricular organs of adult mouse

Authors: *E. FURUBE[1], M. MORITA[2], S. MIYATA[1];
[1]Applied Biol., Kyoto Inst. of Technol., Kyoto, Japan; [2]Develop. of Biol., Kobe Univ., Hyogo, Japan

Abstract: The adult brain contains neural stem cells (NSCs) that are self-renewing and generate neurons, astrocytes and oligodendrocytes. The sensory circumventricular organs (sCVOs), including the organum vasculosum of the lamina terminalis (OVLT), subfornical organ (SFO), and area postrema (AP), are shown to have NSCs, but the characterization and functional significance of NSCs in these regions are completely unknown. Employing Nestin-Cre/CAG-CAT-EGFP mice, we showed that there were many enhanced green fluorescent protein (EGFP)-expressing astrocyte-like cells and tanycyte-like ependymal cells in the sCVOs. Moreover, EGFP-expressing astrocyte-like cells expressed glial fibrillary acidic protein (GFAP) in the SFO, OVLT and AP and tanycyte-like ependymal cells often expressed GFAP only in the SFO. It was shown that these astrocyte-like cells and tanycyte-like ependymal cells showed bromodeoxyurigine (BrdU) incorporation into their nuclei. Lineage-tracing fate determination experiments using Nestin-Cre/CAG-CAT-EGFP mice and BrdU immunohistochemistry provided evidence that NSC originated within the sCVOs provided neural and glial cells to their inside and their neighboring regions such as the medial preoptic area, ventral hippocampal commissure, the nucleus of solitary tract, and 12N. Furthermore, we also found expression of temperature, acid and capsaicin receptor transient receptor potential vanilloid 1 (TRPV1) and TRPV1-depend activation of JAK-signal transducer and activator of transcription 3 in NSCs of the sCVOs. In addition to that, NF-κB signaling was induced in NSCs of the sCVOs via the activation of bacteria lipopolysaccharide receptor Toll-like receptor 4.These results suggest that astrocyte-/tanycyte-like NSCs in the sCVOs act as sensors to detect blood-derived information in addition to the new generation of neurons and glial cells.

Title: Early survival and delayed death of developmentally-born dentate gyrus neurons

Authors: *S. P. CAHILL, R. Q. YU, E. TODOROVA, D. GREEN, J. S. SNYDER;
Dept. of Psychology, Univ. of British of Columbia, Vancouver, BC, Canada

Abstract: Much effort has been spent trying to understand the function of adult-generated hippocampal neurons. At the cellular level, adult-generated neurons progress through defined developmental stages that are characterized by specific patterns of synapse formation, marker expression, physiological function and cell death. Less is known about the developmental timecourse of neurons born during the perinatal period. To address this question we injected rats with the mitotic marker BrdU at postnatal day 6, to label neurons born at the peak of dentate gyrus development. We then counted and characterized BrdU+ cells at 1hr, 1d, 3d, 1w, 2w, 3w, 4w and 8w timepoints. Unlike adult-born neurons, which undergo significant cell death during the first 4 weeks after mitosis, we observed no loss of developmentally-born cells after the 1w timepoint. Developmentally-born neurons upregulated NeuN and downregulated DCX comparably to what has been observed in adult-born neurons. To assess functional integration of BrdU+ neurons, we examined expression of the immediate-early genes c-fos and zif268 (rats explored a novel environment). Similar to what has been observed in adult-born neurons, there was an early peak in zif268 expression. However, peak zif268 expression occurred when neurons were 2w old, which is 1w earlier than adult-born cells and consistent with evidence that developmentally-born neurons mature faster than adult-born neurons. Exploration-induced c-fos expression was present in a smaller proportion of neurons, did not show an early peak, and plateaued at the 4w timepoint. To investigate whether developmentally-born neurons continue to survive throughout adulthood we injected additional groups of rats with BrdU at postnatal day 6 and quantified surviving BrdU+ cells at 2 months and 6 months. In contrast to the stable survival between 1w-8w, we observed a 17% loss of BrdU+ cells between 2-6months. Developmentally-born neurons expressed caspase3 when rats were 2 months old, providing additional evidence that these neurons underwent cell death. Collectively, our findings indicate that developmentally-born and adult-born neurons differ markedly in their patterns of survival: during stages of

neuronal immaturity, adult-born neurons die but developmentally-born neurons are stable; when neurons have reached maturity, adult-born neurons are stable and developmentally-born neurons die. By identifying temporal patterns by which developmentally-born persist throughout the lifespan, these findings may be relevant for understanding the dynamic nature of hippocampal memory.

Title: Study of neurovascular niche in dentate gyrus in Fgfr1 mutant mice

Authors: **A. POMBERO**[1], R. GARCIA-LOPEZ[2], *S. MARTINEZ[2];
[1]IMIB-Arraixaca, Murcia University, Spain; [2]Inst. De Neurociencias. UMH-CISC, San Juan De Alicante, Spain

Abstract: The concept of neurogenic niche in the brain proposes a functional unit between the precursor cells and their local microenvironment. Neural stem cells in the neurogenic areas proliferate in groups close to the perivascular space where their self-renewal and differentiation is regulated. The central nervous system pericytes have been recognized as an indispensable component of the neurovascular unit (NVU). In the hippocampus, this is important for providing an optimal microenvironment for neural proliferation. Hippocampal neurovascular regulatory system include both diffusible signals and direct contact with endothelial and pericytes, which are a source of diffusible neurotrophic signals such as VEGF and FGFs, that affect neural precursors. One of the key growth factors that regulate postnatal neurogenesis in hippocampus is fibroblast growth factor-2 (FGF-2, also called basic FGF). FGF2 is expressed by endothelial and periendothelial cells (pericytes) and FGF2 deficiency produces a decrease of neural proliferation in the dentate gyrus. Interestingly, hippocampal neural precursors express Fgfr1, the major receptor for FGF2 and its absence leads to a decrease in neurogenesis accompanied by a severe

impairment of long-term potentiation and memory consolidation. Previous studies suggest that FGFs act directly on hippocampal stem cells. Since FGF-2 is a potential regulator in neurogenesis and angiogenesis crosstalk, we propose to describe the precise role of FGF signal in NVU development in the hippocampus by studying whether the neurovascular niche is altered in FgfR1 mutant mice. In order to address it we focused on pericytes and endothelial cells to detect vascular abnormalities during development, and subsequent anomalies in neuro-epithelial specification, migration and differentiation of hippocampal granular cells and neurogenic niche in the dentate gyrus. Abstract: Ability to visualize dividing stem cells in the whole animal brain would facilitate analysis of neurogenesis dynamics and increase its accuracy, and may reveal hidden patterns of cell division and neurogenesis. Here we describe new histological techniques for 3D visualization and quantitation of proliferating cells in the whole brain of developing and adult mice. Populations of dividing cells were labeled with 5-ethynyl-2'-deoxyuridine (EdU) and

detected using whole-mount click-reaction with fluorescent azide (WM-CLICK). Our method allowed staining entire adult mouse brain and hippocampi and visualizing patterns of cell division using confocal microscopy, light-sheet microscopy, and two-photon tomography. WM-CLICK is compatible with simultaneous detection of dividing cells and stem cells revealed by whole-mount immunohistochemistry and is well suited for automatic counting of stem and proliferating cells in acquired 3D images. These new approaches were validated by conventional methods for detection and quantitation of dividing stem cells. We applied our techniques for visualization and 3D comparison of division and migration patterns in whole perinatal and adult brain. Our data demonstrate the utility of the WM-CLICK methods for quantitative and descriptive analysis of neurogenesis.

Title: Two-photon polymerized microstructures for guiding *In vitro* human neuron growth

Authors: ***T. JOKI**[1], S. TURUNEN[2], L. YLÄ-OUTINEN[1], M. KELLOMÄKI[2], S. NARKILAHTI[1];
[1]NeuroGroup, Biomeditech / Univ. of Tampere, Tampere, Finland; [2]Biomaterials and Tissue Engin. Group, BioMediTech/ Tampere Univ. of Technol., Tampere, Finland

Abstract: Introduction
Neural cells in vivo have polarized cell morphologies and form tissue with highly organized anatomical structures and functional circuits. These properties are altered due to cell death related to trauma or deficit, leading a decrease in patient's ability to function. In humans the

regeneration capacity of nervous system is very limited. Tissue engineering, e.g. transplantation therapy with either biomaterial scaffold or cells alone or their combination, could in future offer new treatments to enhance functionality. In defected area the scaffold can act as an artificial extra cellular matrix (ECM), supporting transplanted and/or host cells thus enhancing regeneration. Cell growth guidance along the anatomical structure of tissue is desirable for enhancing integration of transplant and regeneration of functional neural circuit. For guidance, mechanical and chemical cues can be used to enhance tissue mimicking organized growth. The aim of this work was to study the effect of topographical cues on growth of human neural cells in vitro using 3D microstructure platform.
Materials and methods
Microstructures for cell cultures were manufactured using two-photon polymerization (2PP). Neuronal cells were produced from human pluripotent stem cells (hPSCs) using a neurosphere differentiation method. Human embryonic stem cell (hESC) line Regea 08/023 derived neurons were cultured on the microstructures up to four weeks. Cultures were analyzed in time points 1, 2 and 4 weeks. Cell viability was studied using fluorescent LIVE/DEAD Viability/Cytotoxicity Kit for mammalian cells. Cell growth was analyzed using scanning electron microscopy (SEM). Cell phenotype was analyzed using immunocytochemical analysis against neuron specific proteins, MAP-2 and β Tubulin III.
Results
Microstructures were manufactured with 2PP successfully and repeatably. Cell viability was good during 4 weeks follow-up time. Both neuronal processes and cell soma migrated along the microstructures according to SEM analysis. Cultured cells had neuronal phenotype confirmed by MAP-2 and β Tubulin III protein expression by immunocytochemistry.
Conclusions
Produced microstructures provided favorable microenvironments for growth of human pluripotent stem cell derived neurons. Cells were able to migrate along topographical cues and form 3D networks utilizing the microstructures. The experimental set-up was successful and offers new ideas for the field of in vitro 3D culturing.

Abstract: GLI1 is one of three GLI family transcription factors that mediate the Sonic Hedgehog (SHH) signal transduction pathway. The pathway plays an important role in normal development and cell differentiation. GLI1 is also a human oncogene with gene targets that sustain proliferation, inhibit apoptosis, promote angiogenesis, and promote tumor cell migration. GLI1 is highly expressed in embryonic stem cells (ESCs), neural stem cells (NSCs), and mesenchymal stem cells (MSCs). Over-expression of SHH and GLI1 in stem cells enhances production of neural progenitor and dopaminergic neurons. GLI1 can bind the promotor of Nanog and activate its transcription for regulating self-renewal of NSCs. However, Nanog binds GLI proteins in ESCs and represses GLI1-mediated transcriptional activation. The effects and mechanisms of action of the SHH pathway on differentiation of human ESCs are incompletely understood. Here, we studied the role of the SHH signal transduction pathway in differentiation of human ESCs. For the spontaneous differentiation, we used embryoid body (EB) assay. Small molecules and genetic modification were used to manipulate GLI1 activity. Gene expression and lineage differentiation were evaluated by qPCR, western blot, immunocytochemistry, and biochemical approaches. The GLI1 antagonist, GANT61, promoted mesodermal and endodermal differentiation, but decreased ectodermal differentiation in human ESCs. The roles of the SHH pathway directing the differentiation of human ESCs were investigated by comparing the results of high-throughout screening assays, including mass spectrometry and chromatin immunoprecipitation sequencing (ChIP-Seq) with published sequencing databases. These results indicate that SHH pathway has lineage specific effects on the differentiation of embryonic stem cells.

Title: Maturation-dependent acquisition of anti-apoptotic brakes in human induced pluripotent stem cell-derived neurons

Authors: *K. KLEINSIMLINGHAUS, J. JATHO-GRÖGER, J. LADEWIG, P. KOCH; Inst. of Reconstructive Neurobio., Bonn, Germany

Abstract: Neurons represent a highly specialized cell population of the central and peripheral nervous system responsible for communicating information throughout the body. They are born during embryonic development and persist throughout the entire life span of an individual. During development, neurons are produced in excess numbers, which are massively reduced during the establishment of mature neuronal circuitries. While cell death pathways are freely active in immature neurons, mature neurons develop elaborate survival strategies to protect themselves against stress and apoptosis. We set out to decipher the pathways associated with increased resistance of mature human neurons to stress and apoptosis using human pluripotent stem cell (iPSC)-derived neuronal cultures. We show that during the time course of maturation, iPSC-derived neurons become increasingly resistant to several types of cellular stressors. This goes along with a failure to activate cellular caspases. Comparative gene expression profiling of immature and mature neurons identified several pathways differentially regulated in both cell types, which are implemented in cell survival, stress response and autophagy. We got interested in a small heat shock protein, which was strongly upregulated in mature neurons compared to their immature counterparts. Small heat shock proteins might be of particular interest, because the classical heat shock response is attenuated in mature neurons. In line with this we could show that Hsp70 and Hsp27 are downregulated in mature neuronal cultures compared to immature neurons. To investigate the specific contribution of the identified protein we generated knockout cell lines using CRISPR/Cas9-mediated gene editing. Indeed, disruption of the genes increased the susceptibility of knockout neurons to some, but not all stress conditions. Our experiments shed new light on pathways associated with increased resistance of mature human neurons to stress and provide a platform to investigate novel mechanistic principles in neuroprotection and neurodegeneration.

Title: Advancing development of stem cell derived neuron/glia co-culture to allow for their optimal physiological testing

Authors: *M. CARNA, V. POZO DEVOTO, V. LACOVICH, K. TEXLOVA, G. STOKIN; Translational Neurosci. and Aging Res. Group, Intl. Clin. Res. Ctr. FNUSA-ICRC, Brno, Czech Republic

Abstract: To date, different protocols have been used to differentiate hESC into neuronal and glial lineages, however, their maturation processes and functionality assays vary significantly among the studies. Moreover, the majority of protocols used to differentiate hESC into astrocytes include serum in the differentiation media, which leads to the production of activated astrocytes since the very beginning of the maturation process. This finding, together with lack of critically addressing interdependency of co-cultures, precludes physiological testing of the interaction between neurons, astrocytes and oligodendrocytes and their functionality.In this study, we have designed a protocol allowing for Neural Stem Cells (NSCs) (H9-derived) to be directed to nearly equivalent proportion of neurons, astrocytes and oligodendrocytes in serum free conditions. The medium was designed to develop brain-like environment to test for their interactions and functionality. More specifically, this protocol allows for simple, fast and efficient derivation of neurons, astrocytes and oligodendrocytes from a single batch of NSCs, which can be sorted into any physiological or pathological combination. We find that this newly designed co-culture system significantly improved both the astrocyte features and adequate support to neuronal activity in culture. These results indicate that the proposed platform can be used as a powerful tool to study neurobiological impact of glial cell on neural differentiation and development and promote different approach to study human neurological diseases in vitro. Further experiments with different types of stem cells will be needed to confirm our preliminary findings.

Abstract: Inhibitory interneurons shape cortical processing through diverse patterns of connectivity, firing pattern, and neurochemical identity. These cells have been implicated in human neurodevelopmental and psychiatric disorders, and multiple protocols have described methods to generate these cells from hESCs and iPSCs in vitro for both research and therapeutic purposes. To assess the diversity of interneuron progenitors and neurons in culture, we developed a protocol to generate them from hESCs. We sorted progenitors from neurons using the DCX-Citrine hESC reporter line, RNAseq was performed at the subpopulation and single-cell level and transcriptomic differences between populations were analyzed over the course of differentiation. We find that the cells generated using this protocol reliably differentiate into MGE-like progenitors and GABAergic neurons, and that many of the genes known to play a role in this process are expressed. When the gene expression of cells generated in vitro were compared to migrating interneurons present in fetal brains, we found that in vitro-derived interneurons present at day 54 of differentiation were most similar to fetal interneurons present at 100 dpc. Multiple distinct populations of progenitors and neurons were present at each timepoint, allowing us to characterize the dynamics of cell type production in this system, as well as identify novel genes involved in cortical interneuron differentiation. We discovered that genes implicated in human diseases, such as epilepsy, autism and schizophrenia, are expressed as SST^+ cortical interneurons differentiate and become functional.

Title: Modeling malformations of cortical development in hiPSC-derived cortical organoids

Authors: *V. IEFREMOVA, G. MANIKAKIS, A. JABALI, R. WILKENS, K. WEYNANS, P. KOCH, J. LADEWIG;
Inst. of Reconstructive Neurobio., Bonn, Germany

Abstract: The development of the human cortex requires a precise choreography of progenitor proliferation, neurogenesis and neuronal migration, which can be disrupted in malformations of cortical development (MCDs). In the past, most studies on MCDs were performed using mouse models. Critical structural differences between human and mice might, however, necessitate the use of additional model systems. In this context, pluripotent stem cell (PSC)-derived three-dimensional (3D) cerebral organoids, which faithfully recapitulate certain aspect of human brain development in vitro, have emerged as an attractive alternative. Here we used cortical organoids derived from human induced pluripotent stem cells (iPSCs) to address pathophysiological changes associated with Miller-Dieker Syndrome (MDS), a severe form of MCD caused by a haploinsufficiency on chromosome 17p13.3 involving the genes *LIS1* and *YWHAE* (coding for 14.3.3ε). Both proteins, LIS1 and 14.3.3ε, are components of an intracellular multiprotein complex including NDEL1, which is essential for the regulation of cytoplasmic dynein, centrosomal protein localization and microtubule dynamics. When applying our cortical organoid model to iPSCs derived from patients with MDS, we found that typical pathological hallmarks of the disease can be recapitulated in vitro. In particular, we observed that organoids from MDS patients show a significant reduction in size, disruption of cortical microtubule, switch in spindle orientation of ventral radial glia cells and early neurogenesis. Phenotypic changes could be rescued by applying CRISPR/Cas9 mediated genome editing of either LIS1 or 14-3-3ε suggesting a role of both, LIS1 and 14.3.3ε, in early cortical progenitor expansion. These data indicate that iPSC derived 3D cortical organoids serve as a promising system to model complex MCD in vitro.

Title: Novel generation methods for difficult giant axonal neuropathy (GAN) hiPS-derived neuronal cells allow studies of mitochondrial function and transport in mutant axons

Authors: P. MANOS[1], C. BJORNNSSON[2], S. LOTZ[2], A. ANNELING[2], *A. MESSER[2]; [1]StemCulture, Renssalaer, NY; [2]Regenerative Res. Fdn, Neural Stem Cell Inst., Rensselaer, NY

Abstract: Giant Axonal Neuropathy (GAN) is a rare pediatric neurodegeneration caused by mutations in the protein gigaxonin. This E3 ubiquitin ligase adaptor protein enables orderly turnover of intermediate filaments in neurons and vimentin filaments in fibroblasts. Neurons that fail to correctly process filaments form large neurofilament and peripherin aggregates, creating giant axons that become increasingly dysfunctional. Effects are most critical in motor neurons, leading to extreme weakness for both locomotion and breathing. Death occurs within two decades for the most severe cases. Although a human clinical trial of AAV9 intrathecal gene replacement has recently begun, a wide range of cells will remain uncorrected even the most effective gene therapy. Drug treatments that can reduce the vulnerability of cells to the stress of accumulating protein remain an important aspect of a combinatorial therapeutic strategy.
In order to screen candidate drugs, neurons generated from patient cells, particularly the most severe cases such as GAN, are very useful. Human induced pluripotent stem cells (hiPSCs) from GAN patients with missense mutations have been generated; however, severe homozygous deletion mutations also show large vimentin aggregates when fibroblasts are grown from biopsies. These donor cells show poor proliferation and reprogramming capacity using standard procedures. We therefore developed a novel culture protocol utilizing a continuous supply of FGF2 and EGF released from StemBeads®. StemBeads® are micrcoencapsulated proteins in a biodegradable polymer allowing the continuous release of proteins. StemBeads® significantly enhanced proliferation, total cell number, and increased capacity to reprogram and yielded higher efficiency. Further improvements in culture protocols for production of multiple types of neurons from homozygous deletion and missense cell lines has enabled us to follow defects in axons to test pharmacological interventions.
hiPSCs differentiated into cortical and motor neurons were stained with JC-1 to reveal mitochondrial dynamics and activity. Three-dimensional images collected on a multiphoton microscope were analyzed to track the movement of mitochondria along axonal processes,

followed by immunolabeling to confirm distribution of cytoskeletal proteins affected by GAN. This approach to use continuous growth factor exposure via StemBeads® to mimic in vivo conditions for optimal cell reprogramming and neuronal differentiation of hiPSCs, while allowing quantitative monitoring of mitochondrial transport and function, should be applicable to a wide range of neurodegenerative diseases.

Title: Systems level analysis of cellular diversity and neuronal activity in long-term cultures of human cerebral organoids

Authors: ***G. QUADRATO**[1,2], T. NGUYEN[1], E. MACOSKO[3,2], J. SHERWOOD[1,2], N. MARIA[1], Y. H. ZHANG[1], S. MCCARROLL[3,2], Z. WILLIAMS[3], P. ARLOTTA[1,2]; [1]SCRB, Harvard Univ., Cambridge, MA; [2]Broad Inst. of Harvard and MIT, Cambridge, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Genomic sequencing has rapidly expanded our understanding of the polymorphisms underlying complex neuropsychiatric disorders. However, we still have a limited understanding of the cellular phenotypes induced by these risk-associated alleles. 3D Cerebral organoids represent an emerging model that meets many of the criteria for an optimal *in vitro* system to phenotype specific mutations. However, current organoids appear to only represent early timepoints in brain development, and whether they can be used to phenotype the functional effects of psychiatric disease risk alleles on neuronal development and network behavior has not been fully explored. We have implemented a modified version of the culturing protocol developed by Lancaster et al.[1] to enable efficient long-term cultures, and have achieved healthy growth of cerebral organoids for over nine months. We have characterized a timecourse of generation of different brain structures and cell types within one to nine month old organoids by immunohistochemistry. This data shows that organoids develop by producing neural progenitors followed by neurogenesis. At later stages of differentiation, following a developmentally-correct temporal sequence, we observed astrogliogenesis and synaptogenesis paralleled by formation of active neuronal circuits. To understand the exact cellular composition of a cerebral organoid, we

used high-throughput single cell RNA sequencing via droplet sequencing[2] to profile a large number of cells (60,000 cells) across 19 six month old organoids. Analysis shows that organoids display a high degree of cellular diversity, including expression of markers of distinct subtypes of progenitors, glial cells, and class-specific markers of excitatory and inhibitory cortical neurons. We also identified cell-type-specific expression of autism and schizophrenia-linked genes, further validating the use of cerebral organoids to model complex neuropsychiatric disorders. Together, our data demonstrate that aspects of human brain development and circuit-level changes in physiological and pathological conditions can be modeled using long-term cultures of cerebral organoids.

Title: Modeling human interneuron migration and integration with a novel 3D forebrain culture approach

Authors: F. BIREY[1], J. ANDERSEN[1], C. D. MAKINSON[2], J. HUGUENARD[2], *S. P. PASCA[1];

Abstract: Progress in dissecting the molecular programs underlying human brain development and the subsequent emergence of network activity has been remarkably slow, stalling advances in understanding neuropsychiatric disorders. This is partly due to the lack of direct access to brain cells from patients, the slow translation of findings from rodent models, and the unavailability of functionally relevant in vitro models. Here, we developed a novel tridimensional (3D) differentiation method of human pluripotent stem cells (iPSC, ES) to generate neural spheroids resembling either the laminated neocortex (cerebral cortical spheroids) or the ventral telencephalon (subpallial spheroids), which includes cortical interneurons. Using labeled spheroids, we engineer two-region human forebrain structures, and employed state-of-the-art live imaging, electrophysiological recordings and calcium imaging techniques, to explore complex cell-to-cell interactions in the developing telencephalon and in the context of neurodevelopmental disease. Our results provide novel insights into the unique features of human cortical interneurons in the developing cortex.

Title: Use of low-density, uncompressed nanofiber electrospun scaffolds for the culture of three-dimensional electrical active human neuronal networks

Authors: *U. ENGLUND JOHANSSON[1], A. JAKOBSSON[2], M. OTTOSSON[2], M. ZALIS[2], D. O´CARROLL[3], F. JOHANSSON[3];

Abstract: For the majority of CNS disorders which leads to neuronal loss and impaired function, no treatment or cure exists. We hypothesize that clinical translation of promising experimental therapies may be more efficient if current 2D *in vitro* models are complemented with 3D *in vitro* models mimicking the native milieu. Although the generally accepted importance of the extracellular matrix (ECM), during nervous system development and in the homeostasis and function of the adult nervous system, this knowledge still need to be translated and its impact explored in *in vitro* neural cell-based systems. Hence, we here explored how a 3D physical culture environment effects the phenotypic differentiation of human neural progenitor cells (HNPCs) as compared to a traditional 2D culture system. Randomly oriented, 3D, sub-micron fiber networks (thickness: 200 µm, fiber diameter: 350-700 nm) of biodegradable polycaprolactone (PCL) was fabricated using a custom built Focused, Low-density, Uncompressed nanoFiber (FLUF) electrospinning setup. A mitogen-expanded multipotent HNPC line was used. At 20 days of culture the survival, neurogenic potential, neurite extension and functional development was studied using immunocytochemical-, biochemical- and electrophysiological techniques, and compared to controls cultured at 2D glass surfaces. Fluorescence-, confocal- and scanning electron microscopy were used. HNPC cultured in the 3D meshes showed excellent survival, potential to physically integrate in all three dimensions of the mesh and extension of long neurites. Importantly, HNPC demonstrated the capacity to mature into functional neurons as revealed by electrophysiological recordings. Notably, in 3D scaffolds *in vivo*-resembling intermixed neuronal- and glial cell network were formed, whereas in parallel 2D cultures a neuronal cell layer grew separated from an underlying glial cell layer. Encouragingly, our results show the potential use of electrospun, 3D, PCL nanofibrous scaffolds for long-term cultivation of human brain stem cells with the potential to form electrophysiological functioning neurons. Hence, 3D cell-scaffolds may be very useful in further developmental- as well as therapeutical studies on the nervous system.

Title: BrainPhys™ Neuronal Medium supports the electrical activities of neurons derived from human pluripotent stem cells and primary CNS tissues in long-term cultures

Authors: C. K. H. MAK[1], *V. M. LEE[1], L. H. CHEW[1], K. MCCORMACK[1], S. LLOYD-BURTON[1], A. C. EAVES[1,2], T. E. THOMAS[1], S. A. LOUIS[1];
[1]STEMCELL Technologies Inc, Vancouver, BC, Canada; [2]Terry Fox Lab., BC Cancer Agency, Vancouver, BC, Canada

Abstract: Action potential firing and synaptic activity are fundamental properties of neurons in the brain. Bardy et al. (PNAS, 2015) have recently reported that Neurobasal™ Medium and DMEM/F-12 support neuron survival but suppress their synaptic activities in culture. To solve this problem, we have developed BrainPhys™ Neuronal Medium (BrainPhys™), based on the formulation published by Bardy et al., to support growth and synaptic function of neurons in long-term cultures. Here we describe the effect of BrainPhys™ and DMEM/F-12 based media on the development of neuronal electrical activity of human pluripotent stem cell (hPSC)-derived and primary E18 rat cortical neurons in 3 and 6 weeks cultures, respectively. For hPSC cultures, neural progenitor cells derived from either induced pluripotent stem cells (iPSCs) or embryonic stem cells (ESCs) were differentiated in BrainPhys™ or DMEM/F-12 (control) with supplements, and cultured for 3 weeks. We performed half-medium changes every 3 - 4 days and measured the neuronal electrical activity twice a week using the multielectrode array (MEA) system. Our data showed that the mean firing rate of iPSC- and ESC-derived neurons (n = 1; 32 electrodes) in BrainPhys™ increased from <0.09 Hz on day 12, to 0.38 Hz and 0.17 Hz by day 25, respectively. In contrast, the mean firing rate of neurons in DMEM/F-12 remained low (<0.06 Hz) over the same 3-week period. For experiments using primary tissues, E18 rat cortical cells were plated in Neurobasal™ Medium with NeuroCult™ SM1 Neuronal Supplement (SM1). After 5 days, cultures were either transitioned to BrainPhys™ with SM1 or maintained in the Neurobasal™ control by performing half-medium changes every 3 - 4 days for 6 weeks. Electrical activities were measured twice a week throughout the culture period. Our data showed that the mean firing rate of neurons in BrainPhys™ cultures increased over time, from 0.03 Hz on day 14, to 1.4 Hz by day 44 (n = 1; 128 electrodes). The percentage of active electrodes (>0.005Hz) also increased from 24% on day 14 to 69% at day 21, and then remained stable at 60 - 70% from days 21 - 44. In contrast, the mean firing rate remained low (<0.1 Hz) in the control, with <5% of electrodes being active over a 6-week period. These data confirm that BrainPhys™ Neuronal Medium with appropriate supplements, supports the survival and synaptic function of hPSC-derived and primary neurons by providing a physiological *in vitro* condition that closely mimics the environment of the brain. BrainPhys™ is therefore, an optimal basal medium for establishing physiologically relevant neuronal cultures for the study of neurobiology *in vitro*.

Title: Effects of environmental changes on iPS cell differentiation and maturation processes

Authors: *Y. YASHIRO, H. MATSUI, H. KAWAGUCHI;
Toyo Univ., Gunma, Japan

Abstract: Induced pluripotent stem (iPS) cells have the capacity to differentiate into various cell types, making them useful for clinical applications, such as tissue engineering. In some cases, iPS cells can directly differentiate into functional organs *in vitro*; however, *in vitro* models are generally required to understand the differentiation and maturation processes that occur *in vivo*. In this study, we investigated these processes using a co-culture system of both iPS and primary culture cells derived from mice. In addition, we consider the possibility that both co-culturing and culturing temperatures have a major impact on these processes. Therefore, we investigated the changes occurring in iPS cells when culturing at different temperatures, such as at 39°C or 41°C. First, iPS cells were plated on feeder cells and cultured for 2-3 days. Subsequently, the iPS cells were moved to non-adhesive plastic dishes and cultured for 6 days to form colonies. iPS cell colonies were plated on 24-well assay plates using a cell culture insert and cultured for 6-30 days with dorsal root ganglia (DRG). We measured NeuN protein expression in differentiated neural cells using a fluorescent image analyzer. The NeuN levels in differentiated neural cells, which were derived from co-cultured iPS cells, decreased from 6 to 12 days of culture. Furthermore, βIII-tubulin protein expression in differentiated neural cells decreased from 12 to 18 days of culture. We also analyzed *NeuN* gene expression in differentiated neural cells using real-time PCR. The *NeuN* levels during differentiation in the control transiently peaked at 12 days of culture. In contrast, levels in the co-culture peaked at 6 days of culture. Our results suggest that co-culturing with DRG slightly inhibits iPS cell differentiation into neural cells compared with that in control. However, *NeuN* gene expression levels in the case of co-culture peaked earlier than those in control. Therefore, iPS cell differentiation and maturation processes might be influenced and regulated by other cells, i.e., DRG cells, in the case of co-culture. The protocols used in this study were approved by the Animal Ethics Committee of Toyo University. This work was partially supported by a grant from the Center for Biomedical Engineering Research, Toyo University.

Abstract: Induced pluripotent stem cells (iPSCs) have immense therapeutic potential to treat many dysfunctions in the nervous system. However, iPSCs generation and differentiation remain contaminated with the use of animal-derived products which limits the predictive power stem cell-derived models of human diseases in basic research and restricts their clinical applicability. Significant efforts are now being invested in finding replacements for animal-derived products for iPSC generation and differentiation. To further facilitate the application of these xeno-free techniques, we are creating an open-access online xeno-free stem cell toolkit. This toolkit will include a database of existing xeno-free protocols as well as help identify procedures that require the development of alternatives. The prototype database is being designed to feature advanced search functions and opportunities for users to report reproducibility, optimizations, sample results, ratings and comparisons relative to similar protocols. This interactive online database of xeno-free stem cell protocols is the first resource of its kind and aims to improve accuracy, transparency, quality, cost and rate of translation of stem cell research into clinical applications. Moreover, this framework can be adopted as a protocol centralization model to promote open xeno-free, human-based scientific research with standardized and reproducible methodologies.

Title: Forebrain organoids generated using mini-bioreactors for modeling Zika virus exposure and microcephaly

Authors: *X. QIAN[1], H. N. NGUYEN[1], M. M. SONG[1], S. C. OGDEN[2], C. HAMMACK[2], B. YAO[3], J. PENG[3], H. TANG[2], H. SONG[1], G.-L. MING[1];

Abstract: Differentiation of human induced pluripotent stem cells (iPSCs) into three dimensional (3D) tissue resembling organogenesis, termed organoids, provides a valuable platform for investigating human development *in vitro*. An immediate application of organoid technology is to address the current global public health emergency concerning the link between Zika virus (ZIKV) and microcephaly, a neurodevelopmental disorder, by modeling human brain development. However, high cost, variability and tissue heterogeneity currently limit the accessibility and broad applications of existing brain organoid technologies. To address these challenges, we engineered a miniaturized multi-well spinning bioreactor (SpinΩ) using 3D printing technology, which dramatically reduced the cost of maintaining organoids and permits comparisons of many culture conditions in parallel for optimization. Using two rounds of patterning factor treatments, we developed a protocol to generate forebrain organoids with minimized heterogeneity that enables quantitative analyses and better recapitulation of the

developing human cortex. Importantly, these forebrain organoids exhibit the neural progenitor cell (NPC) organization unique to primates in the form of a well-developed outer subventricular zone-like region containing prominent NPC populations that share molecular and morphological features of human outer radial glia cells (oRGCs). Forebrain organoids also generate robust and organized populations of neurons expressing markers found in all six layers of human cortex, as well as various GABAergic neuronal subtypes. In addition, large-scale comparisons of global transcriptome analyses confirmed that forebrain organoid development closely correlates with human cortical development at the molecular level. Finally, we employed the forebrain organoid platform to model Zika virus (ZIKV) exposure. Quantitative analyses revealed that both African and Asian strains of ZIKV exhibit specific tropism toward NPCs, including oRGCs, although ZIKV could also be detected in immature neurons, intermediate progenitor cells, and astrocytes. Time-course analysis further shows that ZIKV infection in NPCs is productive, resulting in more infected cells over time. ZIKV infection leads to increased cell death and reduced proliferation, resulting in decreased neuronal cell layer volume and overall organoid size, resembling microcephaly. Together, our forebrain organoids and SpinΩ provide an accessible and versatile platform, for modeling human brain development and disease and for compound testing, including potential ZIKV antiviral drugs.

Title: Human Radial Glia-like cells are targeted and killed by Zika Virus *In vitro*

Authors: *P. TRINDADE[1], E. C. LOIOLA[2], L. M. HIGA[3], R. MADEIRO DA COSTA[2], J. M. NASCIMENTO[2,4], A. TANURI[3], P. P. GARCEZ[3,2], S. K. REHEN[2,3];

Abstract: The recent outbreak of Zika virus (ZikV)-associated microcephaly in Brazil is a major concern in terms of public health around the globe. Few data are available regarding the effects of ZikV on the developing brain. Radial glial cells are major neural progenitors during initial stages of central nervous system (CNS) development. Recently, these cells were pointed as potential candidates to mediate ZikV entry in the CNS during development (Nowakowski *et al*., 2016). Here we test the hypothesis that ZikV is able to infect and induce deleterious effects on human radial glia (RG)-like cells derived from induced pluripotent (iPS) stem cells. RG-like cells were obtained by two subsequent differentiation protocols where iPS cells were differentiated into neural stem cells, which then were differentiated as glial cells (Yan et al., 2013). Immunocytochemistry for radial glia markers showed that 99% of these cells are GFAP+/Nestin+ and 90% PAX6+. To test ZikV infectivity, RG-like cells were exposed to two different strains of ZikV (766 and Br_ABES - isolated from African and Brazilian patients, respectively). Immunocytochemistry using the antibody anti-flavivirus group antigen (clone 4G2) was performed after 24h and 48h following virus exposure. In both groups we found that 10% and 30% of cells were labeled with the ZikV antibody, respectively, suggesting that the virus is not only able to infect but also to replicate in these progenitor cells. Cell viability was assessed after ZikV infection (MOIs: 0.25; 0.025; 0.0025). Live/Dead assay (Thermo) was performed using a high-content screening plataform. Three days after infection, significant increase in cell death was observed in the group infected with the 766 ZikV strain (~60% cells died with the 0.25 MOI). At this time point, no significant increase in cell death was observed in the Br_ABES ZikV strain. Six days after infection, we found significant increase in cell death in all different groups infected with the 766 ZikV strain where the 0.25 MOI exhibited ~100% cell death and the groups with 0.025 and 0.0025 exhibited ~70% and 50% dead cells respectively. In this time point we were able to detect that ~60% of cells died in the group infected with 0.25 MOI Br_ABES ZikV strain. Our results point that the 766 ZikV strain is faster than the Br_ABES strain on promoting cell death. The understanding of differences between these two strains of ZikV is crucial to understand the recent outbreak of ZikV-associated microcephaly in Brazil. Taken together these results demonstrate that the model of ZikV infection in RG-like cells is a potential tool for drug screening against the deleterious effects of ZikV in the developing CNS.

Abstract: Zika virus (ZIKV) has been associated with microcephaly, a rare brain malformation characterized by the reduction of cephalic perimeter; Here we examined morphological changes in neurospheres derived from human neural stem cells infected with ZIKV isolated in Brazil. Reduced size, changes in shape and increased cell death mediated by caspase were observed in neurospheres three days after infection. Reduced number neural progenitor cells and neurons were also observed in ZIKV-infected neurospheres. These results suggest human neurospheres is useful to screen for compounds able to reduce the harmful effects of ZIKV infection for neural progenitor cells and developing neurons.

Abstract: The advent of induced pluripotent stem cells (iPSC) has given rise to new tools for modeling human development and disease progression, and for use in drug screening. In one example, the single nucleotide polymorphism (SNP) rs1799971 (OPRM1 A118G) has been linked to drug and alcohol use disorders. Our preliminary analysis of human neurons derived from iPSC revealed functional differences (e.g., ligand sensitivity as well as receptor recycling) between A118- and G118-carrying human neurons from multiple donors. However, the diverse genetic background of the human genome has hampered the usefulness of iPSC in these applications. Currently, control iPSC lines often consist of age and sex matched non-affected subjects or non-affected family members but these exhibit a great deal of heterogeneity due to individual differences. The use of the CRISPR (clustered regularly-interspaced short palindromic repeats)/Cas system can create isogenic cell lines that will serve as better controls. We hypothesize that conversion of the G118 allele to A118 will reverse the phenotypes. We are in the process of implementing CRISPR technology to generate OPRM1 isogenic iPSCs, to further validate this phenotype as a potential biological basis underlying drug abuse behaviors, and as a proof of principle for establishing this technology. Unfortunately, the use of CRISPR/Cas in iPSC is complicated by many factors, including the resistance of iPSC to common exogenous gene delivery methods, the differences between non homologous end joining and homologous recombination in pluripotent vs. somatic cells and the difficulty of obtaining a clonal iPSC population. At RUCDR we are developing a high throughput, cost efficient strategy for using CRISPR/Cas to genetically modify iPSC for creating isogenic lines. Our strategy revolves around the optimization of 4 steps - delivery of the CRISPR/Cas 9 components, gRNA selection,

donor selection and the clonal isolation of a completely edited cell line. Preliminary results indicate that the use of electroporated Cas9 protein pre-bound with in vitro transcribed guide RNA substantially increases DNA cleavage at the desired site. Either synthetic oligonucleotides or plasmids incorporating drug selection strategies may be used as homologous recombination donor. We have adapted methods for screening pooled cells or single-cell-derived colonies. By optimizing each of these steps our goal is to establish a validated protocol for applying CRISPR technology to a broad variety of genetic variants.

Abstract: Human induced pluripotent stem cells (iPSCs) have recently emerged as a versatile model system to study human diseases. The iPSCs derived from individuals carrying specific gene variants or mutations enable the expression of endogenous genes at the physiological levels, allowing disease modeling of relevant phenotypes *in vitro*. The ε4 allele of the apolipoprotein E (*APOE4*) gene is the strongest genetic risk factor for late-onset Alzheimer's disease (AD) compared to the common ε3 allele or the protective ε2 allele. In the central nervous system, apoE is produced primarily by astrocytes and functions in transporting lipids including cholesterol to support neuronal homeostasis and synaptic integrity. Although mouse models have provided valuable tools for studying apoE isoform-dependent functions, recent studies have shown that human astrocytes have distinct gene expression profile compare with rodent astrocytes. Thus, it is critical to examine isoform-dependent biochemical and functional properties of apoE derived from human astrocytes. We obtained human skin fibroblasts from cognitively normal individuals

with different *APOE* genotypes (ε2/ε2; ε3/ε3; or ε4/ε4) and reprogramed them to iPSC clones by episodic expression of defined transcription factors. The iPSC clones were then differentiated into neural progenitor cells and further into astrocytes. We found that apoE expression appeared in parallel with the appearance of astrocytic markers. Importantly, apoE lipoprotein particles isolated from the conditioned media of human iPSC-derived astrocytes displayed isoform-dependent biochemical properties and functional effects on neuronal viability and synapses. We further converted the *APOE* ε4/ε4 genotype to ε3/ε3 in iPSCs using the CRISPR/Cas9 technology and explored the phenotypic effects on apoE properties and functions. Our studies support apoE isoform-dependent effects using human iPSC-derived astrocytes and provide an in vitro human model in understanding the role of apoE in AD pathogenesis.

Title: Improved differentiation of human pluripotent stem cell-derived neurons through reduction of progenitor proliferation

Authors: *Y. YAN, N. KAUR, J. SAGAL, P. RAVISHANKAR, M. VEMURI, M. POWERS, D. KUNINGER;
Div. of Cell Biol., Thermo Fisher Scientific, Frederick, MD

Abstract: Neurons derived from human pluripotent stem cells (hPSCs), including embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs), are excellent resources for disease modeling and drug screening. Human PSCs derived neural stem cells (NSCs) can be expanded in culture and further differentiated into mature neurons for various experiments. However, cells differentiated from hPSC-derived NSCs often contain mixed population with both differentiated neurons and undifferentiated NSCs by using classical culture medium, typically including a basal medium, B27/N2, brain-derived neurotrophic factor, glial cell-derived neurotrophic factor and other reagents. Due to the continuing proliferation of undifferentiated NSCs, very high cell densities and cell aggregation clumps are usually observed during the differentiation of hPSC-derived NSCs and increase over time, which poses challenges for long-term maintenance and end-point quantification. We have developed supplement which can reduce the proliferation of

undifferentiated NSCs without impacting the rate or extent of differentiation for hPSC-derived NSCs. The overall effect increases the relative population of differentiated neurons in culture. Typically, under these conditions by 2-3 weeks differentiated neurons with extensive neurite networks are seen that are evenly distributed across the culture surface, with very little clumping or aggregation observed. Immunocytochemical staining showed that differentiated neurons expressed mature neuronal marker MAP2 or HuC&D without the contamination of undifferentiated Nestin positive NSCs. Multielectrode array (MEA) showed that differentiated neurons fired spontaneous action potentials, indicating functional neurons. By using this new supplement, differentiated neurons can be maintained for longer time in culture. Furthermore, the evenly distributed mature neurons are more favorable to manual or automated imaging for quantification.

Title: Activin signaling increases photoreceptor precursor yield during early embryonic stem cell differentiation

Authors: *A. LU[1], C. BARNSTABLE[2];
[2]Neural and Behavioral Sci., [1]Penn State Col. of Med., Hershey, PA

Abstract: Activins are members of the transforming growth factor beta family and are involved in stem cell maintenance and differentiation as well as development of multiple organ systems. Specifically, Activin A is expressed during eye field specification and retina development. However, the effect of Activin A on these processes is poorly understood. This is partly due to the difficulty in dissecting and studying the embryonic anterior neural tissue and retina where these early developmental events occur in vivo. In vitro differentiation of pluripotent stem cells provides an alternative approach for studying these developmental events.
We have directed the differentiation of BK3 and HM1 mouse embryonic stem cells (ESCs) into a retinal lineage. The differentiated cultures progress through a series of stages that correspond to the normal progression of development in vivo. These stages include formation of the early eye field, then early retina, and finally generation of specific retina cell types and were identified by

measuring the expression of marker genes. This defined in vitro protocol can be used to investigate the molecular basis for rod photoreceptor development in a strictly controlled in vitro system.
We then used the in vitro differentiation system to test the hypothesis that Activin A increases rod photoreceptor yield during a transient developmental period. Treating BK3 and HM1 ESCs with Activin A results in increased expression anterior neural and eye field marker genes. It also increases and maintains the expression of marker genes associated with photoreceptor precursors and other late retina cell types and decreases the expression of genes associated with early retina cell types and retinal progenitor cells in a dose-dependent manner. This effect is only detectable when Activin A is introduced at stages corresponding to early eye field and retina formation. As these time frames can shift depending on the pluripotent stem cell line used, our results highlight the importance of understanding the variations between pluripotent cell lines and their endogenous levels of Activin expression. Furthermore, while Activin A can increase the proportion of photoreceptor precursors in culture, it does not have an obvious effect on expression of mature rod photoreceptor genes, indicating that Activin A plays a role in eye field specification and retinal lineage determination while other factors may influence maturation of cells committed to the photoreceptor lineage.

Abstract: Neurons and glial cells derived from genome-edited human induced pluripotent stem cells (e-hiPSCs) have become a popular model to study neurological disorders, but we still lack some basic characterization of these cells as models of disease. While studying the transcriptomes of a panel of e-hiPSC-derived neurons carrying identical Alzheimer's disease-associated mutations, we unexpectedly identified a large number of clonal, genotype-independent disparities among neuronal populations derived from single e-hiPSCs. These disparities originate in the obligatory step of single-cell isolation and selection during the process of genome editing. We observed that the intrinsic cell-to-cell heterogeneity within the parental hiPSC line is transformed into heterogeneity among single cell-derived sublines, and each single cell-derived subline becomes a relatively homogenous subpopulation. This effect is particularly evident in the family of fifty-three human clustered protocadherins (c-pcdhs). Most c-pcdhs are expressed in neurons as single cell-specific combinations of different c-pcdhs. We found that each single cell-derived e-hiPSC subline primes the transcriptional fate of a unique c-pcdh signature (or combination), which is robustly propagated and clonally transmitted into derived neuronal progenitor cells (NPCs), neurons, and glial cells. Single cell-derived, non-edited hiPSCs and blastocyst-derived human embryonic stem cell (hESCs) share this c-pcdh priming property with e-hiPSCs. Since c-pcdh signatures and other clonal attributes inherited from progenitor single hiPSCs may interfere with the identification of genome edited-associated phenotypes when comparing edited and non-edited cells, we will suggest modifications in the genome-editing protocol to circumvent this effect. Corollary to our studies, we concluded that neuronal and glial c-pcdh signatures are, unexpectedly, pre-defined and permanently propagated from an early stage in human pluripotent cells, *barcoding* the progeny derived from the same single cell. These barcodes can be erased and *de novo* written upon cell reprogramming, but remain *locked* afterwards. Intriguingly, neurons derived *in vitro* in the absence of an intermediate pluripotency state (iNs) inherit pre-defined c-pcdh patterns from parental somatic cells, which resemble their non-neuronal, non-pluripotent origin. Since c-pcdh signatures dictate cell-to-cell recognition and self-avoidance during the formation of neuronal circuits, and contribute to neuron diversity in the human brain, our findings add an unexpected and unexplored level of complexity to modeling neurological disease in a dish

Abstract: Induced pluripotent stem cells (iPSCs) reprogrammed from patient-derived blood or skin cells have become a key resource for human disease modeling and therapy discovery. The California Institute for Regenerative Medicine (CIRM) recognized the value and need for these resources and created the CIRM Human Induced Pluripotent Stem Cell Bank. To ensure the proper storage, handling, and distribution of these samples, CIRM partnered with the Coriell Institute for Medical Research, a leader in biobanking, to fund the establishment of a satellite repository location in California. Coriell provides clinical data management, data hosting, and biospecimen storage and distribution. In addition to several control donors, a variety of genetically complex brain- and eye-related diseases are represented in the CIRM hiPSC Bank: Alzheimer's disease, Macular Degeneration, Glaucoma, Diabetic Retinopathy, Autism Spectrum Disorder, Cerebral Palsy, and Epilepsy. These iPSCs are reprogrammed by Cellular Dynamics International (CDI), which is funded by CIRM to derive iPSC lines from 3,000 donors using their proprietary non-integrating episomal vector system. To ensure the quality of the lines, each one undergoes a rigorous quality control (Chromosomal Integrity, Pluripotency, Identity Confirmation, Loss of Plasmid, Mycoplasma, and Sterility) prior to being banked by the Coriell Institute. A majority of donors are also screened and negative for HIV, HBV, and HCV. The CIRM hPSC Bank is currently comprised of several hundred iPSC lines with extensive clinical data. The specimens are presented to users via Coriell's online (catalog.coriell.org/CIRM) where users have the ability to perform detailed clinical data searches, browse dedicated disease and sample pages and place orders. Importantly, each of these iPSCs can be fully licensed to afford commercial entities Freedom to Operate. The overall quality of these lines, Freedom to Operate, available clinical data, and accessible catalog experience makes this an unmatched resource for researchers worldwide. The CIRM hPSC Bank at Coriell contributes to fulfill CIRM's mission of

accelerate stem cell treatments to patients with unmet medical needs by making high quality iPSCs publicly available worldwide to investigators from academia and industry.

Abstract: The human brain is a profoundly complex organ composed of billions of neurons, representing tens to hundreds of interconnected cell types, and elegantly assembled into an organ capable of consciousness, reason, and personality. Advances in pluripotent stem cell technologies, and their use in the creation of human cortical neurons provides a promising platform to study human brain development and associated neurodevelopmental disorders. Here, we present an analysis of the lineage of human cortical cell types generated from differentiated human embryonic stem cells (hESCs), and a comparison of those cell types with primary samples. Single progenitors and neurons were transcriptionally profiled throughout the differentiation time-course. Comparison of the transcriptomic data to existing gene expression atlases and primary human fetal tissue putatively identified a major lineage branch in the culture as belonging to the earliest born neurons of the cortex deriving from the preplate, including

Cajal-Retzius and/or subplate neurons. New computational methods were developed to infer a lineage tree from the single-cell gene expression data, highlighting a major early branchpoint dividing the lineage of cortical, preplate-like neurons from a different branch exhibiting a set of mid/hindbrain gene markers, suggesting that the earlies molecular steps in establishing region-specific neural lineages are represented in this culture. In summary, through comprehensive single-cell transcriptomic profiling, we present a hESC-derived lineage tree of multiple brain regions and demonstrate its similarity to progenitors and neurons found in primary tissues.

Title: Modeling GABAergic interneuron deficits in Down syndrome using patient iPSCs

Authors: ***Y. LIU**[1], Z.-Y. QU[1], H.-Q. HUO[1], A. BHATTACHARYYA[2], L. MA[3], F. YUAN[1], M. XU[1], Y. HU[1], S.-C. ZHANG[2];

Abstract: Down syndrome (DS) is the most common genetic disorder of intellectual impairment and is caused by trisomy of chromosome 21. Although DS patient exhibit reduced brain size and diminished GABA transmitter from fetal tissue and postmortem studies, the precise cellular and developmental mechanisms of cognitive disorder in DS remain unclear. Patient induced pluripotent stem cells (iPSCs) provide an opportunity to uncover human developmental disorders. Here, we differentiated iPSCs derived from DS patients into forebrain GABA interneurons. Compared to the disomy iPSC control, the DS GABA interneurons demonstrated

defects of neuronal morphological complexity in vitro. To discern the cellular behaviors of DS GABA interneurons in vivo, we further transplanted these GABAergic progenitors into medial septum of SCID mice. After six months of transplantation, the transplanted DS iPSCs generated GABA interneurons similarly with disomy iPSCs in vivo. However, we found DS GABA interneurons had a reduction of neural soma size, shorter neurites, and less dendritic complexity in the graft and adjacent area. Furthermore, DS GABA interneurons exhibit impaired migration and neurite projection along septohippocampal pathway and in hippocampus. These results suggest the abnormal development of DS GABA interneurons may connect to the diminished GABA transmitter and reduced brain size in DS patients. Our study illustrated pathological features of DS and offered a novel model to study the mechanisms of Down syndrome.

Abstract: INTRODUCTION:
Zika virus (ZIKV) has been associated with microcephaly and other brain malformations; however, the molecular effects of ZIKV over the central nervous system remain to be uncovered. Here we examined the deregulated genes expressed in neurospheres infected with ZIKV.
METHODS & RESULTS:
Human Neral Stem Cells (NSC) were exposed to ZIKV Br_AB_ES- isolated from Brazilian patients. After 2 hours viral exposure (0.025 MOI), NSCs were submitted to a differentiation protocol to form neurospheres. Immunocytochemistry was performed 3 days after ZIKV

exposure. To confirm ZIKV infection, we used flavivirus group antigen (clone 4G2) antibody. Apoptosis was measured with activated caspase immunofluorescence. Three days after infection, there was a significant increase in cell death observed in ZIKV infected neurosheres. After 12 days in vitro, neurospheres were completely depleted. In order to evaluate molecular effects of ZIKV infection, we performed RNA-seq of the infected and mock neurospheres after 3 days in vitro. mRNA transcriptional profile analyses revealed that ZIKV infection alters cell cycle regulators and downregulates neurogenic programmes, in addition to transcriptional regulation due to viral replication.

CONCLUSIONS:

Altogether, ZIKV infection modulated genes involved in different pathways inhibiting cell cycle and neurogenesis. The effect of ZIKV at crucial steps of brain development likely explains the consequences of the so-called congenital syndrome of ZIKV on brain formation and function. Our work provides insights into the molecular mechanisms of ZIKV infection. It implicates the ZIKV in progenitor proliferation, differentiation and survival, thus improving our understanding of human microcephalies.

Title: From neuronal progenitors to human neuronal disease models: a 3D path.

Authors: J. CHOUINARD[1], K. KOSIK[2], *S. PAUTOT[1];
[1]ITAV- CNRS USR3505, Toulouse, France; [2]Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: To help delineate pathways for CNS diseases few challenges in growing and maintaining in vitro neuronal network from human neuronal progenitor cells need to be resolved. The main hurtles come from the difficulties to grow, maintain and differentiate human progenitors cells. To contribute to a standardization of neuronal network recording, we show that, in a 3D environment, neuronal progenitors can autonomously differentiate in all three neuronal cell types to replicate in vivo cell architecture, cell composition, and functional activity. We have first established that neuronal networks obtained with rat neuronal progenitors displayed earlier spontaneous neuronal activity and long-term viability compared to standard in vitro models. We then demonstrated that these findings extended to human neuronal progenitors cells. Our experiments showed that human neuronal progenitors derived from hIPSCs could grow and differentiate in our 3D culture system to display spontaneous neuronal activity after four weeks in culture. Using the expression of fluorescent proteins under neuronal cell specific promoters (nestin and synapsin) we monitored the cell differentiation process and the network formation. In parallel, we recorded the evolution of the spontaneous spiking activity over 8 weeks and follow the developmental stage of the neuronal activity. These networks exhibited a long-term viability with no apparent decay in activity for up to 8 weeks. Furthermore, localized electrical stimulation allowed us to establish the existence of long-range connections with specific response patterns depending on both the location of the stimulation and its frequency as expected in in vivo networks. Our results suggest that this approach could contribute to a standardization of human neuronal network formation and become instrumental in the study human neurological disorder by providing a mean to monitor simultaneously neuronal differentiation and neuronal network activity for patient derived iPSCs.

Abstract: After the recent outbreak of Zika virus (ZikV) in Brazil, this has been associated with microcephaly and other brain malformation, and is a major concern in terms of public health around the globe. Nevertheless, despite increasing efforts to understand the effects of ZIKV infection in the central nervous system, much of the molecular outcomes remain uncovered. Our aim was to analyse the molecular consequences of ZIKV infection in neurospheres derived from human induced pluripotent stem cells. These three-dimensional structures contain diving neural progenitors proliferating undergoing neuronal differentiation, glial cells and neurons. Global protein expression was obtained by state-of-the-art quantitative label-free shotgun proteomics. Comparing the expression of the most differentially regulated proteins ($p<0.05$) in ZIKV-infected neurospheres versus mock neurospheres, we detected 199 downregulated and 259 upregulated proteins, mainly involved with translational and transcriptional machinery and cell cycle. To get further insight into these pathways, we analysed the interactome of those proteins, which indicated G1 arrest of the cell cycle progression and the impairment of the neuronal program. These results suggest that zika virus stops cell cycle progression, depleting the pool neural progenitor cells during brain development.

Abstract: Reports of microcephaly in Brazil in combination with Zika outbreak suggests a link between virus infection and brain malformations. Here, we analyzed if the infection with different strains of Zika virus (ZIKV) could reduce human neural stem cells (NSCs) viability as a potential candidate to mediate deleterious effects of this virus on developing brain. We also investigated the cytotoxic potential of Dengue virus, another flavivirus that circulates in Brazil, on NSCs.Human induced pluripotent stem cells were differentiated as NSCs. To test virus infectivity, NSCs were exposed to two different strains of ZIKV (766 and Br_PE - isolated from African and Brazilian patients, respectively, at 0.25 MOI) and also Dengue Virus (DENV2). Immunocytochemistry using the antibody anti-flavivirus group antigen (clone 4G2) was performed after 24h and 72h following virus exposure. In ZIKV 766 strain and DENV2 we observed 21% and 27 % of cells labeled with anti-flavivirus antibody after 24h, although ZIKV Br_PE could only be detected after a longer time post-infection, and 30% of NSCs were labeled after 72h. Cell viability was assessed after ZIKV infection with a 0.025 MOI. Live/Dead assay (Thermo) was performed in a high-content screening plataform. Three days after infection, significant increase in cell death was observed in the group infected with 766, but not with DENV2. Dead cells corresponded to 4% in Mock controls and 58% and 8% in 766 and DENV2, respectively. Dying cells labeled with an active caspase antibody correspond to 7, 14 and 8% in Mock, 766 and DENV2 groups, respectively.Our results point that the 766 ZIKV strain is able to promote NSCs death, whereas DENV2, another endemic flavivirus in Brazil did not induce significant cell death or caspase activation on similar time points. The Brazilian strain Br_PE of ZIKV showed a slower infection rate, suggesting that there are differences between these two strains of ZIKV that could be related with the increased microcephaly cases in Brazil. Taken together these results demonstrate that ZIKV infection induces cell death in NSCs, which can account to the deleterious effects of ZIKV in the developing CNS.

Title: Use of stem cell derived neurons to study chemotherapeutic induced neuropathy

Authors: *M. DOLAN[1,2], S. DELANEY[2], C. WING[2];
[1]Med., [2]Univ. of Chicago, Chicago, IL

Abstract: Chemotherapeutic-induced peripheral neuropathy (CIPN) is one of the most common and potentially permanent side effects of chemotherapy, second only in frequency to hematopoietic toxicity. CIPN often times irreversible, is a condition with pain, numbness, tingling and sensitivity to cold/hot in hands and feet. About 20-40% of cancer patients with estimates of about 400,000 patients each year develop CIPN as a consequence of treatment with platinum analogues (cisplatin, oxaliplatin, carboplatin), taxanes (paclitaxel, docetaxel), vinca alkaloids (vincristine), thalidomide, epothilones and bortezomib. Moreover, CIPN can lead to dose reduction of the chemotherapeutic agent or possible cessation of treatment. This may have an adverse impact on cancer treatment and disease outcomes. The severity of CIPN is greater among older patients and African Americans. Clinical genome wide association studies of CIPN following treatment with paclitaxel, docetaxel, vincristine and cisplatin have been conducted in efforts to identify genetic variants associated with CIPN; however there is a need for appropriate model systems to determine which associations are the true signals, what mechanisms are responsible, and if they represent treatment opportunities. We have employed the use of induced pluripotent stem cell derived neurons to functionally validate genetic variants/genes identified in genome wide studies of CIPN. We have optimized conditions to identify reproducible differences in relative neurite outgrowth phenotypes following treatment with neurotoxic chemotherapeutics including, but not limited to thalidomide, paclitaxel, vincristine, cisplatin, cannibidiol (component of marijuana) and bortezomib. Similarly to that observed in patients, neurotoxic doses of vincristine are approximately 40-fold lower than those for paclitaxel and 75-fold lower than those for cisplatin. In addition, prior animal studies reveal similar differences in severity among drugs compared to our results. The iPSC-derived neurons allow: a) studies of peripheral neuropathy in human neurons in ways that were not possible previously; b) mechanistic insight on druggable targets to treat or prevent this devastating side effect of chemotherapy; c) provide a model to study genetic components and genes contributing to severe neurotoxicity; d) provide a genetically diverse model that can be used to develop cell based

phenotypic assays for high content screening of all new drugs to determine if they are neurotoxic.

Title: Inducing human embryonic stem cells to differentiate into neuroectoderm by suppressing a novel gene expression

Authors: ***J.-J. LIU**[1], S.-C. YANG[2], J. LU[3];
[1]Univ. of Pennsylvania, Sch. of Med., Philadelphia, PA; [2]Inst. of Biochem. and Mol. Biol., Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Academia Sinica, Taipei, Taiwan

Abstract: Human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSC) are characterized by their robust expansion ability and pluripotency. However, the application of ESC- or iPSC- derived cells is hampered by the low efficiency of differentiation. To reveal the genes inhibit ESC differentiation, a shRNA functional screen is performed with 517 shRNA targets 121 genes. Based on the results of ESC undifferentiated marker alkaline phosphatase activity assay and the relative cell number Alamer blue assays, 21 genes altered ESC pluripotency were identified. Among these hits, the downregulation of one candidate gene, ATF1, can promote ectoderm differentiation by the upregulation of early neuroectoderm genes SOX2 and PAX6 within 3 days with nearly 100% efficiency. Conversely, the overexpression of ATF1 inhibits the upregulation of SOX2, which is required for neuron induction. We also found that ATF1 can bind to the promoter regions of SOX2 and PAX6 by CHIP-PCR assay. These results suggested ATF1 may serve as a suppressor by directly binding to Sox2 and Pax6 promoters. We will further reveal the molecular mechanisms of how ATF1 inhibits neuroectoderm differentiation by the regulating SOX2 and PAX6. The downregulation of ATF1 with shRNA or siRNA provided an efficient method to generate neural lineage cells that might be useful for regenerative medicine in the future.

Title: Phosphorylation of huntingtin at ser421 modulates the phenotype of the mecp2 deficient mice

Authors: *Y. EHINGER[1], L. SAIDI[1], V. MATAGNE[1], J. BRUYÈRE[2], F. SAUDOU[2], J.-C. ROUX[1], L. VILLARD[1];
[1]Aix-Marseille Université, GMGF, INSERM, Umrs_910, Marseille, France; [2]Univ. de Grenoble, Inst. des neurosciences Grenoble, Inserm, U836, Grenoble, France

Abstract: Rett syndrome is a neurological disorder caused by mutations in the X-linked MECP2 gene. We demonstrated that Huntingtin-dependant (Htt) axonal transport is altered when Mecp2 is lacking partly due to a deficit of the molecular motor contents (Roux et al., 2012). However, the neuronal trafficking is also strongly dependent on the phosphorylation level of Htt at serine 421 (S421) (Zala et al, 2008). Therefore, we developed several tools in order to stimulate pharmacologically Htt phosphorylation at S421 in vivo and in vitro using: 1) a direct activation of the Akt pathway, through the stimulation of the insulin/IGF1 receptors and 2) the indirect blocking of the Htt dephosphorylating using Fk506. In a second step we used a genetic approach by crossing Mecp2 deficient mice with knockin mice expressing either an aspartic acid or alanine at position 421 to mimic constitutive phosphorylation (S421D) or to prevent phosphorylation (S421A), respectively. For both pharmacology and genetic crossing we used a battery of behavioral tests : grip strength, rotarod, open field and the respiratory profile from disease onset. Our findings demonstrate that pharmacological and genetic stimulation approaches increase longevity in Mecp2 deficient mice. Altogether, behavioural tests suggest a reduction of motor and respiratory impairments. Further studies are necessary to evaluate the neuronal trafficking at a molecular level. Our results indicate that stimulation of the Htt S421 represents a promising way to improve the neuronal trafficking in RTT and a possible target to develop treatments in RTT.

Title: Stronger contribution and impaired LTP of hippocampal inputs to the medial prefrontal cortex in the Mecp2 mouse model of Rett syndrome

Authors: *M. PHILLIPS, W. LI, L. POZZO-MILLER;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The balance between excitation and inhibition (E/I) in the CNS is crucial for proper brain function. This balance is altered in several brain regions of mouse models of Rett syndrome, a neurodevelopmental autism spectrum disorder caused by mutations in the methyl-CpG binding protein-2 (*MECP2*) gene. E/I imbalance results in altered levels of neuronal activity, causing neural networks to be either hyper or hypoactive. We quantified network activity by imaging voltage-sensitive dye (VSD) signals in slices from symptomatic male *Mecp2* knockout (KO) mice and wildtype (WT) littermates. Evoked VSD signals are larger, longer lasting, and wider spreading in slices of the ventral hippocampus (vHipp) from *Mecp2* KO mice, compared to WT slices. In contrast, VSD signals in slices from the medial prefrontal cortex (mPFC) of *Mecp2* KO mice are shorter lasting and less spreading. These data are confirmed by the number of neurons expressing the immediate early gene c-Fos: the *Mecp2* KO vHipp has more c-Fos positive neurons, while the *Mecp2* KO mPFC has fewer c-Fos neurons. Intriguingly, stimulation of identified vHipp fibers in mPFC slices evoked larger and wider spreading VSD signals in *Mecp2* KO slices. Normalized to intra-cortical stimulation in the same slices, there is a stronger contribution of vHipp inputs to the *Mecp2* KO mPFC (93% of intra-cortical responses *vs*. 71% in WT). Altogether, these data suggest that vHipp fibers drive hyperactivation of the mPFC network in *Mecp2* KO mice, in contrast to the hypoactivity evoked by stimulation of

intra-cortical fibers. In addition, high-frequency stimulation of vHipp fibers triggers an enduring enhancement of the duration and spread of VSD signals in mPFC slices from WT mice, which is reminiscent of long-term potentiation (LTP) of synaptic potentials. This LTP of VSD signals at vHipp-mPFC synapses is absent in *Mecp2* KO mice, which may contribute to behavioral deficits during their social interaction with known and unknown mice. Current experiments are designed to identify the postsynaptic receptors responsible for VSD signals evoked by either stimulation of vHipp inputs or intra-cortical fibers, and whether LTP of VSD signals at vHipp-mPFC synapses in *Mecp2* KO slices is saturated by already potentiated synapses, as occurs in the hippocampus. Title: Deciphering oxidative stress in rett syndrome with genetically-encoded redox sensors

Authors: K. CAN, K. WAGENER, B. KOLBRINK, K. DIETRICH, K. BELINDA, *M. MUELLER;
Univ. Goettingen, Goettingen, Germany, Germany

Abstract: Rett syndrome (RTT) is a progressive neurodevelopmental disorder which affects almost exclusively girls. After a largely normal development in the first year, a complex clinical phenotype manifests. Characteristic symptoms include cognitive impairment, epilepsy, motor dysfunction, and severe breathing disturbances. There is convincing evidence that mitochondrial function is affected in Rett syndrome and that is contributes to the occurrence of oxidative stress. Genetically-engineered optical sensors such as reduction oxidation sensitive green fluorescent protein (roGFP) enable a quantitative assessment of subcellular redox conditions. Detailed redox analyzes in isolated brain tissue of male Rett mice revealed intensified mitochondrial respiration, less efficient cellular redox homeostasis, and oxidative stress in cytosol and mitochondria of MeCP2-deficient neurons. Interestingly, these alterations occur already at neonatal stages, long before first symptoms arise. Therefore, the redox imbalance may critically contribute to the

manifestation of typical Rett symptoms and facilitate disease progression. So far, the mandatory transfection/transduction mostly restricted redox imaging to cultured preparations. To assess subcellular redox conditions also in adult tissue and complex preparations, we generated transgenic redox indicator mice. They express roGFP under the control of the Thy-1.2 promoter in either cytosol or mitochondrial matrix. The roGFP redox sensor is fully functional and almost abundantly expressed in excitatory projection neurons throughout the brain. Currently, roGFP mice are cross-bred with MeCP2-deficient mice. First offspring has already confirmed that the transgene is forward and that the redox balance is also more oxidized in hippocampal neurons of adult, symptomatic male Rett mice. Availability of these roGFP-Rett mice will now reveal subcellular redox conditions during normal maturation and the different stages of Rett syndrome. The extent of redox alterations can be quantified reliably and correlated in detail with disease progression. This will not only allow to map and to identify those brain regions being most severely affected by the redox imbalance, but also to clarify to what extent redox alterations and the resulting oxidative stress drive the progression of this neurodevelopmental disorder. Furthermore, a valuable system is now available to confirm the feasibility of antioxidant/radical scavenger based therapeutic approaches for the treatment of Rett syndrome.

Title: EEA1 overexpression reduces synaptic strength and restores homeostatic synaptic plasticity in cultured hippocampal neurons from Mecp2 knockout mice

Authors: *X. XU[1], L. POZZO-MILLER[2];
[1]Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL; [2]Neurobio., The Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Negative-feedback homeostatic synaptic plasticity (HSP), also known as synaptic scaling, maintains the global synaptic strength of individual neurons in response to sustained

alterations in neuronal activity. This cell-wide homeostatic balance is critical to allow the potentiation or depression at small subsets of synapses during positive-feedback synaptic plasticity (i.e. Hebbian plasticity). Rett syndrome (RTT) is a progressive autism spectrum disorder caused by loss-of-function mutations in the gene encoding methyl-CpG-binding protein 2 (MeCP2). Previously, we discovered an imbalance of synaptic excitation and inhibition (E/I) in the hippocampus of symptomatic *Mecp2* knockout (KO) mice (Calfa *et al.* 2015). Since E/I balance is thought to be maintained by homeostatic mechanisms, we examined the role of MeCP2 in HSP at the excitatory synapses. We found that hippocampal neurons obtained from P1 *Mecp2* KO mice (9-11 days *in vitro*) do not show the characteristic homeostatic scaling-up of mEPSC amplitude and of synaptic levels of GluA1 after 48hs silencing with the Na^+ channel blocker TTX. This deficit in HSP is bidirectional because *Mecp2* KO neurons also failed to scale-down mEPSC amplitude and synaptic levels of GluA1 after 48hs of desinhibition with the GABA-A receptor antagonist bicuculline. The best-characterized mechanism of HSP is the regulated trafficking into and out of synapses of the AMPA-type of glutamate receptors (AMPARs). We focused on early-endosome-antigen-1 (EEA1) because it participates in synaptic removal of GluA1 (Selak *et al.* 2006), and was found to be activated by MeCP2 in a microarray study (Chahrour *et al*. 2008); consistently, mRNA and protein EEA1 levels are lower in the *Mecp2* KO hippocampus (Li *et al.* 2016). Here, we tested whether EEA1 overexpression restores mEPCS amplitudes and HSP in hippocampal neurons from *Mecp2* KO mice. EEA1 overexpression in *Mecp2* KO neurons reduced mEPSC amplitudes to levels comparable to those in WT neurons. In addition, *Mecp2* KO neurons overexpressing EEA1 scaled-down mEPSC amplitudes after desinhibition with bicuculline, suggesting that HSP is restored. Our characterization of the role of EEA1 during HSP in *Mecp2* KO neurons provides novel targets for improving hippocampal function in RTT individuals.

Title: Improved survival in a knock-in model of Rett syndrome after systemic administration of AAV9/MECP2

Authors: *S. R. COBB[1], K. K. GADALLA[1,2], T. VUDHIRONARIT[1], N. BAHEY[1,3], R. HECTOR[1], M. E. S. BAILEY[1], S. GRAY[4];

Abstract: *De novo* mutations in the X-linked gene *MECP2* are responsible for ~95% of typical Rett syndrome (RTT) cases which are characterized by severe motor and cognitive impairments in females. The missense T158M mutation is one of the most common and severe RTT-causing mutations. It is unknown whether the presence of endogenous mutated protein may impede the therapeutic action of a gene therapy approach. The aim of this study was therefore to investigate the effectiveness of systemic administration of scAAV9/h*MECP2* on survival and other phenotypes in the *Mecp2*$^{T158M/y}$ knock-in mice.
A myc-tagged human *MECP2_e1* minigene construct packaged in a self-complementary AAV2/9 vector (10^{12} vg/mouse) was delivered intravenously into juvenile *Mecp2*$^{T158M/y}$ mice which were then monitored for survival, body weight and RTT-like phenotype severity score. Treated *Mecp2*$^{T158M/y}$ mice had significantly extended survival (p =0.001) and increased body weight (p <0.001) compared to vehicle-treated mice. However, there was no improvement in the aggregate severity score. Brain transduction efficiency was relatively low (1-3% of DAPI-positive cells), which likely explains the lack of impact on neurological phenotypes. Similar results were obtained in *Mecp2*$^{-/y}$ KO mice.
These data support the concept that the action of exogenous MeCP2 is unlikely to be confounded by deleterious interactions with endogenous mutated MeCP2 protein. Currently, we are optimizing the route of administration and vector design to enhance brain transduction and maximize therapeutic efficacy.

Title: Novel dendrimer-conjugated glutaminase inhibitor targets glutamate dysregulation in a mouse model of Rett Syndrome

Authors: *E. S. SMITH[1], R. R. REDDY[2], S. P. KAMBHAMPATI[2], F. ZHANG[2], M. V. JOHNSTON[3,4], B. SLUSHER[3,5], R. M. KANNAN[1,2,3], M. E. BLUE[3,4], S. KANNAN[1]; [1]Critical Care Med., [2]Ctr. for Nanomedicine, [3]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Hugo W. Moser Res. Inst., Kennedy Krieger, Baltimore, MD; [5]Johns Hopkins Drug Discovery, Baltimore, MD

Abstract: Glutamate dysregulation plays a neuropathological role in Rett Syndrome (RTT) and in mouse models of RTT. Previous studies have shown that increased glutaminase levels in microglia from *Mecp2*-null mice lead to overproduction of glutamate and cellular toxicity. This combined with other coinciding neuropathology could potentially contribute to cell stress and toxicity as well as neurobehavioral consequences associated with RTT. Glutaminase inhibition has a potential therapeutic avenue for targeting diseases where glutamate levels are excessive. However, glutaminase inhibitors are poor drug candidates for central nervous system applications since they have poor solubility and do not cross the blood brain barrier (BBB). To investigate the use of dendrimer-mediated therapy, we used dendrimer-conjugated to a novel Bis-2-(5-phenylacetamido-1,2,4-thiadiazol-2-yl)ethyl Sulfide 3 analog, JHU-29 (D-JHU-29) in a *Mecp2*-null mouse model of RTT. We first injected generation-4 poly (amidoamine) dendrimers tagged with a fluorescent tag (Cy5; D-Cy5) to determine whether dendrimer nanoparticles penetrate the BBB of *Mecp2*-null mice. Twenty-four hours after injection, D-Cy5 was found to be specifically co-localized in microglia and astrocytes of *Mecp2*-null mice. Secondly, we evaluated the efficacy of D-JHU-29 *ex vivo* to reduce extracellular glutamate (Glu) levels in hippocampal slice culture from *Mecp2*-null mice. The results showed increased Glu levels in cultures from *Mecp2*-null mice compared to those from wild type mice and that D-JHU-29 treatment lowered Glu levels. Further studies are ongoing that will determine the impact of D-JHU-29 in *Mecp2*-null mixed glial cultures and the acute *in vivo* efficacy of D-JHU-29 in reducing phenotypic features of *Mecp2*-null mice. Our preliminary results indicate that dendrimer-mediated glutaminase inhibition may be a viable treatment approach for reducing glutamate-related neuropathology in RTT.

Title: Pharmacological modulation of GABAergic neurons in a mouse model of Rett Syndrome

Authors: *K. M. URE, H. ZOGHBI;
Baylor Col. of Med., Houston, TX

Abstract: Rett syndrome is a postnatal neurological disorder caused by mutations in the gene encoding methyl-CpG binding protein 2 (*MECP2*) and is characterized by ataxia, learning and memory deficits, seizures, breathing abnormalities, and a stereotyped hand-wringing motion. Mice with *Mecp2* deleted from the brain replicate most of the human symptoms. Surprisingly, loss of *Mecp2* specifically from GABAergic neurons replicates most of these phenotypes, and reexpression of *Mecp2* solely in GABAergic neurons reverses many of the disease phenotypes. These findings highlight the importance of proper inhibitory neuronal function in Rett syndrome and suggest that pharmacological enhancement of inhibition may be a therapeutic approach for the disorder. Here, we report the results of two drug trials in *Mecp2*-null male and *Mecp2*-heterozygous female mice: vigabatrin, which irreversibly blocks GABA catalysis, thus increasing somatic GABA content, and SGE-516, a novel neurosteroid that acts as a positive allosteric modulator of the $GABA_A$ receptor. We injected male wildtype and *Mecp2*-mutant mice with either vehicle, vigabatrin (250mg/kg), or SGE-516 (3 mg/kg) daily from weaning through the duration of the study and assessed body weight and disease score weekly, as well as anxiety, motor coordination, learning and memory, and sensorimotor gating at 6-8 weeks of age, and monitored survival (n=15-20 per genotype/drug). We similarly treated female *Mecp2*-heterozygous mice (n=15-20 per genotype/drug) and assessed the same measures at 9-10 weeks and 25 weeks of age. While vigabatrin prevented weight gain in female *Mecp2*-heterozygous mice, neither therapeutic resulted in any survival or behavioral benefit to either male or female *Mecp2* mutant mice. This finding, as well as recent work from our lab showing that reexpression of *Mecp2* solely in glutamatergic neurons also confers significant benefit to *Mecp2* mutant mice, suggests that enhancement of inhibition alone (or excitation alone for that matter) may not be sufficient for reversal of Rett-like phenotypes. We are currently investigating the effect of modulation of both excitation and inhibition using DREADD technology to better understand the

interplay between these two systems in Rett syndrome. The results of these experiments will better direct future therapeutic choices in the search for effective interventions for Rett patients.

Title: Longitudinal study of female Rett syndrome mice: touchscreen testing to characterize the onset and progression of cognitive disability

Authors: *L. A. ROTHBLAT, H. L. H. RUTZ;
Psychology, George Washington Univ., Washington, DC

Abstract: Rett syndrome (RTT) is a monogenic neurodevelopmental disorder that in females leads to life-long intellectual disability. RTT is most often caused by spontaneous mutations in the gene that encodes methyl-CpG-binding protein 2 (MeCP2). Much of what is now known about the brain pathophysiology in RTT is attributable to work with transgenic and knockout mice where *Mecp2* is functionally altered. These mice display many cellular and behavioral symptoms that mirror the human condition. Recent studies with RTT mouse models indicate that it may be possible to correct both circuit and neurological dysfunction in young or even adult animals. However, whether a primary clinical feature of the human disorder, cognitive disability, is a significant component of the mouse phenotype and, if so, whether it is correctable, is currently unknown. To study these questions, we have been using a repeating visual reversal touchscreen task to characterize the neurocognitive profile of heterozygous females with two different mutations, *Mecp2 T158A/+* and *Mecp2+/-*. Daily testing began when the mice were 10 weeks of age and is continuing through adulthood. We have found that even mice with unambiguous motor symptoms (reduced locomotor activity in home cage, bilateral hind limb clasp) can be readily tested in the touchscreen. Neither *Mecp2 T158A/+*, nor *Mecp2+/-*, were significantly impaired on acquisition of the initial visual discrimination. In marked contrast to *Mecp2 T158A/+*, *Mecp2+/-* mice required significantly more trials and made significantly more errors when learning the first visual reversal. *Mecp2+/-*, but not *Mecp2 T158A/+*, continue to display a significant impairment on repeated discrimination reversals (testing to 32 weeks of age). We do not yet know if cognitive disability will become evident in *Mecp2 T158A/+* and worsen in *Mecp2+/-* as the mice get older since there is evidence for an enhanced role of MeCP2

in the aging brain. Our findings do show that different *Mecp2* mutations produce distinct cognitive phenotypes that can be accurately tracked in individual animals through longitudinal testing. Moreover, they illustrate how cognitive outcome measures that extend over time could be particularly useful for evaluating possible therapeutic interventions for preventing or reversing intellectual disability in RTT and other autism-related neurodevelopmental disorders.

Title: Symptom reversal during activation of the medial prefrontal cortex in a mouse model of Rett syndrome.

Authors: C. J. HOWELL[1], M. SCENIAK[2], *D. M. KATZ[1];
[1]Dept Neurosciences, Case Western Reserve Univ., Cleveland, OH; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Rett Syndrome (RTT), a severe neurodevelopmental disorder caused by loss-of-function mutations in the *MECP2* gene, is characterized by postnatal neurological regression leading to severe deficits in motor function, verbal communication and respiratory and autonomic control, among other symptoms. Cardiorespiratory dysfunction severely impacts quality of life and is thought to contribute to early death in some patients (*Kerr, et al., 1997*). Studies of respiratory abnormalities in preclinical models have generally focused on dysfunction in brainstem circuitry, despite the fact that restoring wildtype expression of *Mecp2* in the brainstem of *Mecp2* mutants does not completely restore normal respiration (*Ward et. al., 2011*). Furthermore, behavioral state is known to strongly influence respiratory dysfunction in RTT and *Mecp2* mutants (*Kron et al., 2014)*, suggesting that cortical influences on breathing are abnormal. This hypothesis is supported by recent findings from our laboratory that the medial prefrontal cortex (mPFC), a critical region for cortical modulation of breathing, is hypoactive in *Mecp2* mutants (*Sceniak et al., 2015*). In contrast, *Mecp2* mutants exhibit increased activity in brainstem respiratory nuclei that receive direct projections from the mPFC, including the nucleus tractus solitarius (nTS; *Kron et. al., 2012*). Together, these data suggest that reduced cortical input may contribute to abnormal brainstem function and respiratory abnormalities in RTT. To

test this hypothesis, we took a pharmacogenetic approach to determine whether or not activation of the mPFC in heterozygous female *Mecp2* mutants (Hets) with an excitatory DREADD (Designer Receptor Exclusively Activated by Designer Drugs) would ameliorate respiratory dysfunction. Our findings demonstrate that DREADD activation of mPFC pyramidal neurons that project directly to brainstem respiratory nuclei eliminates apneic breathing in *Mecp2* Hets. Using expression of the immediate early gene product Fos as a surrogate marker of neuronal activity, we find that DREADD activation of the mPFC restores wildtype Fos levels in the mutant nTS. These data indicate that activation of the mPFC reduces brainstem hyperactivity and reverses apneic breathing in *Mecp2* Hets, suggesting that impaired cortical modulation of brainstem respiratory nuclei may contribute to respiratory dysfunction in RTT. Current studies are focused on the role of mPFC circuit dysfunction in other features of the RTT phenotype. This work is supported by NINDS (R01/R56NS057398 to DMK).

Title: Rescuing Rett Syndrome through the choroid plexus

Authors: *A. PATRIZI[1], C. LI[1], Y. ZHANG[1], M. FAGIOLINI[1], T. K. HENSCH[1,2]; [1]Neurol., Boston Children's Hosp. Harvard Med. Sch., Boston, MA; [2]Dept. of Mol. and Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: Parvalbumin-positive (PV+) fast-spiking basket cell maturation controls critical periods of brain development and is typically altered across many neurodevelopmental disorders.

For example, PV+ circuits are hyper-connected in the *Mecp2* knockout (KO) mouse model of Rett Syndrome (Durand, Patrizi et al, 2012; Krishnan et al, 2015). This is detected as early as eye-opening and may contribute to the silencing of cortical circuits in *Mecp2* mutants. Here, we first confirmed an intensified PV+ 'gate' in layer 4 of human *post mortem* visual cortex from Rett patients as compared to neurotypical controls. To identify potential factors underlying such PV+ hyper-maturation, we focused on the Otx2 homeoprotein, a potent non-cell autonomous regulator of PV+ cell maturation and maintenance (Sugiyama et al, 2008). Notably, the choroid plexus (ChP) is a major source of Otx2 in the postnatal brain globally impacting PV+ cell state from a distance (Spatazza et al, 2013). We found a striking increase in Otx2 transcription and production in the ChP of *Mecp2* KO mice as compared to wild type littermates. Two genetic strategies were employed to down-regulate Otx2 synthesis. *Mecp2* KO mice crossed to a conditional Otx2 line (*Otx2* fl/fl) were 1) further crossed to a ChP-specific Cre line (*FoxJ1*-Cre), or 2) injected with virus (AAV-Cre) intracerebroventricularly. Both manipulations produced a selective reduction of Otx2 in the ChP without affecting other known sources (retina, superior colliculus). Notably, both manipulations doubled the lifespan and improved the physical appearance and motor performance of *Mecp2* KO mice. Cortical organization of the rescued *Mecp2* KO mice revealed normal cortical thickness and PV+ intensity, fewer Otx2+ cells and normal protein levels. Finally, local disruption of Otx2 transfer into cortical PV cells by short, interfering peptides rapidly reduced Otx2 and PV expression followed by a gradual renormalization of peri-somatic axon bouton number in *Mecp2* KO mice over a 5 to 15-day time course. Taken together, these results suggest down-regulation of ChP-derived Otx2 as a potential therapeutic route for correcting cortical PV-circuit connectopathies and improving several key aspects of the Rett syndrome phenotype.

Title: Normal phenotypic outcome in a molecular hypomorphic allele of Mecp2 may define the therapeutic window for intervention in MeCP2 disorders

Authors: *C. S. WARD[1,2], S. SORIANO[1], M. R. PITCHER[3], A. CHAHROUR[1], A. J. LIANG[1], C. M. MCGRAW[4], J. L. NEUL[2], R. C. SAMACO[1];

Abstract: Rett syndrome (RTT) is caused by loss-of-function mutations in the gene encoding the transcriptional modulator *Methyl-CpG-Binding Protein 2* (*MECP2*); in contrast, chromosomal duplications spanning *MECP2* result in a progressive neurological disorder. The human conditions and their respective mouse models support the notion that the levels of MeCP2 must be tightly regulated for normal neurological function. Furthermore, previous studies demonstrated several neurobehavioral abnormalities in mice with a 50% reduction in MeCP2 expression. These studies raise the concern that the therapeutic window for intervention with respect to modulating MeCP2 levels may be narrow. Therapies that surpass the upper bound of this window and result in excess MeCP2 may induce disease, whereas therapies that fail to reach the lower bound of this window may not improve disease. We therefore set out to test the neurobehavioral and molecular consequences in a mouse model that has an approximate 20% reduction in MeCP2 levels to determine whether complete restoration of MeCP2 expression is required for normal phenotypic outcome. We found that mice harboring a mild hypomorphic allele of MeCP2 are comparable to wild-type animals in a broad range of behavioral, physiological and molecular measurements. Furthermore, we found that the 20% reduction in this mouse model reflects an overall decrease in MeCP2 expression in both neurons and glia. These data provide a genetic proof-of-concept that absolute normalization of MeCP2 levels may not be necessary for normal neurological function, and suggest that increasing MeCP2 levels to at least 80% of the normal range may be beneficial for RTT.

Title: Optimization of an antisense oligonucleotide therapy in humanized MECP2 duplication mice and human neurons

Authors: *E. SZTAINBERG[1], Y. SHAO[2], M. ZAGHLULA[3], F. RIGO[5], H. Y. ZOGHBI[4]; [1]Mol. and Human Genet. Dept., Baylor Col., Houston, TX; [2]Program in Developmental Biol., [3]Program in Translational Biol. and Mol. Med., [4]Mol. and Human Genet., Baylor Col. of Med., Houston, TX; [5]Ionis Pharmaceuticals, Carlsbad, CA

Abstract: *MECP2* duplication syndrome is one of the most common genomic rearrangements in males and is characterized by autism, intellectual disability, motor dysfunction, anxiety, epilepsy, recurrent respiratory tract infections and early death. Our classic *MECP2* duplication syndrome mouse model (*MECP2*-TG) expresses a human *MECP2* allele in addition to the endogenous mouse *Mecp2* allele, and recapitulates many of the characteristics of the disease at the molecular, electrophysiological, and behavioral levels. We recently showed that treatment with an antisense oligonucleotide (ASO) that targets *MECP2* induces a broad phenotypic rescue in adult symptomatic *MECP2*-TG mice. Antisense oligonucleotides are small, modified nucleic acids that can selectively hybridize to messenger RNA transcribed from a target gene to silence it. Because *MECP2*-ASOs are human-specific and only target human *MECP2* mRNA, one is assured in this model with one human and one mouse copy that ASO treatment will leave the expected 1X levels from the mouse allele. In humans, however, the two copies are identical and one must ensure that the ASO is titrated to target the human allele such that MeCP2 levels go from 2X to 1X. To advance the ASOs approach we must establish models of *MECP2* duplication syndrome that precisely mimic the human condition by having two human *MECP2* alleles and no mouse allele. We therefore generated and characterized a humanized model of the *MECP2* duplication syndrome by breeding *MECP2*-TG mice with *MECP2*-GFP mice (*MECP2* tagged with GFP at the C-terminus), on an endogenous *Mecp2*-null background. These humanized *MECP2* duplication mice are viable, have no apparent physical abnormalities, overexpress MeCP2 by 2-fold, and display properties reminiscent of *MECP2* duplication syndrome. In addition, we generated and validated iPSCs-derived neurons from *MECP2* duplication patients. We are currently studying the pharmacokinetics of the *MECP2*-ASOs and the safety margin of MeCP2 levels in both the humanized mouse model as well as in the iPSCs-derived neurons.

Title: Modulating elevated brain VEGF-A to treat Fragile X Syndrome vocalization deficits

Authors: *A. BELAGODU, A. JOHNSON, R. GALVEZ;
Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Fragile X Syndrome (FXS) is the leading form of inherited mental retardation. It is caused by the transcriptional silencing of fmr1, the gene which codes for the fragile X mental retardation protein. FXS patients have been shown to exhibit numerous behavioral and cognitive impairments, such as ADHD, OCD, and autistic-like behavior. In addition to these behavioral abnormalities, they also exhibit various deficits in speech and language. Studies in human FXS patients have shown that they form abnormal sentence structures, have issues with utterances, increased repetition of sounds and words, and articulation. To study the biological underpinnings of these speech abnormalities, our prior study used a mating separation procedure to conduct a detailed spectral analysis of FXS mouse ultrasonic vocalizations (USVs) and demonstrated similar repetitive vocalization abnormalities, strengthening the neuroethological relevance of this model. Interestingly our prior studies have demonstrated that FXS mice also have elevated brain VEGF-A levels; that when blocked can alleviate neuronal and cognitive abnormalities. The current study set out to determine if decreasing VEGF-A binding to its receptor can alleviate FXS USV abnormalities. In this study, a standard mating separation procedure was used. Individual adult male mice were briefly exposed to an adult female mouse. Once the male expressed an interest in the female, the female was removed which elicited USVs from the male. The male USVs were recorded using an ultrasonic recording system (Avisoft, Germany) and analyzed using an existing custom MatLab program designed to detect, spectrally analyze, and classify mouse USVs. Following the exposure, male mice underwent a series of injections of bevacizumab, a VEGF-A antagonist, every other day for 10 days. The day after the fifth injection, the same aforementioned procedure was used, and the USVs generated were compared to those obtained from the mouse prior to injections. Pretreatment analyses of USV properties demonstrated similar FXS abnormalities as previously reported. However initial analysis has indicated that following blocking of VEGF-A binding to its receptor FXS mice exhibited USV vocalizations more similar to those observed in controls. These findings suggest that modulating VEGF-A levels can have a global effect and potentially help alleviate both cognitive and behavioral FXS deficits

Title: Confirmation of thyroxine treatment for fetal alcohol spectrum disorders in a vulnerable breed

Authors: *E. TUNC-OZCAN, K. M. HARPER, B. M. ANDRUS, E. E. REDEI;
Dept. of Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Fetal Alcohol Spectrum Disorder (FASD) encompasses a continuum of disabilities caused by fetal alcohol exposure (FAE). Hippocampus-based cognitive and affective behavioral deficits are among the most debilitating consequences of FAE. In our rat model, offspring exposed to ethanol (E) *in utero* recapitulates these deficits of FASD. Similar deficits, particularly in the cognitive domain, are found in children of mothers with subclinical hypothyroidism during pregnancy. Since E-consuming women and also the rat dam show decreased levels of thyroxin (T4), we administered T4 into the E-containing diet aiming to reverse the deleterious effects of E-induced maternal hypothyroidism. In two separate studies hippocampus-dependent behavioral deficits were reversed by T4 supplementation to the E-consuming Sprague-Dawley (S) rat dams. Furthermore, the deleterious effects of FAE transmitted to the next generation through the matrilineal lineage were also prevented by T4 administration to the E-consuming S grand-dams. In both studies, adult FAE offspring of the S strain showed a hyperthyroid profile with elevated plasma free T3 and decreased plasma TSH levels, which were normalized by maternal T4. Hippocampal expression of the imprinted *Dio3* gene, which metabolizes the biologically active thyroid hormone, were elevated in the FAE S offspring, and in the progeny of FAE S females mated with a Brown Norway (B) male. *Dio3* transcript levels were also normalized by T4 administration to the E-consuming dam or grand-dam, respectively. In the present study, S females were mated with B males and the S dams received control diets (*ad libitum* and nutritional control) or E containing liquid diet with and without T4 (0.3mg/l diet) as in the previous studies. Adult SB offspring were tested for hippocampus-dependent contextual fear conditioning, despair-like behavior in the forced swim test, thyroid function and hippocampal expression of *Dio3* and the thyroid hormone-regulated neurogranin *(Nrgn)* gene.
Both decreased fear memory and increased depression-like behavior were reversed by maternal T4 administration in the FAE SB offspring. Hippocampal *Dio3* and *Nrgn* expression showed changes in response to FAE and T4 treatment similar to those in the previous two studies, despite the hypothyroid peripheral thyroid profile; opposite to those observed previously. Thus, *Dio3*,

rather than peripheral thyroid function may regulate brain thyroid hormone availability. Maternal T4 administration reproducibly reverses cognitive and affective behavioral deficits induced by FAE, likely via regulating brain *Dio3* levels.

Title: Choline supplementation ameliorates brain and behavior phenotypes associated with prenatal ethanol exposure in a mouse model of FASD

Authors: *R. T. BOTTOM[1], C. W. ABBOTT, III[2], J. A. RUMSCHLAG[1], K. J. HUFFMAN[1]; [1]Neurosci., Univ. of California, Riverside, Riverside, CA; [2]Dept. of Genet. and Sch. of Med., Stanford Univ., Palo Alto, CA

Abstract: Fetal alcohol spectrum disorders, or FASD, broadly describe the spectrum of deleterious effects resulting from prenatal exposure to ethanol (PrEE). Despite widespread warnings, CDC recently reported that nearly 20% of pregnant women age 34-40 admitted to drinking during their pregnancies. Thus, we must look beyond abstinence to new preventative, therapeutic approaches. Recently, choline supplementation has been reported to improve both behavioral (Thomas et al., 2010) and neurological (Bekdash et al., 2013) deficits in PrEE rats. Here, we demonstrate that maternal choline supplementation administered with ethanol reduces genetic, neuroanatomical, behavioral defects associated with PrEE. Abnormal development of intraneocortical connections, neuroanatomical structures, and ectopic neocortical gene expression are previously documented phenotypes in newborn PrEE offspring (El Shawa et al., 2013; Abbott et al., 2016). These effects are ameliorated in PrEE newborn mice supplemented with choline via maternal self-administration throughout gestation. Finally, we demonstrate that PrEE mice supplemented with choline show a reduction in sensorimotor deficits associated with prenatal exposure to ethanol as well as significant improvements in anxiety and depression-like behaviors, as assessed by a battery of behavioral tests at postnatal day 20. These data suggest choline supplementation may be able to reverse the development of neurological and behavioral deficits in PrEE mice. These results implicate choline as a possible clinical prevention for

women who continue to drink during their pregnancies, thus reducing the incidence or severity of FASD in humans.

Title: Developmental vitamin D deficiency ameliorates the effects of prenatal exposure to ethanol

Authors: *M. C. SANCHEZ VEGA[1], S. CHONG[2], T. H. J. BURNE[1];
[1]The Queensland Brain Inst., Brisbane, Australia; [2]Mater Res. Institute- The Univ. of Queensland, Brisbane, Australia

Abstract: There is a high prevalence of vitamin D deficiency and exposure to low levels of alcohol consumption in pregnant women (Bodnar et al., 2007, Daly et al., 2012). However, there are a paucity of studies that have addressed the impact of both of these exposures on the offspring's vulnerability to neuropsychological disorders later in life. The aim of this study was to examine whether the absence of vitamin D during gestation in mice would alter the effects of prenatal exposure to low dose ethanol.
Four-week old female C57Bl/6J and Balb/c mice were placed on a vitamin D deficient or standard diet for 6 weeks and mated at 10 weeks of age. Females were exposed to either 10 %(v/v) ethanol or water for GD 0-8 and offered water for the rest of gestation. Analyses included ultrasonic vocalizations at P7, social interaction (SI) at P21, locomotion and spatial learning and memory at P70. Ex-vivo MRI and Next-generation sequencing (NGS) was carried out in neonatal brains, followed up by gene and protein expression analyses on candidates in P0 and P70 tissue.
The main findings at P7-21 were increased calling rate in prenatal ethanol-exposed (PEE) males, altered distribution of call types among DVD and EtOH groups and impaired SI in PEE males. Hypolocomotion was encountered in PEE adult males, while learning and memory performance in the Active Place Avoidance task was unaffected in all Groups. Gross brain anatomy was unaffected by DVD deficiency and PEE. RNA sequencing data showed that neonatal male offspring were more vulnerable to the effects of DVD and PEE, showing eight dysregulated genes relevant in hippocampal development. Of particular interest, Grin3b is a protein-coding

gene that was downregulated in DVD-PEE males, which encodes an ionotropic glutamate receptor, is expressed in the hippocampus and studies in mice have shown that mice homozygous for a null allele present a behavioral phenotype including mild motor impairment, hypolocomotion and impaired social interaction in a novel environment. Vglut2 was downregulated in PEE adult male hippocampus. DVD-PEE animals showed no difference in Vglut2 expression compared to controls.
We conclude from the present results that DVD deficiency does not increase offspring vulnerability to PEE; on the contrary, the combination of exposures either reversed the phenotype observed with a single exposure or had no effect.
We are currently investigating ultrastructural changes in ventricles and hippocampus at P0, based on previous individual findings on DVD and PEE. We are also investigating the expression of candidate genes obtained from the NGS study to evaluate possible protective mechanisms of DVD deficiency on exposure to ethanol.

Title: Behavioral and plasticity mechanisms of the associative effects of nicotine in the neonatal quinpirole model of schizophrenia

Authors: *A. DENTON[1], S. L. KIRBY[2], C. L. KAESTNER[3], K. C. BURGESS[3], J. D. WHERRY[3], J. M. DOSE[4], R. W. BROWN[3];
[2]Psychology, [3]Biomed. Sci., [1]East Tennessee State Univ., Johnson City, TN; [4]Psychology, St. Norbert Col., De Pere, WI

Abstract: Schizophrenics are significantly more likely to smoke cigarettes than the general population. In Experiment 1, we analyzed the effects of a rewarding versus an aversive dose of nicotine using the neonatal quinpirole (QUIN; dopamine D2/D3 agonist) model of schizophrenia. In Experiment 2, we examined the effects of antipsychotic treatment upon the associative reward of nicotine within this same model. Neonatal QUIN treatment to rats results in increased dopamine D2 receptor sensitivity throughout the rat's lifetime, consistent with schizophrenia. Rats were neonatally treated with QUIN (1 mg/kg dose) or saline from postnatal days (P)1-21.

Animals were then raised to P41 without any further drug treatment. Subjects were administered two consecutive pre-conditioning drug free preference tests in a three chamber shuttle box on P41 and P42 to determine initial preference. In Experiment 1, beginning on P43, animals were conditioned with saline, a 0.6 mg/kg or a 1.8 mg/kg free base dose of nicotine for eight consecutive days. A drug free post-conditioning preference test was given on P51. Approximately 24 h following the post-conditioning test, brain tissue was harvested and analyzed for mammalian target of rapamycin (mTOR) and phosphorylated-CREB (pCREB) in the nucleus accumbens. In Experiment 2, animals were treated identically as in Experiment 1, but were conditioned with nicotine which was preceded by an injection of either a typical antipsychotic (haloperidol, 0.5 mg/kg dose) or an atypical antipsychotic (clozapine, 2.5 mg/kg dose) for a period of eight days which was followed by a drug free preference test. In both experiments, the difference between time spent in the paired context between pre-test and post-test was utilized as a measure of associative reward. Results revealed that neonatal QUIN enhanced the rewarding effects of nicotine, but neutralized the aversive effects compared to controls. Neonatal QUIN also significantly decreased accumbal mTOR and pCREB results will be presented. In Experiment 2, we found that treatment with clozapine reduced the enhancement of nicotine conditioned place preference, but haloperidol completely reduced nicotine place preference to control levels. These findings show that neonatal QUIN enhances the rewarding associative effects of nicotine, and that the typical antipsychotic haloperidol was more effective at eliminating the associative rewarding effects of nicotine likely due to its potent D2 antagonistic effects.

Title: Prepulse inhibition deficits in the neonatal quinpirole model of schizophrenia: Epigenetic evidence and sex differences

Authors: W. D. GILL, J. D. WHERRY, K. C. BURGESS, *R. W. BROWN;
East Tennessee State Univ. Dept. of Biomed. Sci., Johnson City, TN

Abstract: Neonatal quinpirole (QUIN; dopamine D2/D3 agonist) administered from postnatal days (P)1-21 results in an increase of dopamine D2 receptor sensitivity, similar to schizophrenia and is now an established rodent model of schizophrenia. The day after birth, male and female Sprague-Dawley rats were given a daily 1 mg/kg injection of either QUIN or saline from P1-21. One subset of these animals were behaviorally tested on PPI, referred to as first generation (F0). A different subset of animals were allowed to reach adult age (P60) and female and male QUIN-treated pairs from separate litters were bred. Their offspring were also used as subjects (F1 generation). Prepulse inhibition (PPI) is a measure of sensorimotor gating reduced in individuals diagnosed with schizophrenia. Trial types were defined as prepulse trials (73, 76, 82dB), startle stimuli trials (120 dB), or no stimulus (70 dB white noise; no prepulse or pulse). Animals were tested for six consecutive days and given an ip saline injection 10 min before testing, followed by testing for another six consecutive days and given an ip nicotine (0.5 mg/kg free base) or saline injection 10 min before testing. PPI testing for F0 generation animals occurred between P35-46, and testing for F1 generation animals occurred between P44-55. In one subset of generation F1 animals, rats were ip injected with a 0.1 mg/kg dose of quinpirole and immediately observed for 60 min and the number of yawns were recorded at P60. Yawning is a behavioral event mediated by the dopamine D2 receptor. Results revealed that neonatal QUIN resulted in PPI deficits throughout the six days of testing in the F0 generation regardless of the prepulse stimulus, but females demonstrated a less robust PPI deficit as compared to males. Nicotine given during the final 6 days of testing partially alleviated the PPI deficits in both males and females. The F1 generation also demonstrated PPI deficits, but the impairment was only in males and dissipated by day 6. Nicotine did not affect PPI in these animals. Finally, F1 generation rats demonstrated a robust increase in yawning compared to controls, demonstrating an increase in D2 receptor sensitivity. Brain tissue is being analyzed for changes in the dopamine D2 receptor signaling pathway.

Yang-Ming Univ., Department and Institute of Physiology, Taiwan; [4]Dept. of Psychiatry, Natl. Cheng Kung Univ. Hosp., Tainan, Taiwan; [5]Col. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder. The pathogen of autism has been unknown till now, researchers suspected genetic factors as the most likely cause and then be triggered by environmental factor. Valproic acid (VPA) is a well know antiepileptic drugs and thought to alter mood stability like modifying gamma-aminobutyric acid (GABA) levels. The previous literatures illustrated that rats induced by VPA has been seen as animal model of autism. VPA-induced ASD rats change the pattern of dendritic development, but don't affect neural growth or stunt in motor cortex in some studies. VPA can be viewed as an inhibitor of connectivity in motor circuits. Deep brain stimulation (DBS) is considered to be a method for local stimulation, which modulates neural function of broader networks. Consideration of the use of thalamic electrical stimulation to treat patients with severe disorders of consciousness has a long history. In this study, we proposed the central thalamic DBS (CL-DBS) as a potential therapy for VPA-induced ASD rat model. We used the resting-state functional MRI (rsfMRI) and a standard behavioral social testing to evaluate the changes of the functional connectivity in cortico-striatal circuits and the social behavior, respectively. The social testing included three chambered facility, empty, central, and social, and how long the rats spent in each facility were calculated. Results showed that CL-DBS could increase the correlation between primary motor cortex (M1) and stratum (Str), as well as the social behavior of rats could indeed be improved. This study demonstrates that CL-DBS is an effective method to treat the VPA-induced ASD rats.

Title: Evaluating sex differences and the effect of perinatal testosterone in the VPA mouse model of autism

Authors: E. GORDON[1], E. BRYAN[1], M. D. COLLINS[1], S. DUGAN[1], D. DUVALL[1], K. HAMILTON[1], A. JACOB[1], T. KARIM[1], O. OBRIK-ULOHO[1], E. PENA-CALDERIN[1], *C. CORBITT[2];
[1]Biol., [2]Univ. of Louisville, Louisville, KY

Abstract: Autism spectrum disorder (ASD) is a behaviorally-defined condition with a wide range of symptoms, severity, and co-morbidities. The "multiple-hit hypothesis" states that a combination of genetic predisposition and environmental insults increase autism risk. Autism is more common in males than females, pointing to 'maleness' as a potential 'hit', but the mechanism of this bias remains unknown, including whether the presence of fetal testosterone (fT) alone is responsible for the increased ASD risk or if other factors contribute to this bias. Evidence suggests that elevated levels of fT, which is responsible for male-typical brain development, are present in those later diagnosed with ASD. Valproic acid (VPA), an antiepileptic medication, increases ASD risk in humans when used during pregnancy. This drug has been used to develop an animal model of ASD in rodents, which mimics many of the features of ASD, both behavioral (e.g., social deficits, increased repetitive behaviors, deficits in communication) and morphological (e.g., reductions in Purkinje cell number and cerebellar volume). Male rodents are more vulnerable to some VPA effects, making this an appropriate model to study sex differences in ASD. This project uses a mouse model of ASD to mimic differential susceptibility of males and females to a prenatal insult (VPA), and to determine whether masculinizing females perinatally with testosterone propionate (TP) following prenatal VPA treatment will also masculinize their risk for abnormalities in brain development and behavior relevant to ASD. Our study focuses on cerebellar morphology and behaviors applicable to this brain region because it is often affected in ASD, as well as in the VPA animal model. Our results support other research that has indicated VPA treatment causes motor development delays. Further analysis will provide insight into abnormalities in neurodevelopment and behavior caused by VPA treatment alone, if/how these abnormalities vary by sex, and how perinatal TP affects the severity of these abnormalities in each sex.

Abstract: Autism spectrum disorder (ASD) is a behavioral disorder characterized by dysfunction in formation and maintenance of social relationships, in communication, and repetitive/stereotyped behaviors and hyper-reactivity to sensory stimulation. Valporic acid (VPA), an anticonvulsant medication, has been shown to increase the risk of autism in children whose mothers have a history of VPA use. It has become a popular tool for producing a behavioral phenotype consistent with an ASD diagnosis in a variety of non-human animal species. Some pathologies (such as ASD) modeled in animals have been reversed or ameliorated under environmentally complex housing conditions. Typical experimental paradigms assess play behaviors and repetitive behaviors to test effects of VPA on social dysfunction and stereotypy; operant reinforcement paradigms are used less frequently. Experiments that do employ operant designs use only one reinforcer at a time, unlike the natural environment where multiple reinforcers are available simultaneously. This experiment tested 84 Sprague-Dawley rats in a 2x2 design, assessing the effects of a pre-natal VPA manipulation and an environmental enrichment manipulation in a testing chamber with access to different forms of reinforcement. Animals were tested across nine days; a three-day pre-exposure period during which there were no programmed reinforcers, followed by three days where a sensory stimulus (light onset) was available on a VI 1 minute interval schedule, and finally a three-day period where a social stimulus (access to a cage-mate) was available concurrent with the sensory stimulus. A multifactorial analysis was conducted to assess the effects of the manipulation on absolute responding, relative rate of responding, habituation of responding, and contact time, across all three testing conditions. Introduction of the response contingent light stimulus increased responding proportionately more for VPA-treated animals than controls; enrichment did not affect light responding. Upon introduction of the social reinforcer on the opposite side of the test apparatus, enrichment increased relative preference but not absolute responding for the social side; VPA had no effect. The two manipulations did not interact. The current model of VPA-

induced autism in rats may lack ecological validity, given that a concurrent reinforcement paradigm appears to decrease the effects of VPA.

Title: Intranasal oxytocin delivery in juvenile nonhuman primates

Authors: ***T. MURAI**[1,2], C. PHI[1], L. OLSEN[1], S. FREEMAN[1], T. WEINSTEN[1], K. BALES[1], J. CAPITANIO[1], M. PLATT[3], M. BAUMAN[1];
[1]California Natl. Primate Res. Ctr., UC Davis, Davis, CA; [2]Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan; [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Converging evidence from clinical and preclinical research indicates that oxytocin (OT) plays a key role in species-typical social behavior. Although OT-therapy is being investigated as a safe and promising therapy for autism spectrum disorder (ASD), we know very little about the efficacy, safety, and neurobiological mechanisms associated with OT exposure. Preclinical research utilizing macaque monkeys has demonstrated that intranasally administered OT can modulate aspects of primate social cognition, including social perception, imitation, and social vigilance. Here we describe efforts to develop an OT delivery system for juvenile macaque monkeys that is compatible with an expanded behavioral test battery that integrates non-invasive eye-tracking and unconstrained social interactions. Four juveniles (2 males and 2 females) were trained to drink a fluid reward from a small tube embedded below a nebulizer that delivered aerosolized OT or saline placebo over the course of 10 minutes. We utilized a series of positive reinforcement training techniques to reach a target mask exposure time of approximately 5 minutes per each 10 minute session. OT doses ranging from 24-48IU were evaluated in pilot studies and cumulative drinking time was quantified for each experiment as an index of OT exposure. To evaluate peripheral OT concentration, blood samples were collected 15, 30, 60 and 90 minutes after OT or saline exposure. Preliminary evaluation of plasma OT concentration following OT exposure indicates that this delivery system is effective for increasing peripheral OT concentrations. Plasma OT concentration will be compared with central OT concentrations

indexed by cerebrospinal fluid assays, and both measures will be used as predictors of behavior. If effective, this novel delivery system for young rhesus monkeys will provide a testbed to evaluate the effects of OT exposure during development on species-typical social interactions and advance efforts to translate basic science OT research into safe and effective OT therapies.

Title: Positive allosteric modulation of nmda receptors ameliorate behavioral and electrophysiological phenotypes in a pre-clinical model of smith-lemli-opitz syndrome.

Authors: ***M. C. LEWIS**, M. QUIRK, R. HAMMOND, C. MACIAG, M. ACKLEY, G. BELFORT, G. MARTINEZ BOTELLA, J. DOHERTY, A. ROBICHAUD;
Sage Therapeut., Cambridge, MA

Abstract: Smith-Lemli-Opitz Syndrome (SLOS) is a rare genetic disorder caused by mutations in the 7-dehydrocholesterol reductase gene DHCR7, encoding the enzyme that transforms 7-dehydrocholesterol to cholesterol. Loss of function of DHCR7 leads to a reduction in total cholesterol production that contributes to symptoms including microcephaly, moderate to severe intellectual disability, sensory hypersensitivity, stereotyped behaviors, dysmorphic facial features, and syndactyly of the second and third toes, with the severity of clinical presentation being inversely correlated with serum cholesterol levels. Importantly, SLOS patients also have reduced levels of the brain specific cholesterol metabolite 24(S)-hydroxycholesterol (24(S)-HC) due to the reduction in brain cholesterol driven by altered DHCR7 function. As 24(S)-HC is known to be an endogenous positive modulator of the NMDA receptor, it is conceivable that some of the behavioral and cognitive features of SLOS may be driven by NMDA receptor hypofunction. In the current studies, we describe a pharmacological animal model of SLOS induced by chronic administration of the DHCR7 inhibitor AY9944. Chronic inhibition of DHCR7 leads to reductions in cholesterol levels and 24(S)-HC, reduced total brain weight, increased liver weights, deficits in long-term potentiation and paired pulse facilitation, increases in sharp wave discharges, and locomotor hyperactivity, which closely resemble many of the key features of SLOS. Herein, we report that, in the animal model, administration of a positive allosteric modulator of the NMDA receptor, SAGE-718, attenuated AY9944-induced sharp wave

discharges and hyperactivity. These studies provide important data by which to assess proof of concept of the utility of NMDA PAMs in SLOS, and suggest that other cerebrosterol deficit disorders, as well as diseases resulting from NMDA hypofunction, may be areas of interest for further study of this class of compounds.

Title: Rescue of a mutant T8993G mouse model of NARP and MILS with mito-targeted AAV9 containing wild type ATP6

Authors: *H. YUAN, H. YU, J. GUY;
Univ. of Miami, Miami, FL

Abstract: To develop an effective gene therapy for the rescue of a human mutant T8993G ATP6 mouse model of NARP and MILS, we created mito-targeted AAV modified VP2 by mitochondria targeting sequence cox8. We synthesized human normal ATP6 gene fused by a flag epitope at the c-terminal with stop codon followed by mitochondrial encoded *mCherry*, which was cloned under the control of the mitochondrial heavy strand promoter (HSP) into the self-complementary AAV backbone (sc-HSP-*ATP6FLAG+mcherry*). ATP6 expression was significantly increased 35 fold in NARP mitochondria infected by mito-targeted AAV9/ATP6. ATP synthesis was increased 41%. NARP cell proliferation significantly increased 49%. 53 of a mutant T8993G ATP6 founder mouse (A6M) was generated by microinjection of mito-targeted AAV2 with sc-HSP-*mutATP6FLAG+mcherry* into mouse zygotes. A6M mice developed severely leigh syndrome, mortality high to 78%. A6M mice were also observed vision loss, paralysis, seizure and hunched severely leigh syndrome phenotype. 10ul of mito-targeted AAV9/ATP6 were respectively injected into 3 month old A6M and 20 month old A6M mice with a genotype and phenotype of T8993G NARP and MILS, and untreated A6M mice of same conditions as controls. After injection of mito-targeted AAV9/ATP6 at 3 month old, treated A6M mice showed 100% survival compared to 30% survival in untreated A6M mice for 18 months. PERG showed amplitudes of treated A6M mice was increased to 19.6 uV after six month compared to 11.3 uV for untreated A6M mice. At later stage A6M mice with hunched, rota rod testing showed latency-to-fall time was significantly increased after injection for two weeks. Video showed the movement with paralysis hind limbs mice prior to their spontaneous deaths were significantly improved after two days of injection of mito-targeted AAV9/ATP6. Our results showed mito-targeted AAV9-wildtype ATP6 can successfully rescue mutant T8993G ATP6 mice significantly reducing mortality rate, improving defective visual function, ataxia and paralysis suggesting it may be helpful for MILS and NARP patients.

Title: Pregnancy at advanced maternal age affects behavior and hippocampal gene expression in mouse offspring

Authors: S. SAMPINO[1,2], A. M. STANKIEWICZ[1], F. ZACCHINI[1], J. GOSCIK[3], A. SZOSTAK[1], *A. H. SWIERGIEL[4], J. A. MODLINSKI[1], G. E. PTAK[1,5,2];

Abstract: Advanced Maternal Age (AMA) is a risk factor for neurological and neuropsychiatric disorders in offspring. We developed a mouse model in order to investigate whether pregnancy at advanced age may evoke behavioral and brain gene expression changes in the offspring. Mice conceived by 15-18 months old (15-18M) or 3M control females were delivered by cesarean section and fostered after birth by 3M dams. Offspring were subjected to a battery of behavioral tests and genome-wide mRNA expression was then analyzed using microarrays in the hippocampus of 4M male offspring. We observed increased ultrasound vocalization activity during juvenile social isolation and increased anxiety-like behaviors in adult offspring conceived by old females (Figure 1). The hippocampal mRNA expression of several genes involved in protein post-translational modification and protein homeostasis was affected by AMA. In conclusion, pregnancy at advanced age yields offspring with abnormal behaviors and altered patterns of gene expression in the hippocampus, resembling human neuropsychiatric and neurodegenerative disorders. The effects had not been reversed by post-natal maternal cares provided by young foster mothers. This suggests that prenatal conditions associated with AMA may negatively affect fetal brain development and hence post-natal behaviors.

Title: Age-dependent changes might be induced in a rat hippocampal oxidative marker after noise exposure. Potential restoration after rearing in an enriched environment

Authors: S. J. MOLINA[1], M. MICELI[1], F. CAPANI[2], *L. R. GUELMAN[1];
[1]Fac Med, UBA-CEFYBO-CONICET, Buenos Aires, Argentina; [2]Lab. de plasticidad y citoaerquitectura neuronal, ININCA-CONICET, Buenos Aires, Argentina

Abstract: It is well known that noise exposure can induce transient or permanent hearing loss. However, few data are available regarding its effects on extra-auditory structures, mainly within developing Central Nervous System. Previous studies of our laboratory showed that exposure of immature rats (7 and 15-days-old) to moderate noise during 2 hours, can induce hippocampal-related behavioral alterations that differ depending on the age of exposure. Moreover, rearing these animals in an enriched environment (EE) has shown to be an effective protective tool which almost fully prevented noise-induced behavioral changes.
Therefore, the aim of the present work was to test if noise exposure at different ages might generate hippocampal changes in an oxidative marker such as Trx-1. The potential prevention of these changes through the use of an enriched environment (EE) was also assessed.
Rats of 7 and 15 days were exposed during 2 h to white noise (95-97 dB) for one day. After weaning, groups of 3-4 rats were transferred to an enriched cage, consisting of toys, a wheel, tunnels and ramps, while other groups were placed in standard cages. After one week, levels of Trx-1, a member of the family of the antioxidants thioredoxins, were evaluated.
Results showed that Trx-1 levels of rats exposed at 7 days and reared in standard cages were increased, whereas no significant changes were found in rats reared in EE when compared with their respective control animals. In contrast, animals exposed at 15 days showed no significant differences in Trx-1 levels, neither in standard nor in enriched conditions.
These findings suggest that noise exposure at several developmental ages might differentially affect hippocampal oxidative status. The restoration of hippocampal Trx-1 levels in exposed animals reared in an EE might be correlated with a more reduced cellular milieu facilitated by EE rearing, suggesting that this strategy could be useful to aid animals to cope with an unfavorable condition.

Title: Arginine vasopressin at nanomolar concentrations suppresses bumetanide-sensitive network events in the perinatal rat hippocampus

Authors: *A. SPOLJARIC, P. SEJA, E. RUUSUVUORI, I. HIIRONNIEMI, J. LINDFORS, M. SUMMANEN, J. VOIPIO, K. KAILA;
Univ. of Helsinki, Helsinki, Finland

Abstract: During birth, a number of homeostatic and pre-adaptive mechanisms are activated in mammals to facilitate the abrupt transition to extrauterine life. Human studies have shown that birth triggers a massive release of arginine vasopressin (AVP) into the blood. However, there is no information on whether the AVP surge also acts centrally on cortical structures. We performed in vitro electrophysiological experiments on rat hippocampal slices and intact hippocampi at the end of the fetal period (E20-21), within 2h after birth, and during postnatal days 0-2. During the whole perinatal period, exposure to exogenously applied AVP (5-10 nM) produced a strong suppression of CA3-driven bumetanide-sensitive network events, known as Giant Depolarizing Potentials (GDPs), which was prevented by the V1a receptor antagonist SR 49059 (20 nM). Intracellular recordings from CA3 pyramidal neurons revealed that, while lacking a direct effect on intrinsic properties, AVP induced a pronounced V1a receptor-dependent increase in the frequency of spontaneous IPSCs (sIPSCs). The increase in sIPSC frequency was seen in both the presence and absence of ionotropic glutamate receptor (iGluR) blockers, indicating direct activation of interneurons by AVP. Additionally, a pronounced desynchronization of cellular activity took place in the absence of iGluR blockers, readily explaining the suppression of GDPs. Thus, we suggest that AVP exerts neuroprotective actions and prevents pathophysiological plasticity by suppressing neuronal network activity during birth. This conclusion has several important consequences, especially in the light of data showing that AVP release during human birth is further enhanced under pathophysiological conditions such as birth asphyxia.

Title: Neurobiological and functional benefits of a specific nutrient combination in phenylketonuria (PKU): proof of concept in the PKU mouse model

Authors: *V. M. BRUINENBERG[1], E. VAN DER GOOT[1], D. VAN VLIET[2], M. L. DE VRIES[1], D. S. COUNOTTE[3], M. KÜHN[3], F. J. VAN SPRONSEN[2], E. A. VAN DER ZEE[1]; [1]GELIFES, Univ. of Groningen, Groningen, Netherlands; [2]Children Hosp., Univ. Med. Ctr. Groningen, Groningen, Netherlands; [3]Nutricia Advanced Med. Nutr., Utrecht, Netherlands

Abstract: Phenylketonuria (PKU) is an inborn error of metabolism causing the enzyme that converts phenylalanine (Phe) to tyrosine to become non-functional. This in turn leads to a distinct rise in Phe concentrations in blood and brain. The current method to manage the condition is a strict and early introduced diet of protein restriction and specific amino acid supplementation restricting Phe intake. If untreated, PKU leads to severe mental retardation. However, even in treated PKU patients the disorder manifests itself mostly at the level of the brain with changes in neurotransmitter metabolism, white matter integrity, synaptic functioning, and oxidative stress. The purpose of the present study was to investigate the effects of a specific nutrient combination (SNC) containing precursors and cofactors for the synthesis of neuronal membrane on behavioral and neurobiological deficits in PKU mice (BTBR Pah^{enu2}). To this end, we examined the impact of SNC in groups of 24 mice each (12 males, 12 females) with dietary treatment starting on postnatal day 31. The following six groups were compared: wild-type (WT), WT with SNC (WT+SNC), PKU high Phe (6.4 g/kg food), PKU high Phe+SNC, PKU low Phe (2.0 g/kg), PKU low Phe +SNC. Groups without SNC were fed an isocaloric control. The mice were tested in two learning and memory paradigms (novel object recognition (NOR) and spatial object recognition test (SOR)), and a motor performance test (balance beam) at three time points during the dietary intervention (3, 6 and 9 months after the start of the intervention). Here we demonstrate that the diet containing SNC restored the ability of the PKU mice to learn the NOR, but SNC did not improve motor performance in PKU mice despite a significant lower performance compared to their WT litter mates. The SNC diet was nearly equally effective in PKU mice treated with high and low Phe in their diet. The analysis of brain material will shed light on the mode of action of the SNC diet. In conclusion, preliminary data show a beneficial effect of a SNC in a PKU mouse model.

Title: Toward a therapeutic trial in Pelizaeus Merzbacher disease (PMD)

Authors: G. N. TURSKI[1], C. WESTMARK[1], *L. TURSKI[3], I. DUNCAN[2], C. IKONOMIDOU[1], C. A. TURSKI[1];
[1]Neurol., Univ. of Wisconsin, Madison, WI; [2]Univ. of Wisconsin, School of Vet. Medicine, WI; [3]Clin. Translational Sci., German Ctr. for Neurodegenerative Dis., Bonn, Germany

Abstract: PMD is a rare dysmyelinating disorder of the CNS that is inherited in an X-linked recessive manner. The prevalence of the disease is about 1/100,000-200,000. The disease results from duplication of or a mutation in the proteolipid protein (*PLP1)* gene; proteolipid protein (PLP) is the major CNS myelin protein. The majority of boys with PMD have a duplication of *PLP1* (60-65%) while the remainders have a point mutation of the gene. Affected boys/men have significant neurologic impairment consisting of ataxia, rotary nystagmus, pyramidal signs, seizures, extrapyramidal movement disorders, psychomotor delay and intellectual disability. New observations on a canine animal model of PMD indicate that there is a gradual spontaneous differentiation of oligodendrocyte progenitor cells (OPCs) in the spinal cord but not brain

suggesting that drugs that could promote this earlier in the brain and spinal cord of PMD patients could have functional significance. Mei et al. (Nat Med 2014;20:954-960) identified a cluster of anti-muscarinic molecules that enhance oligodendrocyte differentiation and remyelination. One of these drugs is clemastine fumarate, an anti-histamine and anticholinergic medication that is licensed in the United States for treatment of allergic conditions. Clemastine has also been shown to promote *in vivo* remyelination in the lysolecithin induced demyelination mouse model. We tested the potential of clemastine fumarate to promote myelination in two rodent models of PMD, the myelin deficient (md) and the PLP transgenic rat. Pups were treated daily with clemastine (s.c.) doses of 10-30 mg/kg over 3 weeks (postnatal days 1-21). Neurologic phenotypes and myelination patterns in the brain, optic nerves and spinal cords were assessed using post mortem histological techniques. No change in neurological phenotype (whole body tremor, ataxia) was observed at the highest administered dose of clemastine, 30 mg/kg s.c. Postmortem staining with Luxol fast blue revealed islands of myelination in the brainstem of clemastine treated md and PLP rats. No evidence for improved myelination was found in the spinal cords or the optic nerves of treated rats compared to vehicle treated littermates who also developed the disease. Further studies are necessary to determine whether clemastine bears a therapeutic potential in this rare dysmyelinating CNS disorder.

Title: Mice that lack the C-terminal region of Reelin exhibit behavioral abnormalities related to neuropsychiatric disorders

Authors: *K. SAKAI[1], H. SHOJI[2], T. KOHNO[1], T. MIYAKAWA[2,3], M. HATTORI[1];
[1]Biomed. Science, Grad. Sch. of Pharmaceut. Sci., Nagoya City Univ., Nagoya, Japan; [2]Div. of Systems Med. Science, Inst. for Comprehensive Med. Sci., Fujita Hlth. Univ., Toyoake, Japan; [3]Section of Behavior Patterns, Ctr. for Genet. Analysis of Behavior, Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Reelin is a large secreted glycoprotein that is required for normal brain formation and function. Reelin malfunction has been suggested to be assoiciated with the pathogenesis and deterioration of several neuropsychiatric disorders. Reelin protein is composed of the N-terminal domain, Reelin repeats, and the highly basic C-terminal region (CTR). Secreted Reelin binds to very low-density lipoprotein receptor (VLDLR) and apolipoprotein E receptor 2 (ApoER2), and then induces phosphorylation of the intracellular protein Dab1, which leads to activation or modulation of further downstream signaling. The primary sequence of the CTR is conserved in most vertebrates and alternative splicing gives rise to a CTR-lacking isoform of Reelin. We previously revealed that the CTR of Reelin is necessary for efficient activation of its downstream signaling. We generated knock-in mice lacking the CTR of Reelin (ΔC-KI mice) and found that their brain structure is partially impaired. (Kohno et al. J. Neurosci. 35, 4776 (2015)) Here, we performed a comprehensive behavioral test battery on ΔC-KI mice, in order to evaluate the effects of partial loss-of-function of Reelin on brain functions. The ΔC-KI mice were hyperactive and exhibited reduced anxiety-like behavior in the open field test and the elevated plus maze test. Sociability of ΔC-KI mice was partially impaired in the home cage test, whereas social novelty preference was normal in Crawley's three-chamber social approach test. The working memory in ΔC-KI mice was impaired in the T-maze test. There was little difference in spatial reference memory, depression-like behavior, prepulse inhibition, or fear memory between ΔC-KI and wild-type mice. These results suggest that the CTR-dependent Reelin signaling is required for some specific brain functions. We think that the behavioral abnormalities of ΔC-KI mice recapitulate some aspects of neuropsychiatric disorders, such as schizophrenia, bipolar disorder, and autism spectrum disorder. The loss of Reelin CTR and/or reduced Reelin signaling could be the direct cause of some symptoms observed in these disorders. It was also suggested that ΔC-KI mice may serve as a unique tool for studying the mechanisms of neuropsychiatric disorders and their endophenotypes. We are now analyzing molecular mechanisms underlying behavioral abnormalities observed in ΔC-KI mice.

Title: Does inhibition of Reelin processing ameliorate Alzheimer's disease?

Authors: *Y. YAMAKAGE, H. OGINO, T. KOHNO, M. HATTORI;
Dept. of Biomed. Science, Grad. Sch. of Pharmaceut. Sci., Nagoya City Univ., Nagoya, Aichi, Japan

Abstract: Alzheimer’s disease (AD) is the most common form of dementia and is characterized by loss of memory and cognitive dysfunction. The main cause of AD is the accumulation of amyloid beta peptide (Aβ) in the brain. Accumulated Aβ leads to neuronal cell death and synaptic failure.
Reelin, a large secreted glycoprotein composed of 3,461 amino acid residues, is required for normal synaptic functions in the adult brain. Reelin consists of the N-terminal region, eight Reelin repeats, and the C-terminal region. Reelin binds to its receptors via repeat 5 and 6, then the intracellular protein Dab1 is phosphorylated. Reelin is specifically cleaved within Reelin repeat 3 (N-t cleavage) and this cleavage virtually abolishes its biological activity. It was reported that the number and the size of Aβ plaques are decreased in Reelin transgenic mice (Pujadas et al., Nat. Comm. 5, 3443 (2014)) and that Aβ plaque pathology is worsened in Reelin conditional knock-out mice (Lane-Donovan et al., Sci. Signal. 8, ra67 (2015)). Moreover, the amount of full-length Reelin is decreased and the Reelin fragment generated by N-t cleavage is increased in human AD patients (Botella-López et al., Proc. Natl. Acad Sci. USA. 103, 5573 (2006)). These studies suggest that Reelin signaling is important to suppress AD pathology.
In this study, we hypothesized that the inhibition of N-t cleavage of Reelin would upregulate the biological activity of Reelin and might ameliorate the AD pathology. Our laboratory has clarified that A Disintegrin And Metalloproteinase with Thrombospondin motif 3 (ADAMTS-3) is a major protease that mediates N-t cleavage. We generated conditional knock-out (cKO) mice, ROSA26-CreERT2/ADAMTS-3-flox, in which administration of tamoxifen induces global loss

of ADAMTS-3. We crossed these mice with the knock-in mice in which pathogenic human amyloid precursor protein is expressed (Saito et al., Nat. Neurosci. 17, 661 (2014)). We are now investigating these mice to clarify whether the loss of ADAMTS-3 is beneficial for AD.

Title: Hippocampal and thalamic regulation of VTA dopamine neurons occurs via convergent inputs to the nucleus accumbens

Authors: ***S. M. PEREZ**, D. J. LODGE;
Pharmacol., UTHSCSA, San Antonio, TX

Abstract: Schizophrenia patients, and rodent models of the disease, display an enhanced hippocampal activity, which is thought to underlie augmented mesolimbic dopamine function associated with psychosis. Indeed, aberrant dopamine neuron activity can be restored in rodent models of schizophrenia by inactivating the ventral hippocampus (vHipp). In addition to vHipp hyperactivity, recent post-mortem studies have suggested that glutamatergic abnormalities are present in the nucleus accumbens (NAc) of individuals with schizophrenia. Specifically, an increase in vesicular glutamate transporter 2 (vGlut2) expression is observed. Increases in vGlut2 implies that individuals with schizophrenia receive aberrant glutamatergic input, specifically to the NAc. While hippocampal projections express some vGlut2, inputs from the thalamus are more likely to account for this alteration. Interestingly, anatomical studies suggest a convergent input from hippocampal and thalamic afferents to the NAc, which work in concert to regulate dopamine neuron activity. Here we examined the interaction between these pathways in the regulation of dopamine neuron activity in rodent models of schizophrenia. Electrophysiological experiments revealed that both hippocampal and thalamic activation induced a significant increase in population activity, and are dependent on each other. Similar to what was previously observed with vHipp inactivation in rodent models, TTX inactivation of the thalamus restored normal dopamine system function. Thalamus-induced increases in dopamine neuron activity are attributed to a direct projection to the nucleus accumbens. Furthermore, a subset of medium spiny neurons of the NAc receive convergent inputs from the vHipp and thalamus. We believe

that the vHipp is driving spontaneous membrane transitions (up/down states) that are required to enable the thalamic inputs to drive activity in the NAc. Further investigation of the role the thalamus plays in schizophrenia will provide a better understanding of the underlying pathophysiology of the disease, ultimately leading to novel sites of therapeutic intervention.

Title: Medial septum regulates spontaneous dopamine neuron activity in the ventral tegmental area and substantia nigra

Authors: ***D. M. BORTZ**, A. A. GRACE;
Dept. of Neuroscience, Psychiatry, and Psychology, Ctr. for Neurosci., Univ. of Pittsburgh, pittsburgh, PA

Abstract: Dopamine (DA) neuron activity in the midbrain is associated with a wide array of essential behavioral constructs, including reward prediction and association, salience signaling, motivation, and fine motor control, and disruptions in this system are implicated in several psychiatric disorders. Although it is known that the ventral hippocampus potently regulates DA neuron spontaneous activity and that it receives a dense projection from the medial septum, little is known about how the septohippocampal pathway, a pathway known to impact learning and memory, affects the DA system. This was addressed by infusing NMDA (0.75 μg/0.2 μL) into the medial septum of anesthetized male Sprague-Dawley rats and recording dopamine neuron activity in the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc). Septal stimulation produced a prolonged 72% increase in the number of spontaneously active DA cells in the VTA and a 96% increase in burst firing over vehicle infusions. Interestingly, septal stimulation produced the opposite response in the SNc, significantly decreasing spontaneous activity by 40% compared to vehicle. Moreover, ventral hippocampal inactivation by TTX reversed the effects of septal stimulation on DA neuron activity in both the VTA and SNc. In contrast to normal animals, septal stimulation in the MAM developmental disruption model of schizophrenia precipitated an opposite effect, producing a 53% decrease in dopamine neuron firing in the VTA and a 37% increase in the SNc. The number of spontaneously active DA

neurons is important for controlling the amplitude of the phasic dopamine response in the striatum, as only spontaneously active cells can burst fire in response to an incoming stimulus. Thus, these findings demonstrate that the septohippocampal pathway plays a key modulatory role in the regulation of meso-striatal DA transmission, impacting both the limbic VTA and the habit formation-related SNc DA neurons in a manner that is dependent upon the basal activity state of the system.

Title: Effects of ethanol, repeated high-dose methamphetamine & ceftriaxone treatments on dopamine, serotonin, glutamate, & glutamine tissue contents

Authors: Y. S. ALTHOBAITI[1], A. H. ALMALKI[2], S. C. DAS[2], F. S. ALSHEHRI[1], *Y. SARI[1];

Abstract: Repeated exposure of high dose of methamphetamine (METH) is known to alter several neurotransmitters in certain brain regions. METH and ethanol are frequently consumed together by addicts with higher chance of reaching intoxication level. Little is known about the effects of METH and ethanol co-abuse on tissue contents of dopamine, serotonin (5-HT), glutamate, and glutamine in brain reward regions. In this study, Wistar rats were used as an animal model of METH and ethanol co-abuse to investigate their effects on tissue contents of dopamine/5-HT and glutamate/glutamine in nucleus accumbens (NAc) and prefrontal cortex (PFC). We further investigated the effects of ceftriaxone (CEF), a β-lactam antibiotic known to upregulate glutamate transporter subtype 1, on METH-induced alteration of these neurotransmitters. After seven days of either ethanol (6 g/kg) or water oral gavage pretreatment, rats received either saline or METH (10 mg/kg, i.p. every 2 hours x 4) followed by either saline or CEF (200 mg/kg, i.p, 3.) post-treatment. METH induced a significant depletion of dopamine and 5-HT in NAc and PFC. Interestingly, ethanol pretreatment potentiated the depletion of dopamine, but not 5-HT. Importantly, dopamine tissue contents were completely restored while

5-HT tissue contents were restored partially following CEF post-treatment in water group, but not in ethanol group, in NAc. Additionally, METH and ethanol caused differential effects in glutamate and glutamine tissue contents in PFC and NAc. These findings demonstrated for the first time the synergistic effect of METH and ethanol and the attenuating effects of CEF on these neurotransmitters in this co-abuse animal model.

Title: Neuron-specific expression of the protein product of the Rapgef2 gene underlies activation of ERK by dopamine in the central nervous system

Authors: *Z. JIANG[1], A. C. EMERY[2], W. XU[2], T. MUSTAFA[2], C. R. GERFEN[3], M. V. EIDEN[1], L. E. EIDEN[2];
[2]Section on Mol. Neurosci., [3]Lab. of Systems Neurosci., [1]NIMH, Bethesda, MD

Abstract: The Gs-coupled D1a receptor has long been known to signal through the cyclic AMP sensor protein kinase A (PKA) in the nervous system. We now identify two additional cyclic AMP sensors for D1a receptor signaling in neuroendocrine cells, the Rap guanine nucleotide exchange proteins Rapgef2 (NCS-Rapgef2) and Rapgef4 (Epac2). The use of three separate cyclic AMP sensors by D1 receptor activation allows parcellated activation of CREB (via PKA), ERK (via NCS-Rapgef2) and p38 (via Epac2) in the neuroendocrine cell line NS-1, as demonstrated by specific pharmacological inhibition of D1a/cAMP-dependent activation of CREB, ERK and p38 by the PKA-, NCS-Rapgef2-, and Epac2-selective inhibitors H89, SQ22,536, and ESI-09, and consistent with the previous demonstration of Gs-GPCR-coupled parcellated cAMP signaling in this cell line by the neuropeptide PACAP expressing the family B PAC1 receptor (Emery et al., Sci. Signaling 6(281), ra51, 2013). D1 signaling to ERK activation is known to be important for the dopamine-dependent actions of psychomotor stimulants in the nucleus accumbens. To determine if the NCS-Rapgef2 cAMP signaling pathway mediates D1-dependent activation of ERK in the central nervous system, an AAV vector expressing Cre recombinase under the control of the synapsin promoter was injected into the ventral striatum of

floxedRapgef2 mice. Four to five weeks later, these were treated with either the D1 agonist SKF 81297 (2 mg/kg, i.p.), or amphetamine (10 mg/kg, i.p.) and, 15 minutes later, euthanized, and perfusion-fixed for examination of ERK activation using an ERK Thr202/Tyr204 phosphospecific antibody. ERK activation following either psychomotor stimulant or D1 agonist treatment was robust in both shell and core of the nucleus accumbens on the side of the brain contralateral to AAV-syn-Cre-GPF injection but did not occur on the ipsilateral side, in cells which showed evidence of vector transduction (nuclear GPF staining) and corresponding loss of staining for the NCS-Rapgef2 protein. NCS-Rapgef2, is present in neuronal and neuroendocrine cell lines (NS-1, PC-12, SK-N-SH), but not non-neuronal cell lines (e.g. HEK293), and is correspondingly present in neuronal/neuroendocrine tissues (brain, pituitary, adrenal) but not in non-neuronal tissues (skeletal muscle, kidney, lung, spleen). Thus, we have identified a cyclic AMP sensor for the D1a and other Gs-GPCR-coupled receptors, which is expressed only in neurons within the CNS, and is required for dopamine-dependent activation of ERK in D1-dopaminoceptive medium spiny neurons of the nucleus accumbens core and shell.

Abstract: Schizophrenia is a complex neurodevelopmental disease caused by both genetic and environmental factors. It is characterized by a heterogeneous collection of symptoms including altered perception, decreased motivation, and cognitive deficits. The dopaminergic hypothesis of the disease is the most enduring, as pharmacological treatment is based on antagonism of dopamine D2 receptors (DRD2). Strong evidence also demonstrate that Parvalbumin-expressing (PV), fast-spiking interneurons (FSI) have a central role in the pathophysiology of this disease, supporting the GABAergic hypothesis. Besides this, the glutamatergic hypothesis of schizophrenia has emerged based on reports showing that inhibition of NMDA (N-Methyl D-aspartate) receptors causes behavioral responses similar to the positive and cognitive symptoms observed in patients. Although great advances have been made in the last decades, and evidence supports each of the hypotheses, the molecular mechanisms leading to schizophrenia are still to be elucidated. Moreover, antipsychotics are the only treatment, with benefits just for positive symptoms, but limited results for negative or cognitive ones. As DRD2 is expressed in PV interneurons, the aim of the present work was to evaluate to what extent FSI inhibitory control over pyramidal neurons was modulated by DRD2. With this objective, we generated a conditional mutant mice line, by deletion of DRD2 specifically in PV+ interneurons. We first determined the mRNA expression level of many genes, as GAD 67, highly related to the pathophysiology of this disease. Our results showed a significant reduction in the mRNA of this and other relevant genes in the prefrontal cortex and hippocampus in conditional mutants compared to controls. Electrophysiological approach showed neuronal and network perturbations in conditional mutants, but not in control animals. We then followed a battery of behavioral tests to analyze the consequences of this deletion, focusing on locomotor activity, emotional and social behavior and cognitive function. Our results showed an alteration in total locomotor activity, impairments in cognitive capacity and deficits in social and emotional behavior in conditional mutants but not in control mice. In summary, our results show that deletion of DRD2 from FSI causes biochemical and physiological unbalances with functional consequences in behavior, suggesting that DRD2 exerts a fine tuning role in the development of a balanced activity in PV interneurons and, consequently, in the neuronal network.

Title: Characterization of synaptic proteins expressed in dopaminergic axonal terminals

Authors: *C. DUCROT, M.-J. BOURQUE, G. FORTIN, G. CORREA, L.-E. TRUDEAU; Departments of pharmacology and neurosciences, GRSNC, Univ. De Montréal, Montreal, QC, Canada

Abstract: Dopamine (DA) neurons of the substantia nigra compacta (SNc) and ventral tegmental area (VTA) establish a complex axonal arborization comprising axon terminals that are either synaptic or non-synaptic in structure, as revealed by ultrastructural observations. No method other than electron microscopy has previously been used to examine the synaptic or non-synaptic nature of DAergic axonal varicosities. Our objective was to develop a rapid and efficient *in vitro* method for the quantification and analysis of synaptic and non-synaptic terminals established by mouse DA neurons. Considering previous works showing that subsets of DAergic neurons are able to package and release glutamate or GABA as some of their terminals, we took advantage of well-established postsynaptic markers of such synapses (respectively PSD95 and gephyrin), to characterize the axonal domain of these neurons. Primary DA neurons were prepared from the SNc or VTA of tyrosine hydroxylase (TH)-GFP transgenic mice and placed in co-culture with striatal neurons. Immunocytochemistry and confocal microscopy were then used to examine the colocalization of markers of the pre and postsynaptic compartments. Images were quantified using Image-J software. Our results show that the majority of axon terminals established by DA neurons contain the presynaptic markers synaptotagmin 1 (SYT1), SV2 and SNAP25. However, only a minority were found to be associated with the postsynaptic markers PSD95 or gephyrin. In comparison, mono-cultures of glutamatergic neurons from the cortex or GABAergic neurons from the striatum established a majority of terminals associated with a postsynaptic marker. These observations, revealing a fundamental difference between DA neurons and classical glutamate or GABA neurons, is compatible with previous ultrastructural results obtained from striatal brain sections and showing DA neurons to be predominantly non-synaptic. Finally, we also examined DA neurons from the olfactory bulb (OB), a neuronal population known to be structurally very different in their connectivity compared to VTA or SNc DA neurons. Interestingly, our preliminary results show that OB DA neurons are able to develop a majority of synaptic terminals, most of which are GABAergic. Our results validate the establishment of an

experimental strategy allowing quantification of the proportion of synaptic and non-synaptic contacts established by DA neurons, a technique that we will use to further explore the structure-function relationship of these axon terminals.

Laboratory, Dept. of Neurosci. and Pharmacology, Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Tuning dopaminergic signaling is critical for several physiological functions of the brain including motor behavior, reward and cognitive function. The presynaptic plasma membrane dopamine transporter (DAT) sequesters dopamine from the extracellular space, and thereby sustains physiological dopamine levels. DAT contains at its C-terminus, a PSD-95/Discs-large/ZO-1 (PDZ)-domain binding sequence, shown to interact with the scaffolding protein protein interacting with C-kinase 1 (PICK1). PICK1 regulates subcellular trafficking of

its binding partners but the explicit role of PICK1 for DAT function and dopamine homeostasis has remained elusive. Here, we present a detailed investigation of the dopaminergic system in mice lacking PICK1. Compared to wildtype (WT) mice, we found that DAT surface expression was unaltered in striatal terminals from PICK1 knock-out (KO) mice together with DAT localization to membrane microdomains. However, PICK1 KO mice were characterized by hyperlocomotion and attenuated locomotor response to cocaine although unaltered postsynaptic dopamine receptor activation. Intriguingly, PICK1 KO mice showed increased levels of tyrosine hydroxylase (TH), the rate limiting enzyme in dopamine synthesis in striatum and elevated striatal dopamine content. Chronoamperometric recordings in striatum revealed elevated dopamine release in PICK1 KO mice supporting a hyperdopaminergic phenotype. PICK1 KO mice showed impaired behavioral sensitization to a cocaine-challenge and reduced chronic self-administration of cocaine suggesting long-term maladaptive plasticity changes. Lentiviral knock-down of PICK1 in midbrain dopaminergic cultures resulted in elevated TH expression and thus imply that PICK1 acts as negative regulator of dopamine synthesis. We infer that loss of PICK1 alters subcellular distribution of TH in striatum leading to elevated striatal dopamine content and development of a hyperdopaminergic phenotype.

Title: Dynamics of dopamine release in the median eminence studied by fast-scan cyclic voltammetry and optogenetic manipulation.

Authors: *A. S. STAGKOURAKIS, C. BROBERGER;
Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Tuberoinfundibular dopamine (TIDA) neurons project to the median eminence (ME), where they release dopamine into the portal vasculature that drains into the adenohypophysis. At the target site, through its powerful inhibitory action on lactotroph cells, dopamine shapes the plasma profile of the hormone, prolactin. Prolactin mediates key functions in pregnancy, nursing and parental behaviours. Thus, the dynamics of TIDA neurons play a central role in the exhibition of behaviours critical for offspring survival. Recent work has revealed that TIDA neurons exhibit complex network interactions, including the ability to shift between phasic and tonic discharge. Yet, the relationship between the TIDA network electrophysiology and transmitter release is poorly understood.

In this study, the first in-depth analysis of optically and pharmacologically induced dopamine release using fast-scan cyclic voltammetry (FSCV) in the ME was performed. The dopamine transporter (DAT)-Cre mouse line was used to express Channelrhodopsin-2 in TIDA neurons. Brains from adult mice (>2 months old) were sectioned into 300 μm-thick coronal hypothalamic slices with intact ME. Dopamine was detected with high sensitivity (detection threshold; ≥5nM), with single 5msec light pulses evoking release of 28.20±9.59nM (n=6). Optical control of dopamine release exhibits minimal decay over time, with no difference on evoked dopamine levels upon repeated stimulations at five minute intervals. Prolonged 60sec tonic stimulation at 1Hz and 5msec pulse duration evoked dopamine release of 149.80±38.81nM (n=5), whereas constant 1sec light pulses led to release as high as 1μM (913.70±11.89nM; n=3). An inverted U-shaped frequency curve *vs* dopamine release suggests maximal release (53.67±33.18nM, n=3) at 10Hz matching the maximum spike fidelity *vs* firing frequency of TIDA neurons (10Hz, n=6). Phasic stimulation resulted in similar dopamine release as tonic stimulation in short term stimulation protocols (20sec), but long-term (5min) tonic stimulation resulted in diminished dopamine release as compared to sustained release in the phasic stimulation protocols. Lastly, application of the DAT blockers methylphenidate (50μM) and GBR-12783 (10μM), resulted in increased extracellular dopamine (41.50±14.82nM; n=4, and 623.00±202.50nM; n=5, respectively), suggesting the existence of endogenous dopamine release *in vitro*. Taken together, these results suggest that dopamine concentration can be manipulated optogenetically or pharmacologically at the TIDA neuron terminals in the ME, providing a read-out of the relationship between TIDA neuron electrophysiology and dopamine release.

Title: Extracellular levels of glutamic acid and dopamine in dorsal striatum in animals with perinatal asphyxia

Authors: *J. M. ORTEGA IBARRA, SR[1], A. MORALES-VILLAGRAN[2], S. J. LÓPEZ-PÉREZ[2];
[1]Univ. De Guadalajara, Zapopan, Mexico; [2]cellular molecular biology, Univ. of Guadalajara, Zapopan, Mexico

Abstract: During the perinatal period, the brain is particularly sensitive to hypoxia. Newborn rats that are exposed to hypoxia shows apoptosis, neuronal loss and high glutamic (Glu) extracellular levels in the brain. The striatum is a component of main entrance of the basal ganglia, receiving a strong glutamatergic innervation from all cortical regions, and dopaminergic innervation from substantia nigra pars compacta. Insults such perinatal hypoxia affect dopaminergic and glutamatergic developmental patterns connectivity. There are few neurochemical studies *in vivo* to study the hypoxia effects. To analyze the stimulated release of Glu and dopamine (DA) in dorsal striatum this study used a microdialysis method, to estimate the neurotransmitters availability in this brain region. We used 11 posnatal days (PD) Wistar rats, which were asphyxiated by 45 min in a small sealed chamber; when the animals reached 20 PD, were subjected to microdialysis procedure in the dorsal striatum. Samples were collected every 5 min at a flow of 2.5 µL/min under basal conditions for 30 minutes, then a solution containing high potassium concentration (100 mM, during 30 min) was used to stimulate the neurotransmitters release. After, the potassium concentration was returned to baseline for 45 minutes. The collected fractions were used to measure Glu by an electroquimioluminicent method designed in this laboratory, whereas DA was measure by HPLC with electrochemical detection. The results showed that hypoxia induces a low extracellular level of DA, but not of Glu. Under potassium stimulation, we do not found any difference in DA release, whereas in Glu, the hypoxia animals had higher release than controls. The basal low level of DA could be a consequence of neuronal loss observed in substantia nigra in a previous work, so it is possible that the dopaminergic terminals in the striatum are less too, even if we do not analyze these. It is possible that the enzymatic production of DA are more efficient by overexpression of tyrosine hydroxylase. About Glu results, it is possible that the fall of DA levels, that it is known that

regulate the Glu release in striatum, explain, at least in part, the rise in Glu extracellular level after stimulation. Support: P3E-UDG-2016.

Abstract: Dopamine signaling occurs on a subsecond timescale, and its dysregulation is implicated in pathologies ranging from drug addiction to Parkinson's disease. Anatomical evidence suggests some dopamine neurons have cross-hemispheric projections, but the significance of these projections is unknown. Here, we show unprecedented interhemispheric communication in the midbrain dopamine system of awake and anesthetized rats. In the anesthetized preparation, optogenetic and electrical stimulation of dopamine cells elicited physiologically relevant dopamine release in the contralateral striatum. Contralateral release differed between dorsal and ventral striatum due to differential regulation by D2-like receptors. In the freely moving animal, simultaneous bilateral measurements revealed dopamine release synchronizes between hemispheres and intact, contralateral projections can release dopamine in the striatum of 6-hydroxydopamine lesioned rats. These experiments are the first to show cross-hemispheric synchronicity in dopamine signaling and support a functional role for contralateral

projections. In addition, the data reveal that psychostimulants such as amphetamine promote the coupling of dopamine transients between hemispheres.

Title: A critical role for CREB-regulated transcription coactivators (CRTC1 and CRTC3) in the regulation of the human tryptophan hydroxylase-2(TPH2) gene expression

Authors: Y. NAWA[1], H. KANEKO[1], M. TSUBONOYA[1], T. HIROI[1], R. TAKAHASHI[2], *H. MATSUI[3,1];
[1]Inst. RI Res, St. Marianna Univ. Grad Sch. Med., Kawasaki, Japan; [2]Dep Biochem, Fac Pharm Sci, Toho Univ., Funahashi, Japan; [3]Dept Mol Behav Neurosci, St. Marianna Univ. Grad Sch. Med., Kawasaki, Kanagawa, Japan

Abstract: Dysfunction of the central serotonin (5-hydroxytryptamine, 5-HT) system has been implicated in the etiology of the wide range of neurodevelopmental disorders, including depression, anxiety, obsessive-compulsive disorder, and autism. As the rate-limiting enzyme for the synthesis of central 5-HT, tryptophan hydroxylase- 2(TPH2) plays an essential role in the regulation of 5-HT neurotransmission and is thus a promising therapeutic target for the treatment of neuropsychiatric disorders. Previously we reported the NRSF-mediated negative transcriptional regulation of the human TPH2 (hTPH2) gene (Gentile MT et. al, J. Neurochem., 123:963-70(2012)). However, the mechanism by which hTPH2 gene expression is activated remains unresolved. In the present study, we further characterized how the hTPH2 promoter activity is regulated by cAMP-mediated signaling pathways. A 2-kb region of the hTPH2 gene (-1850/+141) was cloned into pGL4-Basic and its 5'-untranslated region (+10/+121; a region containing repression elements including NRSE) was deleted to construct reporter plasmids. Promoter activities were assessed by transient transfections into immortalized rat serotonergic RN46A cells. Overexpression of CREB and PKA-alpha (cAMP-dependent protein kinase catalytic subunit alpha), either alone or in combination, only caused marginal effects. Overexpression of either CREB-regulated transcription coactivator CRTC1 or 3 with PKA-alpha and CREB remarkably increased the hTPH2 promoter activity. PKA-alpha/CREB/CRTC-mediated increase in the hTPH2 promoter activity was abolished when the inverted CRE motif

was mutated. Whereas Sp-6-Bzn-cAMP (a PKA activator) increased the hTPH2 promoter activity under combined overexpression of CRTC1 or 3 and CREB, 8-pCPT-2'-Me-cAMP (the specific EPAC (exchange protein directly activated by cAMP) activator) did not show any appreciable increase in the hTPH2 promoter activity, corroborating that PKA activation is required for enhancing effects of CRTCs. CRTC-mediated increase in the hTPH2 promoter activity was attenuated either by overexpression of R314A-CREB (defective for interaction with CRTCs) or R301L-CREB (defective for interaction with CRE) instead of wild-type CREB. In contrast, overexpression of S131A-CREB (defective for phosphorylation by PKA) increased the hTPH2 promoter activity comparable to wild-type CREB, suggesting that CREB phosphorylation itself is not necessarily essential. Collectively, these results indicate that CRTCs play a critical role for positive transcriptional regulation of the hTPH2 gene via cAMP-mediated signaling pathways and interaction with CRE-bound CREB.

Title: CaMKII does not modulate D3 receptor effect on [^{3}H]-Glutamate release in the rat subtantia nigra.

Authors: *L. BRIONES[1], R. SÁNCHEZ ZAVALETA[2], D. ERLIJ[3], J. ACEVES[2], B. FLORÁN[2];
[1]CINVESTAV, México, DF, Mexico; [2]Physiol. Biophysics and Neurosciences, CINVESTAV-IPN, Mëxico City, Mexico; [3]State Univ. of New York, Department of Physiology and Pharmacology, NY

Abstract: Dopamine D3 receptors (D3R) are highly expressed in substantia nigra pars reticulata (SNr) therein modulating GABA release in from striatal projections. In striato-nigral terminals CaMKII modulates negatively D3R. Additionally, SNr receives glutamatergic projections from subthalamic nucleus (STN) that modulate its output activity. It is well known the presence of mRNA and D3R protein in subthalamic neurons. The effect of D3R on glutamate release has not been well explored and the role of CaMKII in its activity remains unknown. Using high

potassium-induced [^{3}H]-glutamate release in slices of SNr, we have examined the effect of D3R on release and its possible modulation by CaMKII. PD 128,907 [100 nM] inhibited dose dependent [^{3}H]-glutamate release an effect mediated by D3R because co-perfusion with GR 103691 [10 nM] prevented it. D3R does not modulate [^{3}H]-glutamate induced release by adenylyl cyclase (AC) stimulation by forskolin [10 μM]. In order to test if CaMKII modulates D3R activity in subthalamonigral terminals, we tested KN62 [4 μM] a CaMKII inhibitor. KN62 did not modify D3R effect in glutamate release. Dopaminergic denervation with neurotoxin 6-OHDA injected directly in medial forebrain bundle increases the effect of PD 128,907 on D3R activation by inhibiting [^{3}H]-glutamate release by 60%. We concluded that the activation of D3R in subthalamo-nigral terminals modulate glutamate release without inhibition of AC and control of CaMKII.

Title: Determination of the concentrations of d-amphetamine, neurotransmitters and various metabolites in microdialysates taken from the brains of freely-moving rats

Authors: *D. GILL[1], R. KULKARNI[1], L. PINDER[1], H. ROWLEY[1], M. VAN DAM[2], D. MASCHER[2], H. MASCHER[2], D. HEAL[1], S. CHEETHAM[1];
[1]Renasci Limited, Nottingham, United Kingdom; [2]Pharm-analyt Labor GmbH, Baden, Austria

Abstract: In a previous study, we demonstrated that d-amphetamine-induced increases in striatal dopamine efflux measured by microdialysis in freely-moving rats correlated with plasma drug concentrations (Rowley et al, 2012, Neuropharmacology **63**:1064-74). In this investigation, we have taken this one step further by exploring the relationship between d-amphetamine-induced changes in the efflux of dopamine and its metabolites in the nucleus accumbens (ACB) and acetylcholine in the frontal cortex (FC) and the concentration of d-amphetamine in the same microdialysate sample. Two 2.0mm microdialysis probes were stereotaxically implanted into the ACB (AP +2.2mm, ML ±1.5mm, DV -8.0mm relative to bregma) and FC (AP +3.2mm, ML ±2.5mm, DV -4.0mm) of isoflurane-anaesthetised male, Sprague Dawley rats (~300-350g). After ≥16hr recovery, 20min microdialysate samples (1.2μl/min artificial CSF (aCSF) or aCSF+1.0μM neostigmine) were taken from freely-moving rats for 3hr after d-amphetamine dosing.

Dopamine, DOPAC and HVA were measured by Alexys hplc-ecd and acetylcholine by ALEXYS™ uhplc-ecd (Antec). d-Amphetamine (amphetamine-D5 internal standard) was measured in 2.0µl samples by hplc-MS/MS with ESI positive ionization (Shimadzu, AB Sciex API 5000). All results are reported as mean±SE, n=3-8. d-Amphetamine (0.5mg/kg sc) produced rapid increases in the efflux of dopamine in ACB with a peak at 40min of 53.8±9.7fmol/5µl (476% baseline, $p<0.001$). There were concomitant decreases in DOPAC and HVA with maximum reduction to 944±47fmol/5µl (41% baseline at 60min, $p<0.001$) and 779±29fmol/5µl (66% baseline at 80min, $p<0.001$), respectively. d-amphetamine concentrations in ACB microdialysates followed an identical pattern with a peak increase of 44.8±12.9ηg/ml at 40min. In the FC, d-amphetamine produced a more gradual increase of acetylcholine efflux with a peak at 60min of 462±54fmol/10µl (389% baseline, $p<0.001$). The time-course and magnitude of d-amphetamine concentrations in FC microdialysates were very similar to those observed in ACB with a peak of 32.5±5.9ηg/ml at 40min. d-Amphetamine concentrations were highly correlated with the magnitude of increases in ACB dopamine ($r^2=0.967$) and FC acetylcholine ($r^2=0.879$). These findings demonstrate that it is feasible to measure the concentration of d-amphetamine in intracerebral microdialysate samples as well as neurotransmitters and their metabolites. These experiments have shown that the actions of d-amphetamine on the efflux of dopamine in the ACB and acetylcholine in FC are highly correlated with the concentration of the drug in the extracellular fluid surrounding the sampling sites.

Title: Investigating the effects of common dopamine D2 receptor gene polymorphisms on D2/3 striatal and midbrain dopamine receptor availability with [^{18}F]-Fallypride PET: C957T (rs6277) as a key determinant

Authors: *C. T. SMITH[1], J. W. BUCKHOLTZ[2,3], L. C. DANG[1], A. M. TETREAULT[1], S. F. PERKINS[1], J. J. CASTRELLON[1], R. L. COWAN[4,1], R. M. KESSLER[5], D. H. ZALD[1,4]; [1]Psychology, Vanderbilt Univ., Nashville, TN; [2]Psychology, Harvard Univ., Boston, MA; [3]Psychiatry, Massachusetts Gen. Hosp., Boston, MA; [4]Psychiatry, Vanderbilt Univ. Sch. of Med., Nashville, TN; [5]Radiology, Univ. of Alabama Birmingham Sch. of Med., Birmingham, AL

Abstract: Little work has focused on the impact of single nucleotide polymorphisms (SNPs) in the DRD2 gene on dopamine D2/3 receptor availability (assessed as binding potential, BPnd) beyond Taq1A SNP effects on striatal BPnd. Here, we used positron emission tomography (PET) with the D2/3 tracer ^{18}F-fallypride to assess the effect of 3 DRD2 SNPs (Taq1A, rs1800497; C957T, rs6277; -141C Ins/Del, rs1799732) on striatal and extrastriatal BPnd in 84 healthy subjects (ages 18-37, m=24.2±5.1; 53.6% female; 69% Caucasian). We focused our SNP analyses on an *a priori* striatal ROI but also conducted exploratory whole-brain analyses. All DRD2 alleles were present in expected ratios and did not violate Hardy-Weinberg equilibrium. In contrast to prior PET studies performed in smaller samples, we observed no significant effect of Taq1A status on BPnd. However, C957T T allele dosage (TT>CT>CC) was positively associated (pFDR<0.01) with striatal BPnd: Right Putamen, k(cluster size)=395, T=4.41 at MNI coordinates 26, 8, -4; d (Cohen's d effect size)=0.69, 98% confidence interval (CI): 0.59, 0.92; Left Putamen/Caudate, k=422, T=3.83 at -24, 4, -2; d=0.68, CI: 0.59, 0.82; when applying our *a priori* striatal small volume correction. Our whole-brain C957T analysis also identified a large midbrain/pons cluster at 2, -28,-26 where T allele dose was associated with higher BPnd (k=169, T=3.63; d=0.65, CI: 0.59, 0.78). We also observed a -141C Ins/Ins > Del Carriers BPnd effect in a similar midbrain/pons area (k=145, T=3.47 at 0, -26, -28; d=0.64, CI: 0.59, 0.76). Additionally, we constructed multi-locus genotype scores from the three SNPS, and investigated the impact of these scores on fallypride BPnd. The addition of Taq1A A2 allele dosage weakened (d=0.45, CI: 0.30, 0.58) while the addition of Ins/Ins allele status strengthened (d=0.75, CI: 0.53, 0.94) the initial C957T effect (d=0.65) on midbrain BPnd. The addition of Taq1A to the combined C957T + Ins/Ins score decreased the multi-locus effect on midbrain BPnd (d=0.45, CI: 0.22, 0.59), while the effect on striatal BPnd improved minimally (d=0.67 vs. 0.64).
Our results replicate previous work showing C957T T allele dosage is positively related to striatal BPnd and identify a novel effect in the midbrain, which is strengthened with the addition

of Ins/Ins genotype status. Taq1A alone or in combination with the other tested DRD2 SNPs was not associated with striatal BPnd, above our initial C957T effect. Given the strong linkage between the 3 SNPs we studied here, it is possible that C957T drove previously published Taq1A effects on BPnd. These findings demonstrate that DRD2 SNPs beyond Taq1A impact individual differences in D2/3 receptor availability.

Title: Pre-synaptic dopamine release is regulated by post-synaptic activity to induce neuronal plasticity in *Drosophila*

Authors: *K. UENO, M. SAITOE;
Tokyo Metropolitan Inst. of Med. Sci., Setagaya-Ku, Japan

Abstract: Dopamine is an important neurotransmitter required for various higher order brain functions, including locomotor activity, sleep and memory formation. However, its release mechanisms and precise roles in these functions remain largely unknown. In *Drosophila*, long-term enhancement (LTE) of cholinergic transmission from the antennal lobes (ALs) to the mushroom bodies (MBs) is a cellular correlate of olfactory memory, and occurs upon simultaneous stimulation of the ALs and the ascending fibers of the ventral nerve code (AFV). Previous meeting, we have reported that AFV information is mediated by glutamate/NMDA receptors on MBs. On the contrary, activation of D1-type DA receptor on MBs is sufficient to induce LTE. We monitored the dopamine release by fluorescent exocytosis probe, synapto-pHluorin, and found that it occurs when MB neurons are simultaneously activated by acetylcholine and glutamate signaling, thus AL and AFV information. We also found that dopamine release is induced only onto MB neurons that have been coincidently activated. Although these findings suggest that dopamine release may require synaptic output from MB

neurons to activate DA neurons that loop back to the MBs, dopamine release is not disrupted when synaptic transmission from MB neurons is inhibited. Next we considered another possibility, releasing may be regulated by a retrograde message released from MB neurons. By pharmacological and genetic studies, we identified a potential messenger, which is released from activated MBs and retrogradely induces dopamine release. This MB-dopaminergic neurons-MB loop mechanism explains how dopamine functions to reinforce associative learning, and how its release is restricted to reinforce specific associations.

Abstract: The level of GABA in the sustantia nigra pars reticulata is decisive for the firing of nigral neurons and therefore for the motor control. GABA release is modulated by presynaptically located D1 and D4 dopamine receptors. The role of the D4 receptor and its participation in motor behavior has been poorly studied, particularly on experimental Parkinson. To understand this, we performed in vivo microdialysis experiments in sustantia nigra of normal and hemiparkinsonic rats; we measured dopamine, GABA and glutamate levels. In hemiparkinsonic rats we activated dopamine receptors with L-DOPA methyl ester (10 mg/kg i.p.) and the animals were monitored by a system of motor activity recording of with microdialysis.
In normal rats local blockade of D4 receptors with L-745870 produces selectively increase of GABA levels (129 ± 29%) and not of glutamate or dopamine. Motor behavior was also increased significantly at the same time of blockade. Systemic administration of the antagonist did not modify any parameter. In hemiparkinsonic rats L-dopa plus antagonist D4 receptor L-745870

increased levels of the three neurotransmitters and further the level of GABA selectively. L-dopa, by itself increases activity causing contralateral rotation, which was significantly higher by blocking the D4 receptor. These data highlight the role of GABA in motor control by D4 receptor at pallidus-nigral pathway. The effects observed in the hemiparkinsonic rats suggest the possible use of D4 blockers in the treatment of Parkinson's disease.

Title: Loss of function of human-specific Brain-Derived Neurotrophic Factor exon VIII-containing transcripts associated with familial schizophrenia

Authors: ***S. T. MUNSHI**, A. AYO MARTIN, C. BOUWKAMP, N. GÜNHANLAR, G. VAN WOERDEN, Y. ELGERSMA, V. BONIFATI, F. M. S. DE VRIJ, S. A. KUSHNER; Erasmus MC, Rotterdam, Netherlands

Abstract: Despite its high heritability, the genetic basis of schizophrenia is only recently coming into focus. Large cohort genome-wide association studies have converged on a diverse group of common variants, however establishing cellular models to investigate their neurobiological influence has remained challenging. In contrast, rare high-penetrance mutations have been more difficult to identify, but offer a unique opportunity for performing detailed mechanistic studies of schizophrenia pathophysiology. In particular, with the advent of pluripotent stem cell technology, modeling rare highly-penetrant mutations in patient-specific neural cells has provided a novel way forward.
We performed linkage analysis and whole-genome exome sequencing within a family identified with high incidence of schizophrenia and a Mendelian pattern of disease inheritance. Pluripotent stem cell derived-neural lineages were differentiated to perform detailed molecular studies of leading candidates segregating amongst all affected family members.
In total, twenty candidate genes were identified. Among them was a frameshift insertion leading

to a premature stop in exon VIII of *Brain-Derived Neurotropic Factor* (*BDNF*). The regulation of *BDNF* transcription is remarkably diverse, with more than 17 known alternatively spliced isoforms. Interestingly, exon VIII contains a human-specific start codon that results in a larger pre-domain of the protein with as of yet undetermined functions. Depolarization of multiple different neural lineage cell types revealed that exon VIII-containing transcripts are highly activity-dependent in neural precursor cells (50x) and moderately in neurons and astrocytes (5-10x). We identified two novel transcripts that contain exon VIII: transcripts IV-VIII-IX and VI-VIII-IX. Interestingly, exon IV and VI contain many regulatory epigenetic landmarks for altering gene expression and have previously been pleiotropically associated with multiple psychiatric disorders. When overexpressed in various neuronal lineages, BDNF VIII-IX protein levels were at least ten-fold lower compared to that of BDNF IX, suggesting a shorter half-life of exon VIII-containing isoforms.

Title: Identification of novel regulatory mechanisms responsible for TrkB signaling-dependent transcription of BDNF in cortical neurons.

Authors: *J. TUVIKENE, E.-E. ESVALD, A. SIRP, E. ORAV, P. PRUUNSILD, T. TIMMUSK;
Dept. of Gene Technol., Tallinn Univ. of Technol., Tallinn, Estonia

Abstract: Brain-derived neurotrophic factor (BDNF), acting through its receptor TrkB, regulates the survival and differentiation of various neurons in the developing nervous system, and promotes synaptic plasticity in the adult brain. Previously, it has been shown that in neurons BDNF gene is a subject to an extensive autoregulatory positive feedback loop, where TrkB signaling induces BDNF mRNA expression. However, little is known about the molecular mechanisms responsible for the phenomenon. Here, we have elucidated the mechanisms behind BDNF autoregulation using rat primary cortical neurons together with various methods, including AAV-mediated overexpression of dominant negative forms of different transcription factors, luciferase reporter assays, and chromatin immunoprecipitation. Our findings improve the understanding of the regulation of BDNF gene transcription in cortical neurons.

Title: The role of BDNF-trkB signaling in cortical parvalbumin interneurons during cognitive and emotional processes

Authors: *N. G. GUYON[1], C. LOPES AGUIAR[3], Y. XUAN[1], R. ANDERSSON[2], A. FISAHN[2], K. MELETIS[1], M. CARLÉN[1];
[1]Dept. of Neurosci., [2]Dept. of Neurobiology, Care Sci. and Society, Karolinska Institutet, Stockholm, Sweden; [3]Dept. of Neurosci. and Behavioral Science, Ribeirão Preto Sch. of Med., Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: Prefrontal cortex (PFC) interneurons have a vital role in modulating cortical output and plasticity. They were shown to be involved in the regulation of attention, decision-making and memory. Dysfunctions in inhibitory parvalbumin (PV) interneurons have been implicated in

the pathogenesis of depression, anxiety and other neuropsychiatric disorders. Changes in the expression of the brain-derived neurotrophic factor (BDNF) and its receptor tyrosine receptor kinase B (trkB) in PV interneurons have been associated with the pathophysiology of schizophrenia. Furthermore, truncated trkB isoforms, unable to mediate normal neurotrophic response, have an increased expression in schizophrenic patients. These changes in the expression of the wild type and truncaded trkB receptors are correlated with altered GABA inhibition and local network oscillatory synchronization. To directly investigate how trkB signaling in cortical PV interneurons contribute to oscillatory activities in prefrontal cortex and cognitive and emotional behavior we generated Adeno-associated viruses with Cre-dependent expression of a dominant negative trkB receptor (trkB.DN; a truncated receptor that binds to BDNF but does not trigger intracellular signaling cascades). PV-Cre mice injected with trkB.DN into the PFC display normal locomotion but show aggressiveness and disturbances in behaviors related to memory, fear and anxiety. *In vivo* recordings reveal that the behavioral phenotypes are associated with higher delta-gamma phase-amplitude coupling in the PFC. This furthers our understanding of the relationship between BDNF-trkB signaling in PFC PV interneurons, schizophrenia-relevant behavioral alterations and aberrant states of prefrontal hyperactivity.

Title: Dose dependent effects of overexpressed BDNF from BDNF-gene transcripts with short 3'UTR in hippocampal CA1 neurons on memory formation

Authors: M. WANG[1,2], Y. ZHUAN[1,2], D. LI[1,2], P. P. SANNA[3], *T. BEHNISCH[1,2];
[1]Inst. of Brain Science, State Key Lab. of Med. Neurobio., Shanghai, China; [2]Fudan Univ., Shanghai, China; [3]Mol. and Integrative Neurosci. Dept., The Scripps Res. Inst., La Jolla, CA

Abstract: The Brain-Derived Neurotrophic Factor (BDNF) gene with its multiple transcripts takes part in mechanisms of learning and memory, but might have also the potential to promote

epileptogenesis. Here we present data showing that the dose of overexpressed BDNF determines whether memory formation is improved or worsened. A localized transduction of hippocampal CA1 neurons with AAV9-BDNF-short 3'UTR enhanced the expression level of BDNF to about 200% within two weeks. This dose of overexpressed BDNF improved the memory recall of a passive avoidance task and object location. In addition, key kinases of synaptic plasticity related signaling pathways showed enhanced phosphorylation levels, even three weeks after BDNF overexpression. A doubling of the BDNF doses by transduction of a higher number of CA1 neurons caused an increase in the mouse's anxiety level and a decline in the passive avoidance memory performance. In addition, a large number of animals developed seizure-like saliences. Thus, expression of BDNF from the transcript under investigation has the potential to improve memory formation in wild type mouse strains when the expression level of BDNF is well controlled.

Title: Effects of chronic intermittent ethanol exposure or forced swim stress on expression of BDNF exon variants in medial prefrontal cortex and hippocampus in C57BL/6J mice

Authors: *M. SOLOMON[1], R. I. ANDERSON[2], W. C. GRIFFIN[2], H. C. BECKER[2]; [1]Psychiatry, Med. Univ. of SC, Charleston, SC; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: We have previously shown that repeated cycles of chronic intermittent ethanol (CIE) exposure reduced BDNF mRNA and protein in the medial prefrontal cortex (mPFC). Additional

work found that the reduction in mRNA (Bdnf exon 4) after CIE also extended to the hippocampus (HPC) and, further, that reductions occurred after acute forced swim stress (FSS) in both regions. Interestingly, targeting transcripts with the Bdnf exon 2 variant revealed reductions only in mPFC after acute forced swim stress (FSS), suggesting differential regulation of Bdnf exon variants. Therefore, the present study was designed to extend these earlier findings by measuring mRNA levels of 7 known Bdnf non-coding exon variants (1, 2, 3, 4, 6, 7 & 8) that are spliced to the same coding exon (9), and measuring levels of exon 9 mRNA in mouse mPFC and HPC after a history of either repeated CIE exposure or after a single acute FSS. Adult male C57BL/6J mice received 4 weeks of CIE or air exposure in inhalation chambers (16 hr/day x 4 days/wk). Three days following the final CIE (or air) exposure, mice were sacrificed. A separate cohort of mice was exposed to a single 10-min FSS exposure and sacrificed 30 min later. After dissection and isolation of mRNA, expression of all 8 Bdnf mRNA variants was determined by real time quantitative PCR (qRT-PCR) using cyclophilin as the reference gene. Results revealed a diverse pattern of Bdnf exon variant mRNA expression. For instance, both CIE and FSS significantly *reduced* Bdnf exon 3 expression in the HPC by CIE (50±3.9%) and FSS (53±4.6%) (both $p<0.05$) compared to the CTL mice, but there was no reduction in mPFC. Bdnf exon 7 expression in the mPFC was *increased* by CIE (133±17.0%) and FSS (152±17.1%) compared to CTL (both $p<0.05$), but there was no change in the HPC. CIE and FSS exposure *increased* Bdnf exon 8 in mPFC (86±28.7% CIE, 114±29.8% FSS; both $p<0.05$) and HPC (51±15.6% CIE, 42±6.1% FSS; both $p<0.05$). Conversely, both conditions *decreased* exon 4 in the mPFC (22±7.4% CIE, 40±9.5% FSS) and HPC (42±4.0% CIE, 35±3.9% FSS) compared to CTL mice (all $p<0.05$). The BDNF coding exon (9) was found to trend toward a reduction in only the mPFC after CIE (21±4.4%; $p<0.06$). These results suggest there is complex regulation of BDNF expression that is selective to the type of experience and the brain region being analyzed. Since Bdnf exon variants have different subcellular localization that may allow for localized modulation of BDNF expression, ongoing work includes measuring BDNF protein expression in subcellular fractions from the mPFC and HPC after CIE or FSS.

Title: Endocannabinoid-BDNF interactions at cortical excitatory synapses

Authors: ***M. L.-W. YEH**, R. SELVAM, E. S. LEVINE;
Neurosci., Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Endocannabinoids (eCBs) and neurotrophins, particularly brain-derived neurotrophic factor (BDNF), are potent neuromodulators that are highly expressed throughout the mammalian neocortex. Both eCBs and BDNF play critical roles in many behavioral and neurophysiological processes and are primary targets for the development of novel therapeutics, specifically in relation to depression, anxiety and schizophrenia. In mammalian neocortex, eCBs and BDNF bind primarily to the type 1 cannabinoid receptor (CB1R) and the high affinity trkB tyrosine kinase receptor, respectively. These receptors are expressed throughout the cortical mantle, with the highest levels of both trkB and CB1Rs found in layers II/III and V. Our laboratory and others have previously established that at glutamatergic synapses in these cortical layers, BDNF rapidly potentiates excitatory transmission by enhancing presynaptic glutamate release and modulating NMDA receptors. In contrast, we have recently shown that BDNF attenuates inhibitory transmission by inducing postsynaptic release of eCBs that act retrogradely to suppress GABA release from presynaptic terminals. It is not known whether BDNF also induces release of eCBs at excitatory synapses, which could have a mitigating or opposing effect on the direct effects of BDNF at these synapses. Here, we investigate the physiological interactions between eCBs and BDNF at excitatory synapses in layer V using acute slices from mouse somatosensory cortex. Consistent with previous results, we observed an increase in the frequency but not amplitude of spontaneous AMPA-mediated miniature excitatory postsynaptic currents (mEPSCs) after bath application of 0.2 nM BDNF. We also observed an increase in mEPSC frequency following exposure to the specific CB1R antagonist SR141716A, suggesting that tonic eCB signaling is present at these terminals. Bath perfusion of BDNF in the presence of SR141716A typically resulted in a greater increase in mEPSC frequency than BDNF alone, suggesting that BDNF-trkB signaling induced the release of eCBs at these excitatory synapses. Ongoing experiments are further exploring this issue with pharmacological manipulations targeting eCB synthesis, release, reuptake and degradation. We are also using immunohistochemistry to examine colocalization of trkB and CB1R at glutamatergic synapses. These observations bolster the growing evidence for cross-talk between eCB and BDNF signaling at cortical synapses.

Title: Netrin-1 promotes phosphorylation and membrane insertion of GluA1 in hippocampal neurons.

Authors: *I. V. BEAMISH[1], S. D. GLASGOW[2], S. LABRECQUE[4], A. MCKINNEY[3], P. DE KONINCK[4], P. SÉGUÉLA[2], E. S. RUTHAZER[2], T. E. KENNEDY[2];

Abstract: Netrin-1 plays an important role in the establishment of neural circuits during development; however, the functional relevance of netrin-1 in the mature central nervous system remains unclear. Selective removal of the netrin receptor Deleted in Colorectal Cancer (DCC) from adult forebrain neurons results in significant impairments in long-term potentiation (LTP), a form of activity-dependent synaptic plasticity, suggesting a role for netrin-1 in learning and memory. Using electrophysiological recordings in adult hippocampal slices, our lab has recently found that netrin-1 potentiates synaptic responses via activation of DCC. LTP induction has been shown to trigger post-translational modifications of glutamate receptor subunits of the AMPA subtype, which regulate their subcellular trafficking and are correlated with alterations in dendritic spine volume. Here, we show that application of exogenous netrin-1 results in increased levels of CaMKII phosphorylation, as well as phosphorylation of critical serine residues on the GluA1 AMPAR subunit. We also show that application of netrin-1 increases fluorescence intensity of super ecliptic pHluorin-tagged GluA1 (SEP-GluA1) at synaptic sites. Additionally, we demonstrate that brief application of netrin-1 leads to long-term increases in the volume of thin type dendritic spines. Finally, depolarization of hippocampal neurons increases extracellular netrin-1, consistent with an activity-dependent release of netrin-1. These results point to a critical role for netrin-1 in the regulation of synaptic transmission and long-term plasticity via DCC-mediated modulation of the phosphorylation status of GluA1.

Title: Netrin-1 regulates synaptic transmission in CA1 pyramidal neurons of the adult mouse hippocampus.

Authors: *S. D. GLASGOW[1], I. V. BEAMISH[1], E. WONG[1], L. J. TRIGIANI[1], J. GIBON[1,3], E. HAMEL[1], A. MCKINNEY[2], P. SÉGUÉLA[1], E. S. RUTHAZER[1], T. E. KENNEDY[1]; [1]Dept. of Neurol. & Neurosurg., [2]Dept. of Pharmacol. & Therapeut., McGill Univ., Montreal, QC, Canada; [3]Univ. of British Columbia - Okanagan, Kelowna, BC, Canada

Abstract: Netrin-1 is a secreted protein that has been implicated in axon guidance during development; however little is known about its role in adulthood. Netrin-1 protein is readily detectable in the adult mouse hippocampus, suggesting potential roles in synaptic plasticity and learning and memory. Here, we report that brief application of netrin-1 increases thin-type dendritic spine volume, and leads to a significant increase in the frequency of miniature excitatory postsynaptic currents with no detected change in presynaptic function, indicating that netrin-1 can increase the number of excitatory synapses on CA1 pyramidal neurons. Moreover, transient application of netrin-1 induces a long-lasting potentiation of Schaffer collateral-evoked excitatory AMPA-mediated postsynaptic currents in CA1 pyramidal neurons in acute brain slices. We provide evidence that his potentiation is due to an increase in GluA1 AMPA receptor insertion and requires postsynaptic netrin receptor deleted-in-colorectal-cancer (DCC). DCC-mediated GluA1 insertion is dependent on PLC, intracellular calcium, PKC, and CaMKII, but not on NMDARs or mTOR. We also show that genetic deletion of netrin-1 from forebrain excitatory principal neurons results in attenuation of long-term potentiation (LTP), as well as deficits in spatial memory. Together, these findings identify a novel function for netrin-1 in the regulation of synaptic plasticity in the adult brain.

Title: Neuregulin targeting in central neurons

Authors: *D. VULLHORST, T. AHMED, I. KARAVANOVA, A. BUONANNO;
Section on Mol. Neurobio., NICHD, NIH, Bethesda, MD

Abstract: The Neuregulin/ErbB4 signaling pathway is an important modulator of GABAergic inhibitory interneurons, synaptic plasticity and neural network synchronization. Neuregulins are synthesized as membrane-bound proforms that require proteolytic processing by α- or β-secretases to shed their ectodomains and to initiate signaling. Until recently, it was generally assumed that all Neuregulins target to axons or axon terminals and to activate postsynaptic ErbB receptor tyrosine kinases in paracrine or juxtacrine fashion, based in large part on analyses of CRD (type III)-NRG1 function in the peripheral and central nervous systems. However, we recently demonstrated that NRG2, a major NRG isoform in the postnatal brain, accumulates as an unprocessed pro-form on cell bodies and proximal dendrites where it co-localizes with Kv2.1 potassium channels clusters at a subset of neuronal ER-PM junctions characterized by the presence of subsurface cisternae (SSCs). We also demonstrated that shedding of the signaling-competent NRG2 extracellular domain and subsequent autocrine initiation of ErbB4 receptor activation in GABAergic interneurons requires glutamate signaling via NMDA receptors. Therefore, these findings constitute a novel, non-axonal NRG signaling modality in central neurons. Here, we investigate the subcellular trafficking of other major NRG isoforms in cultured hippocampal neurons and in the brain, and begin to delineate the rules that govern their differential targeting to cell bodies vs. axons. Our preliminary data indicate that cell body accumulation, association with SSC-type ER-PM junctions and NMDA receptor-dependent ectodomain shedding are common properties of several NRG isoforms. These findings further support the notion that autocrine signaling in the cell body is a major mode of endogenous NRG/ErbB4 signaling that is potentially important to regulate excitability and/or synaptic transmission onto interneurons.

Abstract: S 47445 is a potentiator of AMPA receptors that possesses both procognitive and antidepressant-like properties (L. Danober, ADPD 2015; S. Bretin ECNP, 2015). Here, the neurotrophic effects of S 47445 were assessed on both 18 months old aged rats (from 1 to 10mg/kg p.o.) and in healthy subjects (20 and 50mg). In rats, mRNA and proteins levels of Brain-Derived Neurotrophic Factor (BDNF), Neurotrophin 3 (NT3) and Nerve Growth Factor (NGF) were investigated in prefrontal cortex (PFC), ventral (VH) and dorsal (DH) hippocampus after 2-week-treatment with S 47445. The effects of the age (vs 3 months/vehicle) and of the drug treatment (vs 18 months/vehicle) were analyzed using two-way ANOVA followed by Fisher's PLSD.The clinical study was an open, monocentric, phase I study in 24 healthy male and female subjects aged between 18 and 55 years. Subjects received orally for 10 days S 47445 at 20 mg (n=12) or 50 mg (n=12). Plasma samples were taken at 3 time points (D1 predose, D10 predose and D10 3h) and BDNF protein was measured with Mesoscale assays. Chronic effect (D10 predose - D1 predose) and acute changes (D10 3h -D10 predose) were analyzed separately using a Wilcoxon rank signed test.When compared to adult animals, aged rats show a significant decrease of total Bdnf mRNA levels in PFC ($p<0.05$), but not in VH or DH. Following S 47445 treatment, increases of Bdnf mRNA were observed both in PFC (1mg/kg; $p<0.05$) and DH (3 and 10mg/kg; $p<0.001$; $p<0.05$, respectively). Similarly, we found a significant age-dependent decrease of proBDNF and mature BDNF (mBDNF) in PFC synaptosomal fraction, which were normalized by S 47445 treatment (proBDNF: 1 and 10 mg/kg; $p<0.05$; mBDNF: all doses; $p<0.01$). Further, S 47445 was also able to upregulate mBDNF protein in DH (3 and 10 mg/kg, $p<0.01$; $p<0.05$). Last, S 47445 normalized the age-related defects of NT-3 protein (all doses;

p<0.01) in PFC and in DH (1mg/kg; p<0.01) and increased NGF protein in DH (1 mg/kg ; p<0.05).In healthy subjects, after a 10-day treatment, S 47445 significantly increased plasma BDNF protein at 20 and 50 mg, pooled results with both doses (median difference D10 predose - baseline = 40.6pg/mL; p<0.05). No difference on BDNF protein at D10 predose and 3hours after S 47445 treatment was observed suggesting a chronic effect rather than an acute one. In conclusion, S 47445 displayed neurotrophic effects in DH and PFC of aged rats and reversed the age-related deficits of mBDNF and NT3 proteins. S 47445 also presented a chronic effect on plasmatic BDNF levels in healthy subjects. On these bases, S 47445 has promising therapeutic potential in Alzheimer's disease and in Major Depressive Disorders.

Title: Gas1 is expressed and released from neuronal primary cultures from mouse cerebellum and hippocampus

Authors: *E. BAUTISTA[1], N. ZARCO[1], P. VERGARA[1], R. AGUILAR-ROBLERO[2], J. V. SEGOVIA-VILA[1];
[1]CINVESTAV, Mexico City, Mexico; [2]Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Gas1 (Growth Arrest Specific1) is a pleiotropic protein that induces a variety of effects, including cell-cycle arrest, apoptosis and proliferation in different cell types. Employing immunohistochemical techniques we had previously observed that Gas1 is strongly expressed in GABAergic, glutamatergic, dopaminergic and cholinergic neurons in the hippocampus, thalamus, s*ubstantia nigra pars compacta* and in the ventral horn of the spinal cord, respectively. Interestingly, we detected a very faint expression of Gas1 in the granular cell layer (glutamatergic neurons) of the cerebellum. Based on these data, we decided to analyze the levels of Gas1 in hippocampus and in both the granular and the Purkinje layers of the cerebellum. We now report that Gas1 mRNA and protein are present in the Purkinje-molecular cell layer, and in the hippocampus but that it is not found in the granular layer of the cerebellum. Moreover, we also detected soluble Gas1 in the medium of neuron-enriched cell cultures obtained from hippocampus and from the Purkinje layer. Interestingly, and consistent with our previous data, we did not detect Gas1 in cultures of cerebellar granular cells. The present results indicate a differential pattern of expression of Gas1 in adult brain, not necessarily associated with neurotransmitter phenotype. Moreover, Gas1 is secreted from neurons suggesting it may act in both autocrine and paracrine manners in the brain.

Title: Exercise in the presence of slight inhibition of GABAergic synapses up-regulate the synthesis of nerotrophin in the motor cortex

Authors: *H. MAEJIMA, K. TAKAHASHI, G. IKUTA;
Hokkaido Univ., Sapporo, Japan

Abstract: Neurotrophins positively modulate neuronal survival and plasticity in the brain. Physical exercise up-regulates the expression of neurotrophins including BDNF in the brain. $GABA_A$ is the most common neurotransmitter associated with IPSP in the brain. Some reports indicate that the inhibition of GABAergic synapses in the hippocampus enhances neural plasticity associated with the increased expression of BDNF, whereas the inhibition of GABAergic synapses removed the exercise-induced expression of nerotrophins in the motor cortex in our previous study. The objective of the present study was to investigate the effects of exercise and slighter inhibition of GABAergic synapses on the expression of neurotrophin in the mouse motor cortex. Female ICR mice at 30 weeks of age were assigned to four groups based on two factors (exercise and extremely slight inhibition of GABAergic synapses). The mice in the exercise groups performed moderate treadmill exercise (15 m/min, 60 min) every day. The slight inhibition of GABAergic synapses was induced by intraperitoneal administration of $GABA_A$ receptor antagonist (bicuculline, 0.25mg/kg). The intervention composed of exercise and bicuculline administration was continued for two weeks. After the intervention, the motor cortex was deprived for quantitative PCR analyses and immunoassays. The mRNA expression and protein level of BDNF were measured based on real time PCR and ELISA. All procedures were approved by the ethics committee for animal research of Hokkaido University. After the intervention for two weeks, bicuculline administration significantly increased the mRNA expression of BDNF, wheareas there was no effects of exercise on the expression. In the protein assay, neither bicuculline administration nor exercise modified the BDNF protein level, whereas exercise in the presence of bicuculline administration significantly increased the BDNF protein level. Taken together, the present study elucidated that the interaction between slight blockade of $GABA_A$ receptor and exercise up-regulated BDNF protein level in the motor cortex. One possibility is that slight blockade of $GABA_A$ receptor could positively contribute to the exercise-induced up-regulation of BDNF synthesis. It was suggested that exercise in the presence of regulated neuronal balance between EPSP and IPSP is crucial for the up-regulation or the down-regulation of neurotrophin syntheses in the motor cortex.

Title: Inositol hexakisphosphate kinase-2 interacts with protein 4.1N in the brain.

Authors: *L. NAGPAL, C. FU, S. H. SNYDER;
Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Inositol hexakisphosphate kinases (IP6Ks) are responsible for the synthesis of the energy-rich Inositol pyrophosphates (PP-IPs) in mammals and regulate cellular functions including chemotaxis, telomere length, endocytic trafficking, exocytosis as well as apoptosis. Among such pyrophosphates, diphosphoinositol pentakisphosphate (IP7) and bis-diphosphoinositol tetrakisphosphate (IP8) have been extensively characterized. IP7 is produced in mammals by a family of inositol hexakisphosphate kinases, namely IP6K1, IP6K2 and IP6K3, which have distinct biological functions. Of these, Inositol hexakisphosphate kinase-2 (IP6K2), has been identified as a pro-apoptotic factor with the ability to sensitize cells to apoptosis. To identify the protein interactome of IP6K2, we subjected wild-type mouse brain tissue lysates to anti-IP6K2 antibody-mediated coimmuno-precipitation followed by Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS). This screen revealed robust binding of protein 4.1N with IP6K2. Protein 4.1N is the neuronal selective isoform of the erythrocyte membrane cytoskeleton protein, 4.1R, also known as erythrocyte membrane protein band 4.1 like protein isoform a or EBP41L1. Protein 4.1N is believed to confer stability and plasticity to the neuronal membrane via interactions with multiple binding partners, including the spectrin-actin-based cytoskeleton, integral membrane channels and receptors as well as membrane-associated guanylate kinases. To further assess the specificity of the observed interaction between IP6K2 and 4.1N, we separately immuno-precipitated IP6K1 and IP6K3 from brain tissue lysates of mice and failed to detect any association with the 4.1N protein. Thus, the interaction of 4.1N is evidently specific to the IP6K2 form of inositol hexakisphosphate kinases. We are presently characterizing functional implications of IP6K2-4.1N interactions.

Title: Chronically expressed BDNF and proBDNF differently regulate pre- and postsynaptic characteristics in primary neuron culture

Authors: *A. BORODINOVA, Y. SPIVAK, I. SMIRNOV, A. MALYSHEV, A. BOLSHAKOV;
Inst. of Higher Nervous Activity, Moscow, Russian Federation

Abstract: Brain-derived neurotrophic factor (BDNF) is a key regulator of synaptic structure and plasticity in developing as well as mature neurons. It is synthesized as a precursor protein (proBDNF) that is subjected to a proteolytic cleavage to mature molecule and a prodomain. Recent evidences suggest that proBDNF has its own biological role, frequently opposite to the BDNF functions. Neurotrophic balance is extremely important for normal brain functioning, especially during development, and abnormal proBDNF/BDNF ratio may play a role in pathogenesis of many neurological disorders, including autism and fragile X syndrome. In the current study we are testing the hypothesis that chronic changes in proBDNF and BDNF expression can differently regulate functional characteristics of the cortical neurons. For continuous neurotrophins overexpression we designed lentiviral constructs, carrying plasmid with coding sequence for either cleavage-resistant proBDNF (pCSC-proBDNF-CR) or proBDNF, which may be cleaved to a mature neurotrophin (pCSC-BDNF). Cultured cortical neurons were transduced with mentioned lentiviruses, and presynaptic effects of chronically expressed neurotrophins were analyzed by immunocytochemical staining of VGlut, which correlates to the quantity of excitatory synapses. It turned out that continuous (2 weeks) pCSC-BDNF overexpression increased the number of VGlut puncta in primary neuron culture (5,96±0,3 per unit of length) as compared to control pCSC (3,35±0,3), whereas cleavage-resistant BDNF precursor had no long-term effects on VGlut distribution (3,26±0,3) and, therefore, the density of excitatory synapses. Next, we estimated the changes in postsynaptic properties during continuous (1 and 2 weeks) neurotrophins overexpression. According to Western blotting data, pCSC-proBDNF-CR significantly decreased the level of the key postsynaptic protein PSD95 after 1 or 2 weeks overexpression (0,85±0,05 and 0,76±0,07, respectively) as compared to control pCSC. Interestingly, BDNF overexpression did not change the PSD95 protein levels over a period of one week (1,08±0,02) but decreased it after two weeks of incubation (0,74±0,17). Using patch-clamp recording we have analyzed spontaneous activity of neural cultures. Preliminary data suggests that pCSC-proBDNF-CR overexpression does not influence activity of cortical neurons, while pCSC-proBDNF overexpression significantly activates spontaneous activity. Our results suggest that proBDNF may be responsible for modulation of postsynaptic characteristics, whereas mature neurotrophin acts both pre- and postsynaptically potentiating synapses formation.

Title: New non-invasive way to rescue neurons in spinal cord injury via intranasal administration of nerve growth factor: pilot study

Authors: *A. DE BELLIS[1], L. ALOE[2];
[1]Neurosurg., Maria Rosaria Maglione Fndn. Onlus, Napoli, Italy; [2]Inst. of Cell Biol. and Neurobiology, CNR, Rome, Italy

Abstract: Nerve Growth Factor is known to play a critical protective role on a number of brain neurons in mammals, including humans. Nerve Growth Factor can be delivered to Central Nervous Sistem (CNS) via nasal route (Chen QX; 1998 Delivery of nerve growth factor to the brain via the olfactory pathway. J Alzheimers Dis 1:35-44) and has a protective action on forebrain, ippocampus (Catteno A, Towards non invasive nerve growth factor therapies for Alzheimer's disease. J Alzheimers Dis. 2008, 15: 255-283) in Alzheimer disease and Parkinson disease. However, its role in the Spinal Cord is not still unclear. Indeed, NGF does not cross the blood-brain barrier if injected subcutaneously or intravenously and another delivery method is therefore required. Hence the aim of this study was first to investigate whether purified NGF reaches spinal cord neurons and has any effect on the motor skills of rats with induced spinal cord injury (de Bellis A; Progress in Neuroscience 2012; Vol 1,N(1-4):83-90,2012;ISSN:2240-5127) and second to determine its effect on NGF concentrations and NGF-receptors in injured spinal cord neurons in adult rats when administered via the nasal cavity (Aloe L;Neural Regeneration Research 2014;Volume:9;Issue:10;Page:1025-1030). Adult male Sprague-Dawley rats with intact and injured spinal cord (SCI-induction T8-T10 by Yasargil's clip for 30') received daily intranasal nerve growth factor administration (via spray) in both nostrils for 1 day or for 3 consecutive weeks. We found an increased content of nerve growth factor (NGF) and enhanced expression of nerve growth factor receptor in the spinal cord 24 hours after a single intranasal administration of nerve growth factor in healthy rats, while daily treatment for 3 weeks in a model of spinal cord injury improved the deficits in locomotor behaviour and increased spinal content of both nerve growth factor and nerve growth factor receptors. These outcomes suggest that the intranasal nerve growth factor bypasses blood-brain barrier and protects damaged neurons in spinal cord injury. They also suggest the potential therapeutic role of intranasally delivered nerve growth factor for the neuroprotection of damaged spinal nerve cells (de Bellis A; Proceedings of 2016 Annual Meeting American Spinal Injury Association, Philadelphia, USA). A new non-invasive way to rescue neurons in spinal cord injury. The future perspective could be to use intranasal NGF in acute spinal cord injury for neuroprotection or as growth factor for stem

cell transplants in cronic spinal cord inury (de bellis A; Proceedings of First International Rita Levi Montalcini's Meeting: Neuroscience and Therapy, 2016 Bologna, Italy).

Title: Aging and an immune challenge interact to produce a prolonged, but transient reduction in hippocampal CA1 late-phase LTP and BDNF in a rodent model of delirium.

Authors: *N. TANAKA[1], G. P. CORTESE[2], R. M. BARRIENTOS[3], S. F. MAIER[3], S. L. PATTERSON[1];
[1]Biol., Temple Univ., Philadelphia, PA; [2]Neurol., Univ. of Wisconsin, Madison, WI;
[3]Psychology & Neurosci., Univ. of Colorado, Boulder, CO

Abstract: Previously high functioning aged individuals who experience an acute infection, injury or surgery are at increased risk for developing an abrupt cognitive decline (sometimes termed delirium) - a very common, rapidly developing, severe but often temporary impairment in attention and cognition. Even if these individuals recover from the delirium, they are at significantly greater risk of eventually developing dementia. Very little is known about the molecular mechanisms that render an aging brain more vulnerable to the deleterious effects of a secondary stressor. However, data from rodent models suggest that aging, but otherwise unimpaired, individuals react to an immune challenge with an exaggerated inflammatory response in the brain. Aging (24-month-old) Fischer Brown Norway (F344xBN) rats generally show no sign of significant physical or cognitive impairments. However, in response to signals triggered by a peripheral immune challenge (an intraperitoneal injection of *E. coli*), they produce higher levels of proinflammatory cytokines and produce them longer than their younger (3-month-old) counterparts. In the aging rats, hippocampal IL-1β levels are significantly elevated 4 hours after infection and remain so for 8 - 14 days. In contrast, in the young rats, IL-1β levels rise transiently but return to near basal levels within 24 hours (Barrientos et al., 2009). Interestingly, the prolonged elevation in IL-1β in aged infected animals is paralleled by

prolonged deficits in a long-term memory task (fear-conditioning). We have previously demonstrated that a memory-related form of long-lasting synaptic plasticity - theta burst-evoked late-phase long-term potentiation (L-LTP) - is impaired in hippocampal area CA1 of aged animals 4 days after injection of *E. coli*. Levels of mature brain-derived neurotrophic factor (mBDNF) - known to be important for long-term memory and L-LTP - are reduced in hippocampal synaptoneurosomes prepared from aged animals at the same time point. Here, we present the results of a time-course study to determine if the deficits in mBDNF and L-LTP persist in parallel with the elevations in IL-1β and the impairments in memory. Aged infected animals showed a reduction in mBDNF lasting as long as the alterations in IL-1β and the memory task (8 -14 days). Interestingly, the deficit in L-LTP took slightly longer to fully recover (sometime between 14 - 21 days) - suggesting a requirement for additional processes and molecular players. We are currently piloting the use of synaptoneurosomes for large-scale screening for immune-driven alterations in additional molecules (RNAs and proteins) necessary for the persistence of plasticity.

Title: Monitoring and visualizing changes in the expression of BDNF gene using bioluminescence imaging

Authors: *M. FUKUCHI, H. MORI, A. TABUCHI, M. TSUDA;
Univ. of Toyama, Toyama, Japan

Abstract: Brain-derived neurotrophic factor (BDNF), a neurotrophin, plays a fundamental role in expressing a variety of neuronal functions in the brain. And also, it has been reported that alterations in the levels of BDNF expression are observed in the brain with neurodegenerative and psychiatric disorders including Alzheimer's disease, depression, and epilepsy. Therefore, monitoring and visualizing changes in the expression of BDNF gene would be useful for understanding changes in the levels of BDNF expression under physiological and pathological conditions in the brain. Recently, we generated a novel transgenic mouse strain to monitor

changes in BDNF expression using luciferase as an imaging probe. We successfully detected the activity-dependent induction of the expression of BDNF gene in primary culture of cortical cells prepared from the transgenic mice using a microscopic bioluminescence imaging. Furthermore, we could detect the bioluminescence signal from the head region of transgenic but not wild-type mice after administration of luciferin, a substrate for luciferase, by *in vivo* imaging. However, we also detected the signal from ear, limbs, and tail of the mice, probably due to the expression of BDNF gene in skin. These results indicate that alterations in the expression of BDNF gene can be continuously monitored and visualized using the transgenic mice both *in vitro* and *in vivo*, however, several improvements would be necessary for visualizing changes in the expression of BDNF gene in the brain.

Title: Examining the role of CaMKIIα in α4β2* nicotinic receptor function

Authors: ***M. B. MILLER**[1], W. ZHOU[2], M. PICCIOTTO[2];
[1]Psychiatry, Yale Univ., New Haven, CT; [2]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Tobacco use is the leading cause of preventable death worldwide, accounting for 6 million deaths each year. Nicotine, the primary psychoactive component in tobacco, exerts its effects on the nervous system through interactions with nicotinic acetylcholine receptors (nAChRs). The primary reinforcing properties of nicotine are mediated by high-affinity nAChRs containing α4 and β2 subunits (α4β2* nAChRs, where * represents the possibility of other subunits), which are both necessary and sufficient for nicotine reinforcement in animal models of addiction. Though the role of α4β2* nAChRs in nicotine-mediated physiology and behavior is well-established, the molecular mechanisms underlying receptor regulation and downstream signaling pathways are not completely understood. Recent work from our lab has identified several protein interactors of α4β2* nAChRs isolated from mouse and human brain. In this study, we aimed to elucidate the role of one of these interactors, CaMKIIα, in nicotinic receptor function and nicotine reinforcement. CaMKIIα is one of the most highly expressed kinases in the brain with well-established roles in synaptic plasticity, learning, and memory. We show that co-

expression of CaMKIIα-mRuby in HEK cells alters surface localization of exogenous α4β2 nAChRs. Using mass spectrophotometry, we also provide evidence that CaMKIIα phosphorylates the α4 nAChR subunit at a previously unidentified site in the intracellular M3/M4 loop, providing a potential mechanism for its effects on receptor localization. Lastly, although the roles of CaMKIIα in cortex and hippocampus have been studied extensively, little is known about its role in the mesolimbic dopamine system. Here, we show that CaMKIIα is expressed in both dopaminergic (DA) and non-DA neurons in the mouse VTA, suggesting possibly novel roles in DA signaling. Current studies are aimed at elucidating the role of the CaMKIIα-nAChR interaction in nicotine-mediated physiology and behavior.

Title: Nicotinic activation of protein kinase A modulates excitatory synapses in pyramidal neurons to regulate sound-evoked responses in the thalamocortical input layers of mouse primary auditory cortex

Authors: ***T. NAGAYAMA**, K. YAMASAKI, K. INAKUMA, H. D. KAWAI;
Dept. of Bioinformatics, Soka Univ., Hachioji, Tokyo, Japan

Abstract: In the study investigating current source density (CSD) profiles in auditory cortex, systemic nicotine administration enhanced the characteristic frequency (CF) tone-evoked responses in layers 2/3 and 4 of primary auditory cortex (A1). This nicotinic enhancement continued about 40 minutes, and was dependent on α4β2* nAChRs activity (Kawai et al., 2011, J. Neurosci., 31, 14367-14377). In addition, this nicotinic activation was also dependent on extracellular signal-related kinase (ERK) activity (Intskirveli and Metherate, 2012, J. Neurophysiol., 107, 2782-2793). However, detailed mechanisms for the nicotinic enhancement need further investigation.
To investigate what molecules are involved in the mechanisms, we prepared synaptoneurosomes from the upper layers of auditory cortex that includes A1 and found that systemic nicotine administration increased the phosphorylation of ERK and Ser845 of GluA1, a subunit of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs). We also found that

a protein kinase A (PKA) inhibitor, myr-PKI, inhibited the nicotine-induced ERK phosphorylation completely, while it significantly reduced the phosphorylation of Ser845 of GluA1, suggesting that the nicotine-induced increase of GluA1-Ser845 and ERK1/2 phosphorylation is mediated by PKA.
These biochemical data also suggest that PKA mediates nicotinic enhancement of sound-evoked responses. To test this possibility, we recorded tone-evoked local field potentials (LFPs). Nicotinic enhancement of tone-evoked LFP in layers 3/4 of A1 was associated with reduced onset latency, and increased 20-80 % slope and peak amplitude. As expected, myr-PKI local injection inhibited these nicotinic effects. To look for the site of nicotinic modulation, we recorded thalamocortical (TC) monosynaptic excitatory postsynaptic currents (EPSCs) and spontaneous EPSCs (sEPSCs) in auditory thalamocortical slices. We found that nicotine didn't modulate the TC synaptic transmission, but increased the amplitude of sEPSCs in neurons with apical dendrites without affecting inter-event interval (IEI) of sEPSCs. In the presence of myr-PKI, nicotine didn't induce the effect on sEPSCs in pyramidal neurons. These results suggest that the nicotinic enhancement of tone-evoked responses recruits intracortical excitatory synapses via PKA in pyramidal neurons.

Title: Role of the nicotinic acetylcholine receptors in Alzheimer's Disease hyperactivity in prefrontal cortex

Authors: F. KOUKOULI, 75724[1], M. ROOY[3], *U. MASKOS[2];
[1]Inst. Pasteur, Paris cedex 15, France; [2]Inst. Pasteur, Paris Cedex 15, France; [3]ENS, Paris, France

Abstract: Alzheimer's Disease (AD) is the most common form of dementia. The condition predominantly affects the cerebral cortex and hippocampus and is characterized by the spread of amyloid plaques and neurofibrillary tangles (NFTs). But soluble amyloid-β (Aβ) oligomers have also been identified to accumulate in the brains of AD patients and correlate with cognitive dysfunction more than the extent of plaque deposition. Here, we developed an adeno-associated viral vector expressing the human mutated amyloid precursor protein (hAPP) sequence harboring three pathogenic mutations associated with early-onset familial AD. Intracranial injection of the

AAV into the prefrontal cortex (PFC) allowed the induction of AD-like deficits in adults, thereby modeling human pathology. The possibility to target a discrete brain region dissects regional vulnerability to AD lesions and potential spreading of the disease. AAV-hAPP expression caused accumulation of Aβ oligomers, microglial activation, astrocytosis and the gradual formation of amyloid plaques. Importantly, *in vivo* two-photon Ca^{2+} imaging at the site of Aβ peptide expression, in awake mice, revealed an increase in neuronal activity, a dysfunction characteristic of the pathology, already during the accumulation of soluble oligomers. Because an interaction of nicotinic acetylcholine receptors (nAChRs) and Aβ peptide has previously reported we used our AD model in mice knock-out for different nAChR subunits and investigated their role in AD hyperactivity. Our data suggest that specific expression of distinct nAChR subunits enables a diverse regulation of cortical activity in the AD brain and could provide a mechanistic basis for understanding the pathophysiology of the disorder.

Title: Areca nut alkaloids as selective nicotinic acetylcholine receptor partial agonists

Authors: ***N. HORENSTEIN**[1], R. PAPKE[2];
[1]Chem., Univ. Florida, Gainesville, FL; [2]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL

Abstract: Arecoline, an active agent in areca nut (*Areca catechu*) and the betel quids prepared from it, has partial agonist activity toward nicotinic acetylcholine receptor (nAChR) subtypes that mediate nicotine addiction. The level of activity of arecoline for these receptors is roughly comparable to that of the smoking cessation drugs cytisine and varenicline, yet arecoline is far more selective for these β2* nAChR than are the current cessation drugs, which are also efficacious for peripheral β4* nAChR and the widely expressed α7-type nAChR. Application of areca nut infusion to α4β2 and α6β2 containing nAChR resulted in a weak partial agonist responses and a subsequent refractory period when the receptor became insensitive to ACh, as determined by two-electrode voltage-clamp (TEVC) electrophysiological measurements made in the *Xenopus* oocyte expression system. Control applications of areca extract to

untransfected *Xenopus* cells showed no effect. Arecoline, the major pyridine alkaloid from the areca nut, was also a weak partial agonist of the α4β2 nAChR, but did not show the same level of subsequent inhibition of the ACh response. The observation of both partial agonism and apparent desensitization by the areca extract provides the impetus for us to discover the active components responsible for this activity, with the hypothesis that such compounds will serve as the basis for development of new, more selective smoking cessation agents compared to varenicline and cytisine. We have surveyed the activities of cytisine, varenicline compared to arecoline, and the related compound, isoarecolone versus key nAChR. It is apparent that both arecoline and isoarecolone have a favorable and advantageous lack of agonist activity at α7, ganglionic, and muscle-type receptors while maintaining the ability to serve as partial agonists at α4β2 and α6β2β3α4β2 receptors, which are the targets for smoking cessation therapies. Further, in comparison of isoarecolone, arecoline, and ACh as muscarinic agonists at 10 μM, isoarecolone was noteworthy in its weak partial agonism, nearly 6-fold less than arecoline on cells expressing multiple muscarinic receptor subtypes and decreased to essentially zero on M1 receptors specifically. These observations suggest that there will be a useful chemical space in which compounds will be developed with enhanced selectivity for α4β2 and α6β2β3α4β2 nAChR with diminished activity at mAChR.

Title: Low dose alcohol modulates alpha6-containing nAChR heterologously expressed in human SH-EP1 cells

Authors: ***J. WU**[1], F. GAO[1], X. MA[1], D. CHEN[1], M. GAO[1], D. H. TAYLOR[2], B. J. EATON[1], P. WHITEAKER[1], S. C. STEFFENSEN[2];
[1]Barrow Neurolog Inst., Phoenix, AZ; [2]Brigham Young University, Provo, UT 84602, Provo, UT

Abstract: Alcohol use disorder (AUD) is a serious public health problem that affects 17 million Americans and results in tremendous social, legal and medical costs. Unlike other addictive

drugs (e.g., morphine, cocaine or nicotine) that have specific molecular targets, there is no clear target for ethanol (EtOH). For example, EtOH concentrations used in many investigations were too high (e.g., >50 mM) compared to the EtOH concentrations in human brain after alcohol drinking, and high dose EtOH likely produces non-specific modulations of a variety of receptors, ion channels, intracellular signaling cascades, and gene expression in the brain. Therefore, it is important to understand the molecular mechanisms underlying low dose (e.g., <10 mM) EtOH effects in the brain. Unfortunately, the molecular and cellular targets that mediate the sensitivity to low dose EtOH remain to be defined. nAChRs containing α6 subunits (α6*-nAChRs) show a highly restricted distribution in midbrain dopaminergic neurons that are associated with drug dependence and addiction. The fundamental goal of this study was to examine the effects of low dose EtOH on α6*-nAChR heterologously expressed in human SH-EP1 cells using patch-clamp recordings. Co-transfection of human nAChR α6(N-terminal)/α3(transmembrane domain) chimera and β2, β3 subunits into human SH-EP1 cells formed functional α6*-nAChRs. Patch-clamp whole-cell recordings demonstrated that nicotine (NIC) currents in SH-EP1 cells were highly sensitive to the α6 subunit selective antagonist α-conotoxin MII (1 μM NIC: MII IC_{50}= 10.3±1.2 nM, Hill coefficients=0.9±0.1, n=10). Nicotine concentration-response relationship curves showed that NIC EC_{50} values and Hill coefficients were 0.34±0.02 μM and 0.7±0.1 (n=10). Different concentrations of EtOH (from 0.01 to 50 mM) on 1 μM NIC-induced currents were tested, and we found that EtOH modulates NIC currents in an EtOH concentration-dependent manner. Low, but not high, doses of EtOH enhanced NIC currents, forming a bell-shaped EtOH concentration-efficient curve with a maximal potentiation effect (about 125%) between EtOH 0.1 and 0.5 mM. Ethanol (0.5 mM) potentiated NIC induced currents (1 nM to 30 μM) in a NIC concentration-dependent manner, characterized by a decrease in EtOH potentiation with increasing NIC concentrations with a maximal potentiation at 10 nM NIC (about 165%). In conclusion, our results demonstrate a functional α6*-nAChR transfected in human SH-EP1 cells that can be used as an excellent cell model to investigate α6*-nAChR function and pharmacology. Under patch-clamp recording condition, low dose EtOH modulates α6*-nAChR function as a positive allosteric modulator.

Title: A correlation between affinities simplifies receptor dose-response analysis

Authors: *A. AUERBACH;
Physiol & Biophysics, Univ. Buffalo, Buffalo, NY

Abstract: Agonists activate receptors because they bind with a higher affinity to active vs. resting conformations. Muscle adult-type nicotinic receptors (AChRs) and GABAA receptors have two approximately-equivalent agonist binding sites. In these receptors E2/E0=(Kd/Jd)2, where E2 and E0 are the activation equilibrium constants with two and without any bound agonists and Kd/Jd is the resting/active equilibrium dissociation constant ratio. All four of these constants have been estimated independently in mouse AChRs. Experiments show that for a family of ACh-like agonists, the resting and active affinities are correlated: $J_d=K_d^m$, with m~2. Hence, the affinity ratio simplifies to $K_d^{(1-m)}$. This correlation indicates that the fraction of the total available agonist binding energy that is used up to form the low-affinity complex (1/m) is the same for all of the tested agonists (~50%). A binding-gating plot, which is a log-log plot of K_d (affinity) vs. E_2 (efficacy) for different agonists, shows a linear correlation in AChRs and $GABA_A$Rs. E_0 and m are receptor-specific and agonist-independent constants that shape the dose-response profile and can be estimated from the intercept and slope of this plot. In these receptors and at the level of equilibrium constants, it is possible to estimate affinity from efficacy and *vice versa*.

Title: The opposing influences of nicotinic acetylcholine receptor subtypes in the medial prefrontal cortex

Authors: *M. H. SABEC[1], P. J. BANKS[1], G. R. I. BARKER[1], S. WONNACOTT[2], Z. I. BASHIR[1], E. C. WARBURTON[1];
[1]Physiol. and Pharamcology, Univ. of Bristol, Bristol, United Kingdom; [2]Biol. and Biochem., Univ. of Bath, Bath, United Kingdom

Abstract: Nicotinic acetylcholine receptors (nAChR) play an essential role in multiple medial prefrontal cortex (mPFC)-dependent cognitive functions, but the complex pattern of nicotinic modulations within the mPFC is still being revealed (Wallace et al, 2013). The influence exerted by nAChR activity in the mPFC is dependent on the receptor subtype, its subcellular loci, the cell-type, and to which cortical layer the cell belongs (Wallace et al, 2013, Poorthuis et al, 2013). It is therefore unsurprising that the precise influence of nAChR on specific long-range inputs required for associative functions of the mPFC, such as associative recognition, are not known. The presented work therefore investigates the involvement of two major subtypes of nAChR in associative recognition memory, and their regulation of transmission and plasticity at the hippocampal-mPFC pathway, an input critical to this form of memory (Warburton et al, 2010). A combination of *in vivo* and *in vitro* approaches were taken to investigate the role of nicotinic receptor modulation in the mPFC. Associative recognition memory was assessed in rats using an object-in-place (OiP) behavioural task which tests the capacity of the subject to combine object and spatial information. Intra-cortical cannulations targeted to the mPFC allowed pharmacological agents to be directly administered at acquisition, consolidation, or retrieval stages of the task. Neuromodulation by nAChR of the synaptic projection between hippocampus and mPFC was examined through slice electrophysiology: Whole-cell recordings were taken from layer V pyramidal neurons in the prelimbic region of rat mPFC slices whilst afferent hippocampal fibres were electrically stimulated.
The data presents a divergence in the roles of the two major subtypes of nAChRs, homomeric α7 and heteromeric α4β2 receptors. Subtype specific antagonism during the OiP task revealed that α7 nAChR are essential in the acquisition of associative memory but not its retrieval, whereas α4β2 nAChR were required for memory retrieval but not acquisition. The subtypes also yielded opposing influences on long-term plasticity of the hippocampal-mPFC pathway *in vitro*. A pattern of paired pre- and post-synaptic activity, which in control conditions induced a transient potentiation of hippocampal-evoked responses, produced long-term potentiation with α7 nAChR agonism, but was converted to long-term depression by α4β2 nAChR agonist application. Thus, the major nAChR subtypes have differing profiles of involvement in associative recognition memory, which may reflect their ability to induce LTP and LTD in the hippocampal-mPFC input that is essential for this behaviour.

Title: Effects of Phantasmidine on neuronal nicotinic ACh and serotonin type 3 receptors

Authors: *A. A. PANDYA[1], J. YAKEL[2];
[1]IAC / CRCD, UAF, Fairbanks, AK; [2]Lab. of Neurobio., Natl. Inst. of Envrn. Hlth. Sci., RTP, NC

Abstract: Phantasmidine is a condensed tetracyclic alkaloid obtained from the Ecuadorian poison frog *Epipedobates anthonyi*. We tested the functional effects of synthetic phantasmidine on various subtypes of neuronal nicotinic ACh receptors (nAChRs; α7, α4β2 and α3β2) and the serotonin 5-HT3 receptors (5-HT3ARs) that had been expressed in *Xenopus* oocytes using two-electrode voltage-clamp techniques. We found that phantasmidine is a full agonist for the α7 receptors (with EC50 values of 9.89 $\pm$ 0.90 μM), and a partial agonist for the α3β2 and α4β2 nAChRs (with an EC50 value of 19.0 $\pm$ 13 μM and 3.06 $\pm$ 0.19 nM, respectively). The relative peak amplitudes of responses induced by phantasmidine (compared to 1 mM ACh) is 1.08 $\pm$ 0.04, 0.32 + 0.04, and 0.25 $\pm$ 0.08 for α7, α4β2 and α3β2 nAChRs, respectively. For the 5-HT3ARs, phantasmidine has a lower potency than that seen with any of the nAChRs (an EC50 value of 29.1 $\pm$ 1.7 μM with a relative peak amplitude of 0.79 $\pm$ 0.05 compared to 10 μM mCPBG). The phantasmidine-induced currents for the α7 and α4β2 subtype of nAChRs, as well as the 5-HT3ARs, were completely blocked by methyllycaconitine (30 nM), dihydro-β-erythroidine (10 nM), and tropisetron (30 nM), respectively. This shows that the functional effects of phantasmidine are due to its binding to the agonist site on these receptors since competitive antagonists are able to inhibit its actions. In summary, phantasmidine is an agonist for α7, α4β2 and α3β2 nAChRs and the 5-HT3ARs with the potential for clinical applications.

Title: Smoking-cessation reagent block of nicotine-induced upregulation results from weak base "trapping" in α4β2 receptor-containing acidic vesicles.

Authors: *A. P. GOVIND[1], Y. VALLEJO[2], J. R. STOLZ[3], J.-Z. YAN[3], G. T. SWANSON[3], W. N. GREEN[1,4];
[1]Neurobio., Univ. of Chicago Dept. of Neurobio., Chicago, IL; [2]Natl. Inst. of Dent. and Craniofacial Res. at the Natl. Inst. of Hlth., Bethesda, MD; [3]Dept. of Pharmacol., Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL; [4]Marine Biol. Lab., Woods Hole, MA

Abstract: The nicotinic acetylcholine receptor (nAChR) ligand, varenicline (Chantix), is thought to promote smoking cessation as a partial agonist competing with nicotine for rapid nAChR activation on mesolimbic dopaminergic neurons. Here we tested whether smoking cessation reagents have additional longer-lasting actions on nAChR nicotine-induced upregulation. Varenicline and lobeline reduced nicotine-induced upregulation measured by α4β2-type nAChR (α4β2R) functional responses in HEK cells or ^{125}I-epibatidine binding to live cultured neurons and HEK cells. The reduction was not observed previously because it does not occur with membrane fragments, only live cells. Furthermore, the reduction in upregulation was not observed if the acidic pH in intracellular compartments was neutralized, suggesting that the actions of varenicline and lobeline were a consequence of weak base "trapping" within intracellular acidic compartments, as was described for nicotine in Xenopus oocytes (Jia et al. 2003. J Neurochem). The degree of trapping appears dependent on ligand pK_a and affinity for α4β2R binding sites. Nicotine and dihydro-beta-erythroid, which have lower pK_as and α4β2R affinities, were not significantly trapped while epibatidine, which has a higher pK_a and affinity, was trapped similar to varenicline and lobeline. α4β2Rs in small acidic vesicles were imaged using α4 subunits tagged with pH-sensitive pHluorin. The numbers of α4β2R-containing acidic vesicles and α4β2R levels in the vesicles increased in parallel to increases in ^{125}I-epibatidine binding. Our findings indicate that smoking cessation reagents alter nicotine-induced upregulation through a novel mechanism in which weak base trapping is enhanced by high-affinity α4β2Rs in acidic vesicles and by a nicotine-induced redistribution of α4β2Rs to acidic vesicles.

Title: Behavioral and receptor pharmacology of nicotinic agonist epibatidine in key brainstem pain modulatory nuclei

Authors: *F. J. JARECZEK, S. R. WHITE, C. M. SANDE, D. L. HAMMOND;
Dept. of Anesthesia, Univ. of Iowa, Iowa City, IA

Abstract: The adverse interaction between smoking and chronic pain has been known for decades. The prevalence of smoking among patients seeking pain treatment approaches 50%, and smoking exacerbates both the intensity and associated impairment of chronic pain. The growing body of literature documenting this association has led to the proposition of a positive feedback loop: individuals smoke in part to relieve their pain, but smoking actually exacerbates the pain. The mechanisms responsible for this adverse interaction remain poorly understood. While the analgesic efficacy of nicotinic acetylcholine receptor (nAChR) agonists in acute pain states is well established, their role in modulating chronic pain is less well characterized. The complete Freund's adjuvant (CFA) model of chronic pain was employed to test the hypothesis that persistent inflammatory nociception diminishes the antinociceptive efficacy of the selective α4β2 nAChR agonist epibatidine in key brainstem pain modulatory nuclei. Paw withdrawal latency to a noxious heat stimulus was used to evaluate the antihyperalgesic and antinociceptive effects of epibatidine microinjected in the rostral ventromedial medulla (RVM) or periaqueductal gray (PAG) of male rats. The effects of epibatidine were assessed both in naïve animals and in animals four days or two weeks after intraplantar CFA injection. Interestingly, pretreatment with an α4β2-selective antagonist demonstrated that the antinociceptive effects of epibatidine in naïve rats were mediated by α4β2 nAChRs in the RVM but not in the PAG. While the antinociceptive effects of epibatidine in the RVM were abolished after two weeks of inflammatory pain, the antihyperalgesic effects remained unchanged. Persistent inflammation did not alter the antinociceptive or antihyperalgesic effects of epibatidine in the PAG. Of note, radioligand binding studies revealed no differences in α4β2 nAChR number or binding affinity in either nucleus in CFA-treated rats. Additional behavioral experiments to probe pharmacological specificity of action demonstrated that, in a persistent pain state, epibatidine may no longer act at α4β2 nAChRs in the RVM. Rather, it may exert its antihyperalgesic effect through serotonergic signaling pathways. Taken together, these data suggest that plasticity in nicotinic signaling within the descending pain modulatory pathways may in part explain the adverse interaction between smoking and chronic pain observed in humans.

Title: The role of lynx2, a nicotinic receptor modulator, in extinguishing fear and anxiety

Authors: *K. R. ANDERSON, H. WANG, J. M. MIWA;
Biol. Sci., Lehigh Univ., Bethlehem, PA

Abstract: Anxiety disorders rank amongst the most disruptive diagnosed mental disorders and are simultaneously amongst the most prevalent. The anxiety response is a normal and adaptive reaction to a stressor, however disorders can develop when individuals cannot return to baseline once the stressor has resolved. There is currently an incomplete understanding of the biological underpinnings of anxiety and anxiety disorders. As such, current anxiety treatments only address the symptoms without treating the cause. To address the cause, it will be necessary to understand the molecular basis for anxiety. A clue to the molecular mechanism arises from the fact that many anxiety sufferers self-medicate by smoking, suggesting a role of nicotine's target system, the cholinergic system, in anxiety modulation. We are using a candidate gene approach focused on the role of a cholinergic modulator, *lynx2,* which is highly expressed in the basolateral aspect of the anxiety structure, the amygdala (BLA). *lynx2* proteins bind to and suppress cholinergic receptors (nAChRs). Consistent with its spatial expression, mice lacking *lynx2* (lynx2KO), demonstrate elevated anxiety levels across several assays (light-dark, open-field, etc.). We hypothesize that experience-dependent plasticity in the BLA plays a role in the return to baseline state, and that this is subject to cholinergic modulation. To address this we are pairing behavioral pharmacology assays and electrophysiology studies in the *lynx2* KO mice to study anxiety behaviors using light dark box and fear extinction assays. Understanding of how amygdalar output can be altered or restored by lynx and cholinergic pathways could help in the development of treatments for anxiety disorders.

Title: Occupation of the alpha4(+)/alpha4(-) subunit interface enhances function of the low sensitivity alpha4beta2-nicotinic acetylcholine receptor isoform by destabilization of receptor closed states.

Authors: *M. M. WELTZIN, A. A. GEORGE, R. J. LUKAS, P. WHITEAKER;
The Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Alpha4beta2-nicotinic acetylcholine receptors (nAChR) are the most prevalent central nervous system subtype. They exist as two isoforms with high or predominantly low sensitivity to nicotinic agonists [HS $(alpha4)_2(beta2)_3$- and LS $(alpha4)_3(beta2)_2$-nAChR, respectively]. Both isoforms contain two, high-affinity, canonical binding sites for agonists at alpha4(+)/beta2(-) subunit interfaces. The LS isoform has a third, non-canonical interface located at its alpha4(+)/alpha4(-) interface that binds acetylcholine (ACh) with lower affinity. The HS isoform displays ACh concentration response curves (CRC) that are monophasic. At low ACh concentrations, the LS isoform exhibits similar ACh potency and efficacy as the HS isoform. However, higher ACh concentrations that occupy the alpha4(+)/alpha4(-) interface of the LS isoform produce a second LS phase, four-times larger in maximal function. The resulting ACh CRC is biphasic, reflecting both smaller HS and larger LS responses. Single-channel patch-clamp recordings were used to define unitary responses to acetylcholine (ACh) at specific concentrations. We expressed either alpha4beta2-nAChR isoform by injecting *Xenopus* oocytes at alpha4:beta2 loose subunit cRNA ratios of 1:10 or 30:1 (biased to produce HS or LS receptors, respectively) and did recordings 3-6 days later. To evoke single-channel responses, we used 1.3 or 0.7 μM ACh (EC_{50} for the HS isoform or for HS responses of the LS isoform, respectively) or 30 μM ACh (EC_{50} for the LS isoform LS response). Parameters measured include unitary amplitude, channel conductance, open durations and closed dwell times. At low ACh concentrations, both isoforms show similar open and closed dwell time characteristics. However, consistent with previous studies, we verified that the HS isoform has one conductance state under these conditions, whereas the LS isoform exhibits two. Critically, at 30 μM ACh, sufficient to occupy the alpha4(+)/alpha4(-) binding site, the LS isoform retains similar open

dwell times and open amplitudes, but exhibits significantly reduced closed dwell times. Our results show for the first time that occupation of the alpha4(+)/alpha4(-) binding site drives increased macroscopic receptor function primarily via destabilization of closed states.

Title: Menthol enhances nicotine's actions on midbrain neurons

Authors: *B. J. HENDERSON, T. R. WALL, C. H. KIM, S. MCKINNEY, H. A. LESTER; Div. of Biol., Caltech, Pasadena, CA

Abstract: Understanding how menthol cigarette use leads to reduced cessation rates compared to non-menthol cigarettes requires identifying the neurons that are altered by nicotine, menthol, and endogenous acetylcholine. To address this, we used the conditioned place preference assay (CPP) to examine nicotine reward-related behavior and found that menthol, co-applied with nicotine, results in greater reward-related behavior than nicotine alone. Using cultured midbrain neurons and patch-clamp electrophysiology we found that menthol potentiates functional upregulation of nicotinic responses on dopamine (DA) and GABA neurons. We also found that menthol combined with nicotine enhances agonist-induced changes in DA neuron firing frequency when compared to nicotine alone. Finally, we observed that menthol combined with

nicotine upregulates α4* (but not α6*) nAChRs more than nicotine alone. These changes in midbrain neurons are likely a critical component in the increased reward-related behavior observed when menthol is combined with nicotine and may explain, in part, how menthol cigarette smokers exhibit reduced cessation rates. Title: Unorthodox acetylcholine binding sites formed by alpha 5 and beta 3 accessory subunits in alpha 4 beta 2* nicotinic acetylcholine receptors

Authors: A. JAIN[1], A. KURYATOV[2], *J. M. LINDSTROM[3];
[2]Neurosci., [3]Inst. Neurolog. Sci., [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: All nicotinic acetylcholine receptors (AChRs) evolved from homomeric AChRs in which all five subunits are involved in forming ACh binding sites at their interfaces. Heteromeric α4β2* AChRs typically have two ACh binding sites at the α4/β2 interfaces and a fifth accessory subunit surrounding the central cation channel. The β2 accessory subunits do not form ACh binding sites, but α4 accessory subunits do at the α4/α4 interface in $(\alpha4\beta2)_2\alpha4$ AChRs. α5 and β3 are closely related subunits that had previously been thought to act only as accessory subunits and not take part in forming ACh binding sites. AChRs containing α5 subunits are important in nicotine responses because knocking out α5 increases self-administration, and because the D398N variation in the α5 AChR gene is associated with nicotine dependence and lung cancer. In the brain, β3 has been found almost exclusively in association with α6, and specific AChRs containing β3 and α6 have been shown to promote dopamine release. Thus, ACh sites incorporating α5 and β3 have the potential to be important drug targets. In this study, the effect of agonists at various subunit interfaces was determined by blocking these interfaces with the

thioreactive agent, 2-((trimethylammonium)ethyl) methanethiosulfonate (MTSET) reacting with a cysteine substituted for a homologous residue in the minus side of α4. Through selective blockage of specific subunit interfaces, we show that $(\alpha4\beta2)_2\alpha5$ and $(\alpha4\beta2)_2\beta3$ AChRs can form functional ACh binding sites at α5/α4 and β3/α4 interfaces. MTSET, like MTSEA, can block all function of $(\alpha4\beta2^{L121C})_2\beta2$ AChRs in which alkylation of the minus side of β2 blocks both α4/β2 ACh binding sites. Alkylation of $(\alpha4^{T126C}\beta2)_2\alpha5$ and $(\alpha4^{T126C}\beta2)_2\beta3$ AChRs, where the minus side of α4 contains a cysteine, with MTSET showed around 45% block of response for $(\alpha4\beta2)_2\alpha5$ AChRs and around 30% block of response for $(\alpha4\beta2)_2\beta3$ AChRs. In addition, a biphasic ACh concentration/response curve showed that $(\alpha4\beta2)_2\alpha5$ AChRs have two high sensitivity ACh sites at the α4/β2 interfaces (EC_{50} = 1.38 ± 0.33 μM) and a low sensitivity ACh site at the α5/α4 interface (EC_{50} = 22.60 ± 5.75 μM). These unorthodox ACh binding sites using α5 or β3 in combination with α4 subunits are a target for specific site-selective agonist drugs. NS9283 is a site-selective agonist for the α4/α4 ACh binding site that potentiates activation of $(\alpha4\beta2)_2\alpha4$ AChRs. Similar drugs might be developed for other accessory ACh sites whose activation may trigger aversion to nicotine.

Title: Alpha 7 nicotinic receptor coupling to heterotrimeric G proteins modulates RhoA activation, cytoskeletal motility, and structural growth

Authors: ***J. KING**, N. KABBANI;
George Mason Univ., Fairfax, VA

Abstract: Nicotinic acetylcholine receptors (nAChRs) modulate synaptic growth and neuronal morphology. Ligand stimulation of the α7 nAChR has been shown to regulate large heterotrimeric GTP binding protein (G protein) signaling in various types of cells. Here, we demonstrate a role for α7 nAChR/G protein interaction in the activation of small monomeric RhoA GTPases leading to cytoskeletal changes in neurite growth. Treatment of cells with the α7

nAChR agonist choline or PNU-282987 was associated with an increase in RhoA activity and an inhibition in neurite growth. Specifically, choline treatment was found to attenuate the velocity of microtubule growth at the growth cone and decrease the rate of actin polymerization throughout the cell. The effects of α7 nAChR activation were abolished by expression of a dominant negative α7 nAChR deficient in G protein coupling. Proteomic analysis of immunoprecipitated α7 nAChR complexes from differentiating PC12 cells and synaptic fractions of the developing mouse hippocampus revealed the existence of Rho GTPase regulating guanine nucleotide exchange factors (GEFs) within the α7 nAChR interactome. The findings underscore the role of α7 nAChR signaling to the cytoskeleton during neurite growth through a direct modulation of G proteins.

Title: Characterization of human alpha3beta2 nicotinic acetylcholine receptor kinetics reveals subtypes based on different subunit stoichiometries

Authors: D. C. JACKSON[1], M. HALL[2], *S. N. SUDWEEKS[1];
[1]Physiol. and Dev. Biol., [2]Neurosci., Brigham Young Univ., Provo, UT

Abstract: The α3β2 neuronal nicotinic acetylcholine receptor (nAChR) is a novel subtype whose behavior is largely uncharacterized. We have found the α3β2 (containing) nAChRs to be one of the predominant subtypes expressed at the mRNA level in rat hippocampal interneurons using single-cell RT-PCR. The α3β2 containing nAChRs are not widely expressed in other brain regions making this receptor subtype a plausible and specific target for cognitive therapies. Here we use voltage-clamp electrophysiology to characterize human α3β2 nAChRs expressed in *Xenopus laevis* oocytes. We injected the subunits at different ratios (1:5 and 5:1) and are able to distinguish receptor subtypes with differences in kinetic properties in response to acetylcholine. Receptors formed by the two ratios have statistically different EC50s and desensitization properties. These findings indicate that the human α3 and β2 nAChR subunits can form multiple functional receptor subtypes.

Title: Paradoxical interactions of alpha7 nAChR silent agonists and allosteric modulators; equilibration between desensitized states and persistent currents.

Authors: *R. L. PAPKE[1], K. MANTHER[1], G. A. THAKUR[2], M. DAMAJ[3], A. R. KULKARNI[2], D. BAGDAS[3], C. STOKES[1];
[1]Dept Pharmacol & Therapeut, Univ. Florida, Gainesville, FL; [2]Pharmaceut. Sci., Northeastern Univ., Boston, MA; [3]Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Investigation of α7 nAChR as a therapeutic target has led to the discovery of promising new drug types, including ago-PAMs and silent agonists. Ago-PAMs are positive allosteric modulators (PAMs) that also produce direct allosteric activation (DAA). While DAA by the prototypical ago-PAM GAT107 is transient, a single GAT107 application followed by a drug washout results in a prolonged period of primed potentiation of acetylcholine responses lasting up to an hour or longer. Silent agonists have little or no efficacy for activating the α7 ion channel but induce desensitization states. Some of these desensitized states can be converted into channel-active states by PAMs. NS6740 is a silent agonist that induces prolonged nonconducting states that are insensitive to activation by acetylcholine but activatible by a PAM. A single application of 30 μM NS6740 leaves receptors in a PAM-sensitive state for over an hour. GAT107 and NS6740 therefore appear to stably induce different peri-activatible states, which can work in concert to produce large ion-channel responses, and with sequential applications these two drugs induce varying levels of activation that persist following washout. With 30 μM GAT107 application following 30 μM NS6740, there was a biphasic activation with an initial peak 60 ± 20-fold greater than the amplitude of a response to 60 μM ACh alone. Within 60 seconds, current decreased to a level about 20-fold higher than ACh controls. This late-phase current decayed with a time constant of about 10 minutes and was still detectable as a mecamylamine-sensitive baseline current after 1 hour. Drugs that are intermediate in their induction of desensitization or allosteric potentiation are also intermediate in their ability to induce persistent currents. Despite their seemingly opposite effects on channel activation, both GAT107 and NS6740 have been shown to be very effective analgetic agents in the same in vivo pain models. This suggests that the different peri-activational states induced by GAT107 and NS6740 have common signal transduction activity, which we hypothesize is due to similar

effects on the receptor's intracellular interactome that is independent of their opposing effects on channel activation.

Title: Calcium imaging with GCaMP6s reveals differential responses to nicotine in sex-segregated hippocampal cultures

Authors: *K. A. REES[1], A. H. MAHNKE[1,2], S. D. WEYAND[1], A. M. SHARP[1], U. H. WINZER-SERHAN[1,2];
[1]Neurosci. and Exptl. Therapeut., [2]Women's Hlth. in Neurosci. Program, Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Sex differences have been shown to occur at the cellular level, even before puberty and the onset of high rates of sex hormone production. We have previously shown that chronic neonatal nicotine treatment can have long term effects on hippocampal excitability in a sex-specific manner. Since calcium is an important regulator of cellular function, we studied intracellular calcium dynamics in hippocampal cells in response to acute and chronic nicotine using the genetically encoded calcium indicator, GCaMP6s. Sex-segregated primary hippocampal cultures were derived from postnatal day 1 mouse pups, and transduced with an AAV5-viral vector encoding GCaMP6s. After 14-15 days *in vitro*, cells were imaged using a confocal microscope. GCaMP6s fluorescent signal dynamics, indicative of changes in intracellular calcium levels, could be visualized in cell bodies, and into proximal and distal neuronal dendrites and spines, and glial processes and micro-domains. Male and female hippocampal cultures had similar neuron to glia ratios, gross neuronal morphology and equivalent AAV5 transduction rates of neurons and glia. However, male and female neurons showed different responses to acute nicotine administration. In the presence of bicuculline (10 μM), male and female neuronal somas showed differential responses to increasing doses of bath-applied nicotine (0.01 μM to 10 μM). Notably, at 0.1 μM nicotine, female neurons reached their peak calcium response ($p = 0.005$ compared to 0.01 μM nicotine) and exhibited more robust calcium signal amplitude compared to male neurons ($p = 0.042$) which reach their peak response at 10 μM nicotine ($p = 0.011$ compared to 0.01 μM nicotine). Furthermore, we examined the

effects of acute, bath-applied nicotine in cultures chronically exposed to 0.1 μM nicotine for 5 days. Data suggest that chronic nicotine treatment increased the overall calcium response amplitude to acute nicotine in neurons. Glia cells from male and female cultures changed firing patterns in response to acute nicotine, and chronic nicotine exposure increased their calcium dynamics to bath-applied acute nicotine. These data reveal novel sex differences in the response to acute and chronic nicotine administration in hippocampal cultures. The results demonstrate sex differences that occur at the cellular level and in the absence of sex hormones, and therefore, may be due to either differences in intrinsic sex programming or patterning *in utero* in response to hormone surges. The observed differential responses may explain sex-specific long-term changes in hippocampal excitability that are seen after chronic neonatal nicotine administration.

Abstract: Depression is among the most common and debilitating symptoms of psychiatric disorders and has thus been the subject of extensive study. Despite the successes so far, currently available drugs have a number of shortcomings including limited efficacy, a need for chronic administration to achieve efficacy, and undesirable side effects from nausea and loss of libido to suicidal ideation and mania. Most research has focused on improving currently available drugs, but gains have been modest. More desirable would be the development of new classes of antidepressants. We have done so via the National Cooperative Drug Discovery/Development Group (NCDDG) Program involving a multidisciplinary research partnership to discover superior agents to treat mental illness. Here we summarize the results of a five year collaboration involving three research groups pursuing the development of novel antidepressant drugs targeting α4β2 nicotinic acetylcholine receptors (nAChR). Using sazetidine-A as a template, medicinal chemists developed multiple series of novel ligands with modifications to the pyridine core, azetidine ring, and alkynyl side chain with the objective of designing α4β2-nAChR partial agonists of high specificity. These ligands were characterized *in vitro* across an array of nAChR subtypes, and those with the best functional profiles were advanced for behavioral testing, primarily utilizing the SmartCube® assay (Psychogenics, Inc.) and the Forced Swim Test. Isoxazole substitutions of the pyridine core of sazetidine-A produced a few high-affinity compounds, but generally reduced ligand activity and were abandoned. The azetidine ring was successfully replaced with more stable heterocyclic structures of five to seven atoms. Compared to analogs that retained the azetidine ring, compounds with expanded rings trended toward affinities decreased by three to ten-fold. This affinity decrease was impacted by substitutions for the alkynyl group in the distal side chain, with a cyclopropane spacer enabling affinities to be retained. Compounds were generally well tolerated by mice, and a number exhibited antidepressant-like qualities. Side effect and ADME profiles were favorable, but given the high potency of ligands in the *in vitro* assays, the doses required to achieve *in vivo* efficacy were surprisingly high. In light of the pharmacokinetics, we believe that *in vitro* vs *in vivo* discrepancies in potency are likely due to lower than expected permeability of, or efflux across, the blood brain barrier. Thanks to very high specificity, this higher than expected dose does not appear problematic, and several ligands are suitable candidates for further development.

Title: Differential cAMP changes induced by α7 nicotinic acetylcholine receptor between hippocampal dentate granule cells and GABAergic interneurons

Authors: *Q. CHENG, J. L. YAKEL;
Neurobio. Lab., NIEHS, Durham, NC

Abstract: The activation of α7 nicotinic acetylcholine receptors (nAChRs) has been shown to improve hippocampal-dependent learning and memory. Recently, our studies showed that activation of α7 nAChRs potentiated glutamate release through calcium and subsequently cAMP rises. It is well known that α7 nAChRs are widespread among different cell types in the hippocampus. However it is unclear if α7 nAChRs mobilize differential signaling mechanisms among distinct neuronal populations. To address this question, we compared α7 nAChR agonist-induced current responses, calcium and cAMP changes between granule cells and GABAergic neurons in hippocampal dentate region. We cultured hippocampal slices from POMC-cre (dentate granule cell-specific cre line) and GAD2-cre (GABAergic interneuron-specific cre line) transgenic mice, and infected with AAV virus containing either floxed EPAC-H150 (cAMP sensor) or GCaMP6s (calcium sensor). Consistent with previous studies, application of the α7 nAChR-selective agonist choline (4 mM; in the presence of the α7 nAChR positive allosteric modulator PNU-120596, 5 μM) evoked larger currents (618±87 pA) in GABAergic interneurons than that of dentate granule cells (108±24 pA). This suggested that GABAergic interneurons have higher α7 nAChR density than granule cells. Next, we found that activation of α7 nAChRs induced a significant increase in intracellular cAMP levels in the somas of granule cells, but not of GABAergic interneurons. The increase of cAMP in granule cells was blocked by MLA, suggesting the requirement of α7 nAChR activation; and by NB001 (a selective AC1 inhibitor), suggesting the involvement of AC1. We hypothesize that the lack of cAMP responses is due to the expression of a large number of calcium-regulating proteins in GABAergic interneurons. Indeed, GCaMP6 imaging revealed robust and prominent calcium rises induced by choline and PNU-120596 application in the soma and processes of most granule cells; while the change of intracellular calcium of GABAergic neurons was rather small and slow in the soma because of a higher endogenous Ca^{2+}-buffering capacity. Increasing external calcium concentration to 10 mM enhanced calcium responses to activation of α7 nAChRs in GABAergic neurons, and conferred them the ability to produce a cAMP rise. This suggests that the restriction of the Ca^{2+} transient

could limit α7 nAChR's action in GABAergic neurons, at least concerning intracellular signaling cascades. Our findings also provide better understanding of the complex molecular mechanisms of the positive cognitive effects of α7 nAChR agonists in hippocampal circuits.

Title: The alpha7 nicotinic acetylcholine receptor partial agonists NS6740 and GTS-21 reduce LPS-induced TNF-alpha release from primary cultures of human microglia cells

Authors: *J. D. MIKKELSEN[1,2], M. H. SØRENSEN[1], L. H. PINBORG[1], H. H. HANSEN[1]; [1]Univ. Copenhagen - Rigshospitalet, Copenhagen, Denmark; [2]Bionomics Ltd, Adelaide, Australia

Abstract: The penta-homomeric alpha7 nicotinic acetylcholine receptor (alpha7 nAChR) is a potential drug target for alleviating cognitive symptoms. Polymorphisms in the alpha7 nAChR gene (*CHRNA7*) and the duplicated alpha7 nAChR gene (*CHRFAM7A*), both show genetic linkage to schizophrenia. *CHRFAM7A* is truncated and not coding the ligand binding domain, and is a gene that in contrast to *CHRNA7*, is unique to humans. Due to the lack of the ligand-binding domain, co-transfection of the *CHRFAM7A* gene product (dup-alpha7) with the primal alpha7 nAChR subunit suppresses ACh-induced alpha7 nAChR currents in oocytes. The dominant-negative property of dup-alpha7 may have important implications for the physiology and pharmacology of the alpha7 nAChR in the human brain. We used primary neocortical microglia cells isolated from the temporal cortex from neurosurgical samples to study the expression of *CHRNA7* and *CHRFAM7A*, respectively. Furthermore, we explored the effect of different alpha7 nAChR agonists on LPS-induced TNF-alpha release from these cells. While *CHRFAM7A* mRNA was expressed in mature human primary microglia cells, *CHRNA7* mRNA was almost undetectable. By contrast, human whole-cortical extracts showed higher levels of *CHRNA7* versus *CHRFAM7A* mRNA. Interestingly, the very weak partial alpha7 nAChR agonists, NS6740 and GTS-21, significantly inhibited LPS-induced TNF-alpha release from

human primary microglia cells. Effect of the same compounds, in contrast to stronger partial agonists, was observed in rat microglia cells. These data suggest that dup-alpha7 is relatively highly expressed in human microglia cells. Despite the presence of dup-alpha7 in human microglia cells, they respond significantly to partial alpha7 nAChR agonists.

Title: The heteromeric nicotinic receptors of the Renshaw cell are likely 3α-2β LS receptor

Authors: *B. LAMOTTE D'INCAMPS[1], D. PETERS[2], P. ASCHER[3];
[1]Ctr. For Neurophysics, Physiol. and Pathology, Paris, France; [2]DanPET AB, Malmö, Sweden;
[3]Cerebral Physiol. lab., CNRS-UMR 8118, Univ. Paris Descartes, Paris, France

Abstract: At the motoneuron-Renshaw cell synapse in young mice (P5-P10) , the component of the synaptic current mediated by heteromeric nicotinic receptors (nAChRs) has a bi-exponential decay with a large fast component (time constant around 10 ms) and a small slow component (time constant around 100 ms). Because the Renshaw cell nAChRs are known to contain multiple α and β subunits, we had initially considered the possibility that the two components of the decay may involve different subunits, but found that the decay of the EPSCs remained bi-exponential in a series of knock-outs in which a given subunit had been eliminated (Lamotte d'Incamps and Ascher, 2013). We now explored the possibility that the two time constants of the decay may arise from the dual affinity of heteromeric "low sensitivity" (LS) nAChRs with a 3α-2β stoichiometry. The concentration response curve of ACh on LS nAChRs has a small foot (high affinity) and a main part (low affinity) (Harpsoe et al. 2011). Our hypothesis was that the fast decay of the EPSC may result from the fast dissociation of ACh from the low affinity sites, while the slow decay would be due to slow dissociation from the high affinity sites. This hypothesis is well supported by the effects of two compounds known to act selectively on the 3α2β stoichiometric variants of α*β* receptors, NS9283 and Zn^{++}. NS9283 has been shown to potentiate selectively LS nAChRs receptors (Timmermann et al. 2012) by slowing deactivation (Grupe et al. 2013) and transforming the concentration-response curve to ACh from a two-

component curve into a single high affinity curve (Wang et al., 2015). NS9283 (10 μM) induced a marked prolongation of the Renshaw cell EPSCs, reducing the fast component and prolonging the slow one. NS9283 also prolonged the mEPSCs. Zn^{++}, which at 100 μM has been shown to potentiate LS and inhibit HS nAChRs (Moroni et al. 2008) also prolonged the mEPSCs, as expected from the increased burst duration observed at the single channel level (Hsia et al. 2008). These results support the hypothesis that the two components of the Renshaw cell EPSC mediated by heteromeric receptors can be attributed to a single stoichiometric assembly associating 3α and 2β subunits.

Title: Tropisetron enhances cognitive performance in young and aged rodents and non-human primates

Authors: *A. V. TERRY, JR[1], P. M. CALLAHAN[1], M. R. PLAGENHOEF[1], D. BERTRAND[2], S. BERTRAND[2];

Abstract: The α7 nicotinic acetylcholine receptor (α7 nAChR) is considered a therapeutic target for neuropsychiatric disorders such as Alzheimer's disease (AD) and schizophrenia. In the present investigation we assessed the effects of the 5HT3 receptor antagonist/α7 nAChR agonist tropisetron in memory-related tasks in rats and monkeys. Administration of tropisetron (0.1-10 mg/kg, po) improved the performance of a novel object recognition (NOR) task in young Sprague-Dawley rats at a long (48 hr) delay interval and these pro-cognitive effects were blocked by the α7 nAChR antagonist methyllycaconitine (MLA). In old Fischer 344 rats, tropisetron (0.3-3 mg/kg, ip) reversed the age-related deficits of NOR performance at a shorter (5 hr) delay. In a delayed match to sample (DTMS) task, tropisetron (0.03-1 mg/kg, im) improved accuracy (% correct) at the longest (i.e., presumably the most difficult) delay intervals in both aged male and

female rhesus monkeys. In subsequent experiments, a combination of sub-effective doses of donepezil (0.1 mg/kg) and tropisetron (0.03-0.1 mg/kg) also resulted in improved DMTS accuracy at the longest delay intervals. These later experiments would appear to support the electrophysiological (priming) experiments where exposure to low concentrations of tropisetron enhanced the current evoked by acetylcholine in *Xenopus* oocytes expressing human α7 and α7β2 nAChRs (see companion poster). Collectively, these studies improve our understanding of the nAChR pharmacology of tropisetron and support the argument that the compound has the potential to improve certain domains of cognition (i.e., recognition memory, working/short memory) that are often impaired in neuropsychiatric disorders such as AD and schizophrenia.

Title: Effects of low concentrations of tropisetron at the human α7 nAChR

Authors: *S. BERTRAND[1], P. M. CALLAHAN[2], E. NEVEU[1], A. V. TERRY, Jr[2], D. BERTRAND[1];
[1]Hiqscreen, Vesenaz - GE, Switzerland; [2]Dept. of Pharmacol. and Toxicology, Augusta Univ., Augusta, GA

Abstract: The structural similarities between the $5HT_3$ and the α7 nicotinic acetylcholine receptor (nAChR) suggest that these ligand gated ion channels share some pharmacological properties. For example, the high affinity of $5HT_3$ receptors to curare was the first demonstration of the commonality between these receptors. The observation that the $5HT_3$ receptor antagonist, tropisetron acts, albeit at high concentrations as an agonist at the α7 nAChR, provided another example of the pharmacological promiscuity between cholinergic and 5HT pathways. However, due to the difference in sensitivity these data are not sufficient to explain the pro-cognitive activity observed with low concentrations of tropisetron and its positive outcome in

schizophrenic patients.
To examine further the possible mechanisms by which low concentrations of tropisetron mediate the cognitive benefits we hypothesized that this compound might cause priming of α7 containing nAChRs. To evaluate the effects of tropisetron at α7 nAChRs we recorded the agonistic, antagonistic and priming activities of this compound at human α7 and α7β2 receptors expressed in *Xenopus* oocytes.
Data presented herein show without ambiguity that tropisetron acts as an agonist but with distinct properties at α7 and α7β2 receptors. Moreover, in priming experiments exposure to low nanomolar concentrations of this compound caused a significant enhancement of the current evoked by 40 μM acetylcholine.
Comparison of these data with results obtained from behavioral experiments (see accompanying poster) confirm that the pro-cognitive effects of tropisetron can be attributed to its activity at α7 nAChRs.

Title: Selective activation of $(A4)_3(B2)_2$ nAChRs reduces alcohol consumption

Authors: *J. WANG[1], C. DOEBELIN[2], A. KURYATOV[3], J. LINDSTROM[3], T. M. KAMENECKA[2], P. J. KENNY[4], R. O. MESSING[1];
[1]The Univ. of Texas At Austin, Austin, TX; [2]Scripps Res. Inst., Jupiter, FL; [3]Univ. of Pennsylvania, Philadelphia, PA; [4]Icahn Sch. of Med. at Mount Sinai, New York City, NY

Abstract: Tobacco and alcohol are highly co-abused. The FDA-approved smoking cessation aid varenicline (Chantix®), a selective partial agonist of α4β2 nicotinic acetylcholine receptors (nAChRs), also reduces alcohol consumption in humans and rodents. α4β2 nAChRs can assemble in two stoichiometries: $(\alpha4)_3(\beta2)_2$ and $(\alpha4)_2(\beta2)_3$. It is unknown whether varenicline

modulates one or both stoichiometries to reduce alcohol consumption. The two stoichiometries share two high sensitivity acetylcholine (ACh) binding sites, but $(\alpha4)_3(\beta2)_2$ nAChRs have an additional low sensitivity ACh site at its unique α4/α4 subunit interface. The $(\alpha4)_3(\beta2)_2$ nAChRs have been largely overlooked because of their apparent "low" sensitivity to cholinergic agonists. In fact, low doses of ACh can activate both stoichiometries, but high doses of ACh can further activate $(\alpha4)_3(\beta2)_2$ nAChRs and evoke a 5-fold larger current. This makes $(\alpha4)_3(\beta2)_2$ nAChRs appear to be less sensitive than $(\alpha4)_2(\beta2)_3$ nAChRs after normalization to maximum evoked current. Traditional agonists and competitive antagonists all bind to the high sensitivity ACh site and cannot distinguish the two stoichiometric forms. The small molecule 3-[3-(3-pyridinyl)-1,2,4-oxadiazol-5-yl]benzonitrile (NS9283) selectively binds to the low sensitivity ACh site at the α4/α4 subunit interface and thereby enhances the sensitivity of $(\alpha4)_3(\beta2)_2$ nAChRs for ACh. However, NS9283 itself does not directly activate or inhibit activation of nAChRs. Here we used NS9283 to increase function of $(\alpha4)_3(\beta2)_2$ nAChRs and investigated their role in alcohol consumption, using C57BL/6J mice in an intermittent access 2-bottle choice procedure. We found that administration of 10 mg/kg NS9283 significantly reduced ethanol intake by 29% during the following three hours of drinking. This decrease was similar to that produced by 2 mg/kg varenicline. NS9283 potentiated activation and desensitization of $(\alpha4)_3(\beta2)_2$ nAChRs by varenicline *in vitro*. To confirm that the effect of NS9283 on ethanol consumption was through its action at $(\alpha4)_3(\beta2)_2$ nAChRs, we tested whether subthreshold doses of NS9283 and varenicline would synergize to reduce ethanol drinking. Indeed, we found that while 2.5 mg/kg NS9283 and 0.1 mg/kg varenicline had no effect, in combination at those doses, they significantly reduced ethanol consumption. These results indicate that modulating the activity of $(\alpha4)_3(\beta2)_2$ nAChRs contributes to the ability of varenciline to reduce ethanol consumption. Drugs selective for $(\alpha4)_3(\beta2)_2$ nAChRs could prove to be new therapeutics for the treatment of excessive drinking.

Title: Perinatal nicotine exposure transiently increases NACHO protein levels in the rat frontal cortex

Authors: *M. S. THOMSEN[1], F. WICHERN[1], M. C. GONDRÉ-LEWIS[2], J. D. MIKKELSEN[3], H. B. HANSEN[3];
[1]Univ. of Copenhagen, Kobenhavn O, Denmark; [2]Dept. of Anat., Howard Univ. Col. of Med., Washington D.C., WA; [3]Neurobio. Res. Unit, Univ. Hosp. Copenhagen, Rigshospitalet, Copenhagen, Denmark

Abstract: Maternal smoking during and after gestation can have detrimental effects on the neuronal development of the offspring. The underlying molecular mechanisms involved in this effect are not completely understood, but it is believed that the major pharmacologically active chemical found in tobacco smoke, namely nicotine, is responsible via activation of the nicotinic acetylcholine receptors (nAChRs) in the developing brain.
NACHO (from the *TMEM35* gene) protein was recently shown to bind and influence the functionality of the α7 (alpha7, alpha 7) and α4β2 nicotinic acetylcholine receptors (nAChRs, Gu et al., Neuron, 2016, PMID: 26875622). We hypothesized that expression of the NACHO protein underlie the nAChR upregulation after perinatal nicotine exposure.
Nicotine (4mg/kg/day) was delivered through osmotic minipumps to SPRD rats from gestational day 7 until postnatal day (PND) 21, when the offspring was weaned. The male offspring were sacrificed at PND 7, 21, or 60 and the frontal cortex was subjected to western blotting. We found that nicotine significantly increased NACHO protein levels at PND7 and PND21 (2-fold increase, $P<0.05$ at both time points), but not at PND60. By contrast, adult exposure to nicotine (0.4 mg/kg, s.c., twice per day for 7 days), had no effects on NACHO protein levels in the frontal cortex. This indicates that exposure to nicotine during early development transiently increases NACHO levels in the brain. This increase in NACHO may explain nicotine-induced upregulation of nAChRs during development.
In summary, our results suggest that NACHO is sensitive to nicotine during early development, but that the effect is transient, and in adulthood NACHO levels are no longer affected by nAChR agonists. This suggests that NACHO protein is not involved in agonist-induced nAChR upregulation in adulthood.

Title: The alpha7 nicotinic acetylcholine receptor regulator chaperone (NACHO) is expressed in high levels in the hippocampus and prefrontal cortex of the rat

Authors: *H. B. HANSEN[1], F. WICHERN[2], M. S. THOMSEN[2], J. D. MIKKELSEN[1,3]; [1]Neurobio. Res. Unit, Copenhagen Univ. Hosp., Copenhagen, Denmark; [2]Dept. of Drug Design and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark; [3]Bionomics Ltd., Thebarton, South Australia, Australia

Abstract: The alpha7 nicotinic acetylcholine receptor (alpha7 nAChR) is one of the most abundant nAChR subtypes in the CNS and considered a potential drug target for alleviating cognitive deficits. The nicotinic acetylcholine receptor regulator chaperone (NACHO) has recently been reported to interact with the alpha7 nAChR subunit, resulting in markedly enhanced cell surface expression of mature alpha7 nAChRs. It is important to reveal the regional distribution of NACHO in the brain, because the presence of NACHO in the cell is essential for functionality of the alpha7 nAChR. In this study, we used immunohistochemistry to map the distribution of NACHO immunoreactivity in the rat brain. While NACHO immunopositive cells were observed predominantly in the cell soma, fiber structures were also labelled. NACHO immunoreactive neurons were found in high numbers in the hippocampus. The prefrontal cortex was particularly labelled, as compared to other cortical regions. Intense labelling was also observed in the ventromedial and arcuate nuclei of the hypothalamus, as well as in the lateral habenula. Moderate immunostaining was localized to the amygdala, lateral septum, bed nucleus of the stria terminalis and thalamus. The substantia nigra pars compacta showed low expression of NACHO. In conclusion, NACHO distribution corresponds to a major extent, but not fully, to brain regions with high alpha7 nAChR binding levels in the rat. NACHO immunoreactivity was also represented in brain regions with high alpha4beta2 nAChR expression. This suggests that NACHO plays an important role in regulating both alpha7 and alpha4beta2 nAChR activity.

Title: Role for α7 nicotinic acetylcholine receptors in naïve T cell differentiation into regulatory T cell

Authors: *K. KAWASHIMA[1], M. MASHIMO[2], T. FUJII[2], Y. MORIWAKI[3], H. MISAWA[4], S. ONO[5];
[1]Kitasato Univ. Sch. of Pharm., Tokyo, Japan; [2]Pharmacol., Doshisha Col. of Libeeral Arts, Fac. of Pharmaceut. Sci., Kyoto, Japan; [3]Pharmacol., Keio University, Fac. of Pharm., Tokyo, Japan; [4]Pharmacol., Keio Univ. Sch. of Pharm., Tokyo, Japan; [5]Immunol., Osaka Ohtani Univ. Sch. of Pharm., Osaka, Japan

Abstract: We have shown that $CD4^+$ T cells have the ability to synthesize acetylcholine (ACh) by choline acetyltransferase (ChAT), and that immunological activation of T cells via the T-cell receptor (TCR) stimulation increases ChAT mRNA expression and the ACh content. Furthermore, immune cells including T and B cells, macrophages and dendritic cells express various subtypes of both muscarinic and nicotinic ACh receptors (mAChRs and nAChRs, respectively). These findings suggest that ACh synthesized and released from $CD4^+$ T cells plays a role in the regulation of immune responses acting in autocrine and/or paracrine fashion via mAChRs and nAChRs on various immune cells. Among nAChR subtypes, α7 nAChRs down-regulate the synthesis and release of TNF-α in macrophages activated with LPS. Moreover, we showed that production of antigen-specific IgG_1 antibody and the pro-inflammatory cytokines, such as TNF-α, IFN-γ and IL-6, is elevated in α7 nAChR-deficient (α7-KO) compared with the wild-type C57BL/6J (WT) mice, suggesting a regulatory role for α7 nAChR in immune responses. In the present study, we investigated the role for α7 nAChRs in the differentiation of FoxP3-expressing regulatory T cells (Tregs) using α7-KO and WT mice. The spleen cells were stimulated with anti-TCR and anti-CD28 mAbs in the presence or absence of GTS-21 (3-30 μM), a partial α7 nAChR agonist, for 5 days in 24-well plate. At the end of the culture, we analyzed Tregs induction by the expression of CD4, CD25 and Foxp3 using flow cytometry. GTS-21 at 30 μM up-regulated significantly the generation of Tregs in WT spleen cells, while GTS-21 did not change the induction of Tregs in α7-KO spleen cells. The results show that GTS-21 up-regulates Tregs differentiation via the action on α7 nAChRs, and they support the notion that ACh released

from activated T cells acts on α7 nAChRs in naïve T cells and promotes Tregs induction leading to suppression of immune responses. Collectively, these findings suggest that a failure of Treg induction in α7-KO mice is responsible for elevated production of antigen-specific IgG_1 antibody, at least in part.

Title: Dynamic regulation of astrocyte cholesterol level and its impact on transmembrane ion gradient and glutamate transport

Authors: ***Z. YE**[1,2], Y. ZHOU[2], B. YE[2], T.-T. SHI[2], L. WANG[2], B. R. RANSOM[1];

Abstract: Oxidative stress has been reported to reduce glutamate transport, with suggested mechanisms ranging from lipid peroxidation to modification of transporter properties. However, little attention has been paid to the potential impact of oxidative stress on transmembrane ion gradients, particularly the Na^+ gradient, the chief driving force for Na^+-dependent glutamate transporters. We now report that oxidative stress caused deregulation of intracellular [Na^+] ($[Na^+]_i$) leading to reduced astrocyte glutamate transport, specifically reduced uptake. we also found significant reduction of cholesterol levels in astrocytes. Using cultured mouse astrocytes, oxidative stress was achieved by application of hydrogen peroxide (20 to100 uM). Meanwhile, application of the cholesterol binding compound MβCD also led to dose- and time-dependent increases in astrocyte $[Na^+]_i$, reversible upon removal of MβCD and inhibited by application of water soluble cholesterol. Accompanying the restoration of $[Na^+]_i$ in astrocytes after MβCD removal, cholesterol level also recovered even in the absence of precursors for cholesterol synthesis, indicating abundant intracellular storage of the precursors in astrocytes and their ability to be rapidly utilized. In summary, oxidative stress and MβCD both reduced cholesterol levels, presumably via different mechanisms. These mechanisms could operate in parallel to increase astrocyte $[Na^+]_i$, inhibiting glutamate uptake and increasing glutamate release from

astrocytes. Our results indicate that astrocytes dynamically regulate their cholesterol content and that this regulation can affect one of their major functions, the uptake of the neurotransmitter glutamate.

Title: Ankyrin G is an anchor for myosins and voltage-gated sodium channels in the nervous system

Authors: ***B. DASH**, C. HAN, F. DIB-HAJJ, P. SHAH, S. G. WAXMAN, S. D. DIB-HAJJ; Neurol., Yale Univ. Dept. of Neurol., West Haven, CT

Abstract: Ankyrin G (AnkG) serves as an adaptor protein that links membrane proteins to the underlying cytoskeleton in neurons. Functionally it is comprised of a membrane binding domain (MBD), a spectrin binding domain and a C-terminal regulatory domain that also contains a death domain. Various proteins including integral membrane proteins (such as voltage-gated sodium channels, sodium-calcium exchangers, sodium-potassium ATPase; etc.), signaling molecules and cytoskeletal components interact with each of these domains. This enables AnkG assemble the axon initial segment (AIS); and organize and stabilize protein networks. In this work, using immunochemical methods, we show for the first time that Class II, V and VI myosins interact with AnkG. Specifically, all the three isoforms of class II non-muscle myosin [i.e., non-muscle myosin IIA, IIB and IIC, respectively know as myosin heavy chain 9 (myh9), myosin heavy chain 10 (myh10) and myosin heavy chain 14 (myh14)], myosin Va (MyoVa) and myosin VI (MyoVI) interact with both the 270- and 190-KDa isoforms of AnkG. Preliminary results indicate that the MBD of AnkG is involved in its interaction with myosins. We hypothesize that this novel interaction of AnkG and myosins is important for formation of the AIS; and trafficking and targeting of voltage-gated sodium channels to functionally distinct axonal and somatodendritic compartments.

Title: Multiplicity of sodium channel genes in crustaceans

Authors: *D. K. HARTLINE[1], P. H. LENZ[2], V. RONCALLI[3];
[1]Univ. Hawaii, Honolulu, HI; [2]Bekesy aboratory of Neurobio., [3]Bekesy Lab. of Neurobio., Univ. of Hawaii at Manoa, Honolulu, HI

Abstract: Multiplicity of function at the transcriptional level within a gene family is commonly achieved through gene duplication followed by divergent adaptive evolution or by alternative splicing within a single gene. While vertebrates achieve extensive diversity of their voltage-gated sodium channels (Na_Vs) though gene duplication, most invertebrates, and particularly insects, obtain diversity through alternative splicing within a single gene designated "Na_V1." Surprisingly, several Na_V1s have been reported recently in a planktonic crustacean, the calanoid copepod *Calanus finmarchicus* (designated CalfiNa_V1.1, 1.2 and 1.3). Using a canonical *Drosophila melanogaster* sequence as query (DmNa_V1), we utilized the availability of an increasing number of transcriptomic databases to search for multiplicities of Na_V1 genes in other crustaceans. Databases from the Malacostraca, Cladocera and Maxillopoda consistently yielded Na_V1 sequences with good homology to DmNa_V1, including multiple putative splice variants in several cases, similar to the pattern present in insects. In addition to an insect-like Na_V1 with multiple splice variants ($Na_V1.1$), we found evidence in several other copepods of additional Na_V1 genes, with patterns of substitutions and insertions/deletions not easily explained by a splice-variant hypothesis. Using Calfi $Na_V1.2$ or 1.3 as query sequences we have failed so far to find close homologs of these genes, or indeed of comparable multiplicities, in available databases from arthropods and invertebrates outside of the Copepoda. We suggest that

exceptional selective pressures on copepods have resulted in the evolution of a greater diversity of Na_V1 genes than has been found among the rest of the Arthropoda, suggesting unexpected roles for this channel group in the taxon. Title: Estimating ion channel models with prior knowledge

Authors: *M. A. NAVARRO, A. SALARI, L. MILESCU;
Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: Ion channel gating mechanisms can be complex and difficult to extract from experimental data. A solution is to apply parameter constraints, which reflect prior knowledge or tested hypotheses and reduce model complexity and speed up computation. Soft constraints balance the existing knowledge with the new experimental data and limit the parameter search engine to a smaller space of more acceptable values. In contrast, hard constraints enforce a mathematical relationship involving one or more parameters of the model. These constraints can be formulated as an invertible transformation between a set of model parameters and a set of "free" parameters. Each constraint reduces the number of free parameters by one. Linear constraints, such as microscopic reversibility or scaling between sequential transitions, can be conveniently obtained with the singular value decomposition. Here, we show how this method can be generalized to implement arbitrary linear constraints. We also show how to make these constraints depend on arbitrary model parameters. This can be applied, for example, to enforce allosteric constraints where the allosteric factor itself is a free parameter. Furthermore, we demonstrate how slack variables can be used to implement inequality constraints.

Ctr., Veterans Affairs Connecticut Healthcare Syst., West Haven, CT

Abstract: Voltage-gated sodium channels (VGSCs) play essential roles in initiation and propagation of action potentials in excitable cells, and are subjects to many protein modifications such as phosphorylation, ubiquitylation, and proteolysis. Nine genes have been identified to encode VGSC α subunits, generating Nav1.1 to Nav1.9 channels. Previously it has been reported that Fyn kinase, a member of Src tyrosine kinase family, interacted with Nav1.2 and Nav1.5, and differentially altered channel properties. Here, using constitutively-active form (Fyn^{CA}) or dominant-negative form (Fyn^{DN}) of Fyn kinase, we investigated the effects of Fyn kinase on the expression and gating properties of Nav1.2, Nav1.6, Nav1.7, and Nav1.8 channels. Fyn^{CA} significantly elevated the protein levels of all four VGSC subtypes expressed in both HEK 293 and ND7/23 cells, when compared with cells transfected with Fyn^{DN}. Voltage-gated sodium currents were recorded from HEK 293 or ND7/23 cells transiently transfected with sodium channels plus Fyn^{CA} or Fyn^{DN} using whole-cell recordings. In HEK 293 cells, Fyn^{CA} significantly increased Nav1.2 and Nav1.7 current densities, when compared with cells transfected with Fyn^{DN}. In contrast, Fyn^{CA} had no effect on current densities of Nav1.6 and Nav1.8 channels recorded from transfected ND7/23 cells, despite it increased the total protein levels of Nav1.6 and Nav1.8. Small yet significant shifts in channel gating induced by Fyn^{CA} were observed, with no consistent changes among the four sodium channel subtypes. Our results demonstrate that Fyn kinase could regulate the expression of VGSCs, which might enable it to participate in the physiological and pathological functions of VGSCs.

Title: Functional inactivation of adult rat hippocampus through neosaxitoxin intrahippocampal injection

Authors: ***J. GALINDO**, N. LAGOS W, J. VALDES;
Univ. of Chile, Santiago, Chile

Abstract: The Neosaxitoxin (NeoSTX) is a marine toxin which blocks the voltage-gated sodium channels, producing an arrest of action potential propagation. The effects of NeoSTX are well characterized in the peripheral nervous system. However, there is no information about its effects in the central nervous system (CNS).
This research gives the first approach to elucidate the effects of NeoSTX over the CNS. With the purpose of evaluating this; adult rats were injected with NeoSTX at different doses (2.5 ng y 5.1 ng) in the CA3 region of the hippocampus and then the animals were tested for performance in a hippocampal-dependent spatial memory task. Also, we evaluated the effect of the toxin on the neuronal activity through immunohistochemical analysis by using the marker of neuronal activity c-Fos in the affected zone. Finally, we evaluated the presence of neuronal damage in the toxin injection zone, using histological analysis.
The results showed that NeoSTX can inactivate the hippocampus trough the blocking of voltage-gated sodium channels. The inactivation of the hippocampus cause a disruption in the spatial memory capacity and a decrease in the hippocampal neuronal activity, essayed by c-Fos immunoreactivity, which lasts up to 48 hours, after the toxin injection. The functionality of the hippocampus and its neuronal activity was fully recovered after 72 hours of treatment, without damage to the nervous tissue. These results demonstrated that the intrahippocampal

administration of NeoSTX generates a long lasting and reversible inactivation of this structure without neuronal damage.

Title: The role of cellular adhesion molecules on voltage-gated sodium channel distribution and action potential generation at the axon initial segment

Authors: *S. ALPIZAR[1], M. HOPPA[2];
[2]Biol., [1]Dartmouth Col., Hanover, NH

Abstract: Voltage gated sodium channel (VGSC) types 1.2 and 1.6 are recruited to the axon initial segment (AIS) following the enrichment of the scaffolding protein AnkyrinG during development. Previous studies have proposed that an ankyrinG-binding motif within an intracellular loop of the VGSC is sufficient for targeting VGSCs to the AIS. However, despite the shared homology of an intracellular loop known to bind AnkyrinG, the two VGSC types segregate at the AIS and exhibit differing distributions. Thus, the mechanisms enabling preferential targeting of VGSCs within the AIS remain unknown. Also uniquely localized at the AIS are cellular adhesion molecules (CAMs) such as Neuronal Cellular Adhesion Molecule, Neurofascin-186, and the sodium channel beta subunits. While these molecules are known for their functions in neurite extension, axon formation, and neuron-glial interactions, the effect that they may have on VGSC trafficking at the AIS in unknown. Our aim is to identify a potential role for CAMs to segregate VGSCs within the AIS and elucidate the functional consequence of their loss on action potential (AP) initiation.
Using primary rat hippocampal cultures, we combined localization measurements of fluorescently tagged VGSCs with genetic ablation of select CAMs using shRNA. These findings were combined with AP measurements that allow for firing and waveform analysis using synaptophysin- GCaMP, a genetically encoded Ca^{2+} indicator localized to synaptic vesicles that

provides accurate detection of single action potentials. Titrating the current until a lack of calcium influx (firing) is observed allowed us to measure the firing threshold of neurons with ablated CAMs. The loss of select CAMs altered the localization of VGSCs, but did not change trafficking of AnkyrinG. Additionally, not all changes in VGSC distribution correlated with AP initiation properties. Therefore, proper localization of VGSCs and AP initiation are coordinated in part by CAMs.

Title: Engineering iPSCs from inherited erythromelalgia patients with Nav1.7 mutations to study the firing properties and drug responsiveness of human sensory neurons

Authors: *Y. YANG, S. D. DIB-HAJJ, M. ESTACION, J. HUANG, S. G. WAXMAN; Neurol., VA CT Healthcare Syst., West Haven, CT

Abstract: Inherited erythromelalgia (IEM), a severe pain syndrome characterized by episodes of intense burning pain, is caused by mutations in sodium channel Nav1.7 which is preferentially expressed in sensory and sympathetic neurons. IEM provides a genetic model of chronic pain. Most IEM patients do not respond to pharmacotherapy, and it is critically important to understand the molecular mechanisms behind the pattern of pharmacoresponsiveness of IEM patients, which may facilitate the development of personalized treatment for chronic pain based on genetic information. Indeed, using a precision medicine approach, we matched a medication (carbamazepine) to two IEM patients with the Nav1.7-S241T mutation based on our genomic analysis and functional profiling. In vitro models might also contribute to the precision medicine approach to chronic pain. Induced pluripotent stem cells (iPSCs) are promising tools to model human neurological diseases, and with CRISPR/Cas9 genome-editing technology, accurate modification of specific genes within iPSCs is possible. To develop a “chronic pain in a dish” disease model, we have obtained blood samples from IEM patients with Nav1.7-S241T mutation

and generated iPSCs. We have differentiated these iPSCs into sensory neurons for functional and pharmacotherapeutic studies. As Nav1.8 is a primary marker for sensory neurons, we have also engineered a Venus fluorescent tag fused with Nav1.8 gene in the genome of H9 embryonic stem cells and iPSCs. Isogenic controls are being produced by correcting the S241T mutation in the iPSCs. These engineered iPSCs will serve as valuable tools to study the firing properties and drug responsiveness of human sensory neurons with disease-causing mutations.

Title: Energy-efficient action potential signaling in inhibitory interneuron axons

Authors: H. HU[1], *P. JONAS[2];
[1]Dept. of Mol. Med., Univ. of Oslo, Oslo, Norway; [2]Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: Fast-spiking, parvalbumin-expressing GABAergic interneurons (PV+ interneurons) play a key role in several microcircuit functions, such as feedforward and feedback inhibition, high-frequency network oscillations, and temporal encoding of information in the brain (Hu et al., 2014, Science 345:1255263). For all of these functions, the fast initiation, propagation, and termination of axonal action potentials (APs) is critically important. However, previous studies suggested that short APs are metabolically highly expensive (Carter and Bean, 2009, Neuron 64: 898-909). Together with the AP high frequency in PV+ interneurons in vivo, this suggests that a substantial part of the total energy budget of the brain may be used by processes associated with APs of PV+ interneurons. However, previous conclusions regarding AP energy efficiency in PV+ interneurons were made based on analysis of Na^+ channels in interneuron somata. Whether these conclusions hold for PV+ interneuron axons, where the majority of voltage-gated Na^+ channels is located, remains an important, but entirely open question. To estimate the energy efficiency of APs in interneuron axons, we performed confocally targeted subcellular patch-

clamp recordings in interneuron axons. Na^+ currents were recorded in outside-out patches using APs as voltage-clamp commands at near-physiological temperature (34-37^{o}C). Our results indicated a Na^+ inflow of 1.2 ± 0.5 pmole cm^{-2} per AP in the interneuron axon (n=11). This value is comparable to those of other cell types, including axons of glutamatergic principal neurons (1.76 pmole cm^{-2}, Alle et al., 2009, Science 325:1405-1408). Thus, in terms of total Na^+ inflow, PV+ interneurons appeared to be as energy efficient as other types of neurons. We next compared the total Na^+ entry during the AP with the theoretical minimum (Na^+ entry ratio) in the PV+ interneuron axons. Although the entry ratio in the interneuron axon (2.6 ± 0.3, n=21) appeared to be higher than in pyramidal neurons, it was substantially lower than the value of 4 previously obtained in the squid giant axon. Computer modeling of AP initiation and propagation in PV+ interneurons indicated an inflow of 581 × 10^8 Na^+ ions during a single AP. With the stoichiometry of the Na^+-K^+-ATPase, this would correspond to 194 × 10^8 ATP molecules per AP. Thus, the energy requirement per AP is significantly smaller in PV+ interneurons than in layer 5 neocortical pyramidal neurons (800 × 10^8 ATP molecules per AP, Hallermann et al., 2012, Nat Neurosci 15:1007-1014). In conclusion, AP signaling in GABAergic interneuron axons is more energy-efficient than previously thought.

Title: Temperature dependence of neurophysiological properties of IB4-positive and -negative mouse DRG neurons

Authors: *M. A. MIS[1], S. DIB-HAJJ[1], E. B. STEVENS[2], A. D. RANDALL[3], S. G. WAXMAN[1];
[1]Neurol., Yale Univ., West Haven, CT; [2]Pain and Neurosci. Res. Unit, Pfizer, Cambridge, United Kingdom; [3]Med. Sch., Univ. of Exeter, Exeter, United Kingdom

Abstract: Temperature can exert a variety of effects on voltage-gated ion channels, thus affecting cellular excitability. In pain-related electrophysiology, a sum of currents differently affected by temperature may result in dissimilar nociceptor properties at room and near-physiological temperatures. However, temperature effects on voltage-gated Na^+ channels and on

the output of DRG neuron firing are not well understood. The current project is focused on studying the effect of temperature on the neurophysiological properties of IB4-positive and -negative mouse dorsal root ganglia (DRG) neurons and the TTX-sensitive and -resistant Na^+ current expressed in these neurons. DRG neurons from 4-week-old male C57Bl/6 mice were cultured for up to 48 hours. Voltage- and current-clamp recordings were performed on IB4-positive and -negative small-diameter neurons at room temperature (RT, ~22°C) and 35°C. Preliminary IB4-positive data revealed resting membrane potential (RMP) hyperpolarization, a significant drop in input resistance and a decrease in firing frequency at 35°C. Interestingly, the decrease in firing frequency was only apparent at potentials close to the RMP. For cells that were held at more hyperpolarized pre-stimulus potentials, firing frequency increased at 35°C, but decreased at RT. These alterations could be partly driven by differential temperature-dependent changes in biophysical properties of the TTX-sensitive and TTX-resistant Na^+ current expressed in these cells. Specifically, while the peak TTX-sensitive Na^+ current increased significantly at 35°C, there was no change in the peak TTX-resistant Na^+ current. Consequently, the ratio of TTX-sensitive to TTX-resistant Na^+ current was found to be different at RT and 35°C. We also observed hyperpolarized shifts of the activation and inactivation curves for both types of current. IB4-positive and -negative DRG neurons were shown to be neurobiochemically distinct and have been suggested to convey information about distinct noxious stimuli and maintain different types of pain. Since the expression pattern of voltage-gated ion channels, including Na^+ channels, varies between IB4-positive and -negative mouse DRG neurons, it is expected that the two groups of cells will react to an increase in temperature in disparate ways. This question is currently being addressed by ongoing detailed characterization of the temperature dependence of IB4-negative mouse DRG neurons.

Abstract: Idiopathic trigeminal neuralgia (TN) is a debilitating pain disorder characterized by episodic unilateral facial pain along the territory of branches of the trigeminal nerve. Human painful disorders other than TN have been linked to gain-of-function mutations in voltage-gated sodium channels ($Na_V1.7$, $Na_V1.8$ and $Na_V1.9$) which are expressed in the peripheral nervous system (PNS). Gain-of-function mutations in $Na_V1.6$, which is expressed in myelinated and unmyelinated CNS and PNS neurons and supports neuronal high-frequency repetitive firing, have been linked to epilepsy but not to human pain disorders. Here, we describe a 64-year-old female who presented with evoked and spontaneous paroxysmal unilateral facial pain, and carried a diagnosis of TN. Magnetic resonance imaging showed unilateral neurovascular compression, consistent with classical TN and pain in areas innervated by the second branch of the trigeminal nerve. Genetic analysis as part of a phase 2 clinical study in patients with trigeminal neuralgia conducted by Convergence Pharmaceuticals Ltd (NCT01540630) revealed a previously undescribed de novo missense mutation in $Na_V1.6$ (c.A406G; p.Met136Val). Whole-cell voltage-clamp recordings show that the Met136Val mutation significantly increases peak current density (1.5-fold) and resurgent current (1.6-fold) without detectable effects on gating properties. Current-clamp studies in trigeminal ganglion (TRG) neurons showed that Met136Val increased the fraction of high-firing neurons, lowered the current threshold and increased the frequency of evoked action potentials in response to graded stimuli. Our results demonstrate a novel $Na_V1.6$ mutation in TN, and show that this naturally-occurring mutation potentiates transient and resurgent sodium currents and leads to increased excitability in TRG neurons. We suggest that this gain-of-function mutation of $Na_V1.6$ may exacerbate the pathophysiology of vascular compression and contribute to TN.

Title: Anchoring of ankyrin G to its membrane partners drives the establishment and maintenance of the axon initial segment

Authors: *C. LETERRIER, N. CLERC, F. RUEDA-BORONI, A. MONTERSINO, B. DARGENT, F. CASTETS;
CRN2M, Marseille Cedex 15, France

Abstract: In neurons, the axon initial segment (AIS) concentrates multiple types of ion channels (sodium, potassium, calcium) and cell adhesion molecules (CAM). These membrane proteins are associated with scaffolding proteins and cytoskeletal components at the AIS. Many studies have established the crucial role of the scaffolding protein ankyrin G (ankG) in the recruitment of membrane components at the AIS. However, the possible reciprocal role of these membrane components in ankG targeting and stabilization has been largely ignored so far. In cultured hippocampal neurons and cortical organotypic slices, we found that shRNA-mediated knockdown of voltage-gated sodium channels VGSCs led to an impaired formation and maintenance of the AIS, independently of their ion channel activity. A similar decrease in ankG concentration was found after knockdown of the AIS CAM neurofascin-186. In both cases, this decrease could be rescued by the expression of a recombinant VGSC, but also by a minimal construct containing the VGSC Nav1.2 ankyrin binding domain and a membrane anchor (mABD). These results show that anchoring of ankG to its membrane partners, in particular VGSCs, is a key step for the establishment and stabilization of the AIS assembly. Moreover, overexpressing mABD in mature neurons led to ankG delocalization, suggesting that ankG association to VGSCs may occur before its insertion at the AIS.

Title: Sodium channel beta2 subunits control action potential propagation fidelity

Authors: *I. CHO, M. HOPPA;
Dartmouth Col., Hanover, NH

Abstract: The arrival of an action potential at a presynaptic terminal dictates both calcium channel opening and the driving force for calcium entry, which are powerful levers in sculpting synaptic efficacy. Excitatory hippocampal neurons contain highly ramified axons (~200 branch points) that form a large number of en passant boutons (~8,000). When an axon dilates or branches this will cause an increased electrical load due to impedance mismatches that can alter the biophysical fidelity of the action potential (AP), or in extreme cases stop transmission. This impedance mismatch can be addressed at the subcellular level by endowing larger diameter axonal structures with a higher density of ion channels to compensate for the increased electrical load. At present, we have little idea about how cells regulate the density and subcellular distribution of ion channels to ensure AP delivery and signal fidelity. This question has been particularly difficult to study in hippocampal neurons due to the fine structures of distal axonal branches that preclude detailed electrophysiological analysis. Here we have used a combination of optogenetic indicators to make subcellular measurements of both membrane potential and calcium influx at nerve terminals to study sodium channel distribution across the axon of cultured hippocampal neurons. We demonstrate that very low (~6 nM) application of tetrodotoxin (TTX) revealed selective branch point failures suggesting a heterogeneous distribution of sodium channels. To determine a molecular mechanism, we ablated all four sodium channel beta subunits ($Na_v\beta$s) to investigate a potential role for these subunits for functionally enrichment voltage-gated sodium channels at branch points and synaptic boutons. Ablation of $Na_v\beta2$ uniquely caused high (~50%) branch point failure rates in AP propagation as well as a loss of signal fidelity with large variability observed in synaptic AP amplitudes across the axonal arborization. Finally, we show that geometrical dilations, especially synaptic bouton densities, alter the biophysical fidelity of propagating action potentials. Our results suggest that $Na_v\beta2$ regulates the function of Na^+ channels at branch points to compensate for the morphological properties of axons, ensuring signal transmission fidelity. Given the fact that synaptic transmission is highly sensitive to changes Ca^{2+} influx controlled by the biophysical

properties of the AP, this finding reveals a new important role for $Na_v\beta$ subunits to control the spread of excitability in the nervous system.

Title: *In vitro* biophysical and pharmacological characterization of four human Nav1.7 mutations associated with pain phenotypes

Authors: *D. LIU[1], N. RAMPAL[1], B. GRUBINSKA[2], P. ROSE[3], J. GINGRAS[2], B. MOYER[1]; [1]Neurosci., AMGEN, Inc., Thousand Oaks, CA; [2]Neurosci., [3]Biologics, AMGEN, Inc., Cambridge, MA

Abstract: Genetic and functional studies have demonstrated that $Na_v1.7$ plays a critical role in human pain signaling: gain-of-function mutations underlie pain syndromes such as inherited erythromelalgia (IEM), paroxysmal extreme pain disorder (PEPD), and small fiber neuropathy (SFN), and loss-of-function mutations underlie channelopathy-associated congenital insensitivity to pain (CIP). $Na_v1.7$ is considered an attractive target for the development of next-generation analgesics to reduce pain. In this study, we characterized the biophysical properties of four human $Na_v1.7$ sodium channel mutations associated with disease (L858H-IEM, M1627K-PEPD, I720K-SFN and R896Q-CIP) in parallel with wild-type (WT) human $Na_v1.7$ expressed in U2OS cells using the BacMam expression system and evaluated by manual patch clamp electrophysiology. Compared to WT $Na_v1.7$, the L858H mutant left-shifted the $V_{1/2}$s of activation and slow-inactivation (30 second pre-pulse duration) curves by 17 mV and 15 mV respectively, indicating increased activation and slow inactivation; the M1627K mutant right-shifted the $V_{1/2}$ of fast-inactivation (1 second pre-pulse duration) by 18 mV, indicating reduced fast inactivation; the I720K mutant right-shifted the $V_{1/2}$s of activation and slow-inactivation by 10 mV and 9 mV respectively, indicating reduced activation and slow inactivation. The R896Q mutant did not produce robust macroscopic currents under control conditions. However, when co-incubated with 500 uM mexiletine for 48 hours, sizable sodium currents >800 pA were recorded from cells expressing R896Q mutant channels after mexiletine washout, suggesting that mexiletine may function as a pharmacogical chaperone for this non-stop codon-based CIP mutation. Sodium currents recorded from WT and the four $Na_v1.7$ mutations were completely blocked by a $Na_v1.7$-selective small molecule inhibitor. qRT-PCR and Western blot analyses

revealed that mRNA and full-length protein were present in U2OS cells transduced with BacMam viruses harboring either WT or the individual $Na_v1.7$ mutations. $Na_v1.7$ inhibitors may reduce pain not only in individuals expressing WT $Na_v1.7$, but also in individuals harboring gain-of-function $Na_v1.7$ channelopathy mutations.

Title: Temperature dependent changes in neuronal dynamics in a novel SCN1A mutation

Authors: *C. H. PETERS[1], R. E. ROSCH[2], E. HUGHES[3], P. C. RUBEN[1];
[1]Dept. of Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Burnaby, BC, Canada; [2]Inst. of Neurol., Univ. Col., London, United Kingdom; [3]Dept. of Paediatric Neurol., Evelina London Children's Hosp., London, United Kingdom

Abstract: Dravet syndrome is a severe SCN1A-mutation associated epilepsy. It is characterised by prolonged seizures, typically provoked by fever. We describe the evaluation of an SCN1A mutation in a child with early-onset temperature-sensitive seizures.The patient carries a heterozygous missense variant (c3818C>T; pAla1273Val) in SCN1A which encodes the $Na_V1.1$ brain sodium channel. We compared the functional effects of the variant vs. wild type $Na_V1.1$ using patch clamp recordings from channels expressed in Chinese Hamster Ovary Cells at different temperatures (32, 37, and 40°C). The variant channels produced a temperature-dependent destabilization of activation and fast inactivation. Implementing these empirical abnormalities in a computational model produces a higher threshold for depolarization block in the variant, particularly at 40°C, suggesting a failure to autoregulate at high-input states. These results reveal direct effects of abnormalities in $Na_V1.1$ biophysical properties on neuronal

dynamics. They illustrate the value of combining cellular measurements with computational models to integrate different observational scales (gene/channel to patient).

Title: Gating pore currents in novel S4 arginine mutant $Na_V1.4$ channels: myotonia and block by Heriaeus melloteei spider toxin

Authors: ***M. THOR**[1], D. KUZMIN[1], S. DURRAN[1], E. MATTHEWS[1], R. SUD[1], A. A. BERKUT[2], S. SCHORGE[1], M. G. HANNA[1], D. M. KULLMANN[1], A. A. VASSILEVSKI[2], R. MÄNNIKKÖ[1];

[1]Univ. Col. London, London, United Kingdom; [2]M.M. Shemyakin & Yu.A. Ovchinnikov Inst. of Bioorganic Chemistry, Russian Acad. of Sci., Moscow, Russian Federation

Abstract: Gain of function mutations in the skeletal muscle sodium channel $Na_V1.4$ (*SCN4A*) cause myotonia and hyperkalemic periodic paralysis (hyperPP). In contrast, hypokalemic periodic paralysis (hypoPP) is caused by mutations that introduce gating pore currents through the voltage sensing domain by neutralizing arginine residues in the fourth transmembrane segment, S4. We identified the novel *SCN4A* mutation R222Q located in S4 of domain I in a patient with myotonia. The patient also carries a mutation in the chloride channel ClC-1, associated with recessive myotonia congenita. A different mutation in the same *SCN4A* residue, R222W, was found in a patient with hypoPP. Mutant sodium channels were expressed in HEK293 cells and *Xenopus* oocytes, and studied by whole-cell patch clamp and two-electrode voltage clamp, respectively. The ability of a gating modifier toxin Hm-3 to block gating pore currents was also studied using molecular dynamics and electrophysiological recordings. Both mutant channels produced gating pore currents. The R222Q mutation also caused a hyperpolarizing shift in the voltage dependence of activation. Gating pore currents from both R222 mutant channels were blocked by Hm-3 ($IC_{50} \approx 3$ μM). Hm-3 failed to block gating pore currents caused by homologous mutations in domain II and III, or by mutagenesis of R219 in domain I. We have performed molecular dynamics simulations to look into the potential molecular basis of these differences. Gating pore currents of R222W channels are consistent with hypoPP, while the enhanced activation of R222Q mutant channel is consistent with myotonia. Gating modifier toxins may be useful as gating pore blockers in hypoPP therapy, especially due to their putative domain- and isoform-specific mechanism of action.

Title: Investigation of background Na^+ channels important for pacemaking in the nigral dopamine neurons

Authors: *S. HAHN, M. PARK;
Sungkyunkwan Univ. Sch. Of Med., Suwon-City, Korea, Republic of

Abstract: Dopamine neurons in the midbrain are slow pacemakers. Without any afferent inputs they produce regular APs. However, it is still not known what ion channels are responsible for pacemaking in dopamine neurons. Among many candidates, unidentified Na^+-permeable leak channels appear to be one of major channels for driving pacemaker activity. Since resting membrane potentials of midbrain dopamine neurons are maintained between -55-45 mV far from the equilibrium potential of K^+(E_k), there could be a conductance responsible for persistent depolarization of membrane potential. Therefore, we have investigated background Na^+-permeable ion channels responsible for maintaining membrane potential depolarized in nigral dopamine neurons, using Ca^{2+} measurement and patch-clamp techniques. Since extracellular Ca^{2+} and Na^+ can play a key role in determining resting leak conductances, we examined whether extracellular Ca^{2+} and Na^+ influence membrane potentials, firing rates, and inward currents in dopamine neurons. Lowering $[Ca^{2+}]_e$ from 2.0 to 0.5 mM increased the Na^+ leak inward current and heavily affected spontaneous firing rates. A nonselective cation channel blocker for TRPC channels, SKF-96365, did not completely block background Na^+ conductances. Despite usage of TTX and Cs^+ which block Na_v and K_v channels, the component of Na^+ leak conductances survived. RT-PCR showed the presence of mRNA for NALCN, a background Na^{2+} leak channel, in dopamine neurons. These results suggest that there could be a TTX- and Cs^+-resistant Na^+ leak channel controlled by $[Ca^{2+}]_e$ and that NALCN could play an important role in the pacemaking of the midbrain dopamine neurons.

Title: Kernel-based classification of a GSK3-centric protein network at the axonal initial segment

Authors: ***W.-C. HSU**[1], P. NEGI[3], S. PRASAD[4], D. LABATE[3], F. LAEZZA[2];
[1]MD/PhD Combined Degree Program, [2]Pharmacol. & Toxicology, UTMB Galveston, Galveston, TX; [3]Mathematics, [4]Electrical & Computer Engin., Univ. of Houston, Houston, TX

Abstract: The axonal initial segment (AIS) in neurons integrates electrical inputs from neurites and converts it into an electrical output through the action of voltage-gated sodium (Nav) channels, providing a mechanism to regulate excitability and plasticity. Nav channels are just one of the many elements in the Nav macromolecular complex, which contains proteins with important regulatory and structural roles such as ankyrin-G, neurofascin, spectrin, and intracellular fibroblast growth factors (iFGFs, FGF11-14). Dysfunction in any of these components has been linked to serious psychiatric and neurological disorders in both humans and in animal models. By applying a nonlinear kernel-based Support Vector Machine (SVM) classifier on a large data set of high-resolution confocal images, we discovered several novel phenotypes in downstream AIS complex proteins caused by perturbation of a GSK3-centric kinase network, including alterations in spectrin/Nav channels as well as neurofascin/spectrin expression and co-localization upon treatment with Wee1 and GSK3 inhibitors. This methodology is a novel, powerful approach towards interrogation of large imaging data sets to better understand the phenotypic significance of intracellular signaling pathways controlling the molecular determinants of neuronal excitability in the brain.

Title: FGF14 is a master organizer of the beta-IV spectrin complex at the axonal initial segment and the paranodal junction in cortical regions

Authors: *M. A. ALSHAMMARI[1], T. K. ALSHAMMARI[1], M. N. NENOV,[2], F. SCALA[2], F. LAEZZA[2];
[1]Pharmacol. and Toxicology, Col. of Pharmacy, King Saud Univ., Riyadh, Saudi Arabia;
[2]pharmacology and toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: The macromolecular complex of proteins at the axonal initial segment (AIS) and at paranodal junctions is a critical determinant of neuronal excitability. By providing the scaffolding matrix for anchoring the voltage-gated Na+ channel (Nav) complex and its accessory proteins, these two subcellular compartments are subject to a tight control in neurons. Loss of such homeostatic regulation leads to neurodegeneration and cell death, common across many brain disorders. The intracellular fibroblast growth factor 14 (FGF14) is a functionally relevant component of the AIS that through binding to the intracellular C-tail of the Nav channel controls the channel trafficking and function via direct modulation and through kinase activity. In translational studies, mutations and/or changes in FGF14 gene expression level have been identified in ataxias and recently in schizophrenia raising interest in the mechanism of action of this molecule in animal models. Here, we show that genetic deletion of *Fgf14* leads to a selective loss and disruption of the beta- IV spectrin and of Caspr/neurexin IV complex in hippocampus and in myelinated cortical fibers. Correlative changes are found in Nav1.6 immunoreactivity and in functional properties of neurons. With patch-clamp electrophysiology in acute brain slices, we show that CA1 pyramidal neurons of *Fgf14*$^{-/-}$ mice exhibit increased action potential threshold and lower firing frequency. These results provide new insights into the biology of FGF14 further supporting its pivotal role as a structure-function organizer of the macromolecular complex of Nav channels and as a brain disease-associated risk factor

Title: Altered $Na_v1.2$ inactivation kinetics in a case of brain malformation, refractory seizures, and death

Authors: N. ELIA[1], S. DHILLON[1], E. DELA CRUZ[1], A. MONTALVO[1], X. XIONG[1], P. CHEN[1], S. HIROSE[2], T. L. KLASSEN[3], *D. H. FELDMAN[1], C. J. SAUNDERS[4], C. LOSSIN[1]; [1]Neurol., UC Davis, Sch. of Med., Sacramento, CA; [2]Pediatrics, Fukuoka Univ., Fukuoka, Japan; [3]Univ. of British Columbia, Vancouver, BC, Canada; [4]Children's Mercy Hosp., Kansas City, KS

Abstract: Voltage-gated sodium channels (Na_v channels) initiate action potentials in excitable tissues, which makes them strategic participants in excitation disorders of skeletal muscle, heart, and brain. For many of these conditions, the basic Na_v channel dysfunction has been established at the molecular level. Much less is known about how Na_v channels contribute to development, in particular that of the central nervous system. While it is recognized that neural activity shapes synaptic interactions and the development of patterns of connectivity, the details are poorly understood. We here report on the functional abnormalities of one particular Na_v channel mutant that was found in an infant with brain anomalies, epilepsy, and death at age 2 months. The Na_v channel in question, $Na_v1.2$, has established ties to epilepsy. Its connection to brain development, however, is less clear. Whole-genome sequencing of patient DNA had revealed no alterations of significance, with the exception of an *SCN2A* variant (p.Arg1626Gln or R1626Q) that predicted neutralization of a positively charged arginine in the voltage sensor of the fourth homologous domain (D4/S4). To characterize the functional impact of this exchange, we stably transfected HEK cells with either a wild-type or an R1626Q-mutant $Na_v1.2$ plasmid construct and conducted whole-cell voltage clamping. Several channel parameters were relatively unaffected, including the current-voltage relationship and the voltage dependence of activation, as well as the voltage dependence of both, fast and slow inactivation. Mutant channels, however, tended to require longer hyperpolarization to recover from fast inactivation, and, more clearly, R1626Q channels displayed markedly slowing of the fast inactivation kinetics. These biophysical changes might lead to an overall gain-of-function and augmented excitability, which could, at least partly, underlie the seizures observed in the patient. Rodent modeling will help determine how alterations of ion channel kinetics can affect complex developmental processes to produce a severe, and ultimately, life-incompatible phenotype.

Title: Palmitoylation modifies biophysical properties of voltage-gated sodium channel 1.6.

Authors: *Y. PAN[1,2], Y. XIAO[2], T. R. CUMMINS[2];
[1]IUPUI, Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Palmitoylation has been identified as a reversible post-translational lipid modification that dynamically regulates protein trafficking and membrane association. It was previously shown that brain voltage-gated sodium (Nav) channels are subjected to palmitoylation and Nav1.2 channels exhibit different functional properties in different palmitoylation states. We investigated how palmitoylation modulates the biophysical properties of Nav1.6, one of the most abundant Nav in the central nervous system. Nav1.6 play a major role in neuronal excitability, underlying the initiation and propagation of action potentials. Our aim was to identify palmitoylation sites that potentially can be pharmacologically modified in this channel. We transiently expressed the mouse isoform of Nav1.6 in ND7/23 cell line and performed whole-cell patch clamp. We discovered that interrupting palmitate incorporation with 2-Br-palmitate, a palmitate analog, results in a hyperpolarizing shift of the voltage-dependence of inactivation and slower kinetics of recovery from inactivation in the channel. To identify the palmitoylation sites responsible for these functional alternations, we substituted two cysteines (C1169, C1170), predicted to be palmitoylated in Nav1.6, with alanines and found that the double cysteine mutant exaggerated the hyperpolarizing shift we observed with 2-Br-palmitate treatment, but did not display slower recovery from inactivation. We concluded that 1) the functional properties of Nav1.6 can be regulated by its palmitoylation states; 2) C1169, C1170 in Nav1.6 are potential palmitoylation sites that could be modulated to change channel gating properties and potentially to alter neuronal excitability; 3) palmitoylation at different cysteine residues may exert distinct regulatory effects in channel biosynthesis, membrane association, gating and pharmacological properties.

Title: Modulation of the FGF14:Nav1.6 channel interaction through short peptide-based probes

Authors: *S. R. ALI, Z. LIU, M. NENOV, F. SCALA, T. JAMES, A. SINGH, H. CHEN, J. ZHOU, F. LAEZZA;
Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: Voltage-gated sodium (Nav) channels are responsible for initiation and propagation of action potentials in neurons. Dysregulation of specific Nav channel isoforms is found across a wide range of brain disorders associated with motor and cognitive disabilities. Unfortunately, currently available probes and drugs targeting Nav channels are directed against highly conserved domains of the channels and as such lack specificity. The macromolecular complex of Nav channels is a source of less conserved protein-protein interaction (PPI) interfaces that represent a unique opportunity for the design of potentially novel chemical probes to interrogate the brain circuitry and future more targeted leads to treat Nav channelopathies. The intracellular fibroblast growth factor 14, FGF14, is a biologically relevant component of the neuronal Nav channel complex controlling gating, stability and trafficking of native Nav channels. Through a monomeric interaction with the intracellular C-terminal tail of Nav channel α subunits, FGF14 binds and modulates the activity of Nav channels in an isoform-specific manner. Using molecular modeling and *in silico* docking as guidance, we designed a peptidomimetic fragment based on the FGF14:Nav1.6 interface and validated its activity using a combination on *in vitro* and *ex vivo* assays including the split-luciferase assays surface plasmon resonance and whole-cell patch clamp electrophysiology in heterologous systems and in nucleus accumbens (NAc) acute brain slices. Overall, our data indicate that the newly synthesized peptidomimetic fragment may compete with FGF14 for binding to Nav1.6 channels suppressing neuronal firing in medium

spiny neurons in the NAc. This study will lay ground work for the development of a new class of PPI-based allosteric modulators of Nav channels with potential therapeutic values for a variety of brain disorders.

Ctr., Nijmegen, Netherlands; [4]Dept. of Neurol., Fundacion para el Estudio de las Enfermedades Neurometabolicas, Buenos Aires, Argentina

Abstract: Sodium channel Nav1.9 is preferentially expressed in peripheral nociceptive somatosensory neurons and visceral afferents, and myenteric neurons. Gain-of-function mutations of Nav1.9 have been linked to human painful disorders, including painful peripheral neuropathy and familial episodic pain and in a case of painless channelopathy. Here we report a novel Nav1.9 mutation, an arginine 222 substitution by histidine (R222H) in the domain I S4 segment, identified in a family with episodic pain. The affected family members experienced pain mainly in distal extremities including joints and gastrointestinal disturbances with onset in early childhood, with pain severity diminishing with age (less after 16-18 years). Multistate modeling study suggested that mutation from arginine to histidine disrupts the interactions between this residue and negatively charged residues at physiological pH, which would destabilize the channel's resting and early activation states and favor channel opening. Voltage-clamp analysis demonstrated that the mutation hyperpolarizes channel activation by 6.4 mV compared with wild-type Nav1.9 channels. Current-clamp analysis showed that the R222H mutant channels render dorsal root ganglion neurons hyperexcitable, including depolarized

resting potential, reduced current threshold, increased evoked firing and increased spontaneous firing. Taken together, our observations show that the new gain-of-function mutation in Nav1.9 which can confer hyperexcitability on peripheral sensory neurons underlies episodic pain. This data expands the spectrum of inherited pain disorders related to mutations of sodium channel Nav1.9.

Title: Distinct pre- and postsynaptic localizations of Na_v1 subtypes in rat hippocampus areas CA1 and dentate gyrus.

Authors: *J. PLATHOLI[1], K. JOHNSON[1], K. HEROLD[1], T. MILNER[2], H. C. HEMMINGS, Jr.[1];
[1]Anesthesiol., Weill Cornell Med., New York, NY; [2]Neurosci., Feil Family Brain and Mind Res. Institute, Weill Cornell Med., New York, NY

Abstract: Voltage-gated Na^+ channels (Na_v) initiate and propagate action potentials crucial for neuronal excitability and signal transduction. Plasticity of synapses can be regulated by forward and back-propagating action potentials leading to long-term potentiation (LTP) and long-term depression (LTD) depending on frequency and strength of stimulation. Abnormal Na_v activity is also central to the pathophysiology of epileptic seizures. How Na_v channels mediate excitability for these dual synaptic functions is unclear; cellular and regional differences in Na_v subtype expression and localization could underlie both roles. Axonal and somatodendritic Na^+ currents vary in their gating properties suggesting different subtypes are preferentially localized with distinct physiological functions. Three major subtypes (Na_v 1.1, 1.2, 1.6) are highly expressed in adult mammalian brain, but their neuroanatomical organizations in hippocampal subregions with distinct with layer-specific differences in excitatory and inhibitory inputs are unknown. To delineate differences in Na_v channel expression relevant to their diverse neurophysiological functions, roles in disease and pharmacological effects, we utilized light and electron microscopy to determine the spatial distribution of Na_v 1.1, Na_v 1.2, and Na_v 1.6 in hippocampal subfields of area CA1 and dentate gyrus (DG) in rat. All three subtypes were localized postsynaptically in area CA1 and were associated with asymmetric or excitatory synapses. Interestingly, in the DG

Na_v 1.1 was localized presynaptically, while Na_v 1.2 and Na_v 1.6 showed no preference but all subtypes were also associated with asymmetric synapses.

Title: Structure-function determinants of the FGF14:Nav1.6 channel complex

Authors: ***A. K. SINGH**, S. ALI, F. LAEZZA;
Pharmacol. & Toxicology (MRB Build.), Univ. of Texas Med. Br. (UTMB), Galveston, TX

Abstract: The voltage-gated Na^+ (Nav) channel complex provides the basis for electrical excitability in the brain and has been linked to the etiology of brain-related channelopathies. In native conditions, the Nav channel is regulated by a number of accessory proteins including fibroblast growth factor 14 (FGF14), a member of the intracellular FGFs family. Through protein:protein interactions (PPI) FGF14 controls biophysical properties of Nav1.6-encoded currents such as peak transient current, voltage-dependence of activation, steady-state inactivation and fast inactivation. In previous studies, we used a combination of molecular modeling, split-luciferase assay, and patch-clamp electrophysiology to map and validate critical hot-spots at the FGF14:Nav1.6 channel complex interface. Our results indicate that either the $FGF14^{V160A}$ or the $FGF14^{K74A/I76A}$ mutations are sufficient to abolish FGF14-dependent regulation of peak transient Na^+ currents and voltage-dependence of activation and steady-state inactivation of Nav1.6, but that only V160A with a concomitant alanine mutation at Y158 can impede FGF14-dependent modulation of the channel fast inactivation. Here, we apply biophysical measurements to parse out the structural role of these critical amino acid residues in regulating binding to the Nav1.6 C-tail. Intrinsic fluorescence spectroscopy (IFS), Surface Plasmon Resonance and circular dichroism were used to characterize the binding properties of FGF14 wild type and mutants to the Nav1.6 C-terminal tail. IFS confirmed significant binding

reduction of $FGF14^{V160A}$ to the Nav1.6 C-tail indicating a key role of this residue in mediating PPI. Altogether these studies identify critical structure-function determinants of the macromolecular complex of Nav1.6 channels that might provide guidance for therapeutic development against brain disorders.

Title: Experimental diabetes mellitus preferentially alters the myelinated fibers of the vagus nerve and increases the TTX-S sodium currents of nodose ganglia

Authors: *K. S. SILVA-ALVES[1], F. W. FERREIRA-DA-SILVA[2], T. A. ALVES-FERNANDES[3], A. N. COELHO-DE-SOUZA[3], J. H. LEAL-CARDOSO[3];
[2]Superior Inst. of Biomed. Sci., [1]State Univ. of Ceara, Fortaleza, Brazil; [3]Superior Inst. of Biomed. Sci., State Univ. of Ceará, Fortaleza, Brazil

Abstract: Diabetic neuropathy is the most common diabetes mellitus (DM) complication and can affect many nerves of the organism. The vagus nerve (VN) is the longest cranial nerves and innervates several visceras of the body. Since DM is already known to affects firstly long nerves, this study aimed to investigate the alterations produced by DM on VN and nodose ganglion (GN) neurons. Wistar rats were randomly divided into control (CONT) and diabetic (DB) groups. The DB group was induced by administration of streptozotocin (65 mg/kg, via i.p.) at 8^{th} week of life, while CONT group received solely sodium citrate buffer (vehicle). Rats were sacrificed at the end of 12^{th} week and VN and NG were dissected. The fuction of myelinated and unmyelinated VN axons was evaluated through the extracellular recording of compound action potential (CAP). The patch clamp technique was used to record Na^+ currents from dissociated neurons of

NG. In 12th week, the glycemic level of CONT and DB groups were 112.8 ± 4.0 and 456.9 ± 15.9 mg/dL (n = 22). The CAP of VN myelinated fibers presented 3 distinct waves and the conduction velocities of each in CONT were 32.4 ± 3.6, 13.9 ± 1,4 e 5.4 ± 0.5 m/s and the duration of the 1st and 2nd waves were 0.4 ± 0.1 e 0.5 ± 0.1 ms, respectively. For DB group, there was a reduction of about 50% of conduction velocity (17.6 ± 1.3 and 7.6 ± 0.1 m/s) and an increase of 150% in the duration (1.1 ± 0.3 and 1.4 ± 0.3 ms) of the 1st and 2nd CAP components compared to the CONT group. For VN unmyelinated fibers in DB group there were no alterations in the conductibility and excitability parameters but when challenged with tetrodotoxin (TTX), VN unmyelinated fibers become more sensitive. The IC_{50} for 2nd and 3rd waves in CONT were 979.5 ± 30.6 and 879.2 ± 20.2 nM and for DB group were 662.8 ± 104.3 e 718.2 ± 179.8 nM. The patch clamp recording in dissociated neurons of NG showed an increase in normalized amplitude of total Na^+ current (INa^+) from 71.0 ± 8.3 in CONT to 113.4 ± 16.7 pA/pF (n = 11) in DB group. There was a shift of ~ 10 mV to hyperpolarized potentials in Na^+ current activation and steady state inactivation curves. Voltage separation of total INa^+ in their sensitive (TTX-S) and resistant (TTX-R) components, showed that only TTX-S INa^+ conductance was increased in DB group neurons from 39.0 ± 3.9 pA/pF in CONT to 115.7 ± 20.9 pA/pF (n = 8) in DB group. In conclusion, streptozotocin-induced DM preferentially alters myelinated fibers of VN, increases the amplitude and conductance of total INa^+ and INa^+ TTX-S of NG. Also, there was a shift in voltage-dependence of activation and inactivation curves and these changes in Na+ current in NG partially explain the alteration seen in VN fibers.

Title: The persistent sodium current increases near-threshold input resistance and membrane time constant via a negative slope conductance

Authors: *C. C. CEBALLOS[1], A. C. ROQUE[1], R. M. LEAO[2];
[1]Dept. of Physics, Univ. of São Paulo, Ribeirao Preto, Brazil; [2]Dept. of Physiol., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: A change of the input resistance (R_{in}) of the neuron involves a change in the membrane conductances by opening and closing of ion channels. In passive membranes, i.e., membranes with only linear leak conductances, the increase or decrease of these conductances leads to a decrease or increase of the R_{in} and the membrane time constant (τ_m). However, the presence of subthreshold voltage dependent currents can produce non-linear effects generating deviations from this relationship, especially the contradictory effect of negative conductances, as produced by the sodium-persistent current (I_{NaP}), on the R_{in}. In this work we aimed to analyze experimentally and theoretically the impact of the negative conductance produced by I_{NaP} on R_{in}. Experiments of whole-cell patch-clamp conducted in CA1 hippocampus pyramidal cells from brain slices showed a paradoxical voltage-dependent decrease of the R_{in} and the τ_m in subthreshold membrane potentials close to the firing threshold after the perfusion with TTX, which inhibits I_{NaP}. This effect is postulated to be a result of the negative slope conductance in the subthreshold region produced by this conductance. The analysis of the experimental data, together with simulations found that the slope conductance of I_{NaP} is negative for subthreshold membrane potentials and its magnitude is voltage dependent in the same range observed for the voltage-dependence of R_{in} and τ_m. The injection of an artificial I_{NaP} using dynamic-clamp in the presence of TTX restored the R_{in} and τ_m to its original values. Additionally the injection of an artificial leak current with a negative conductance in the presence of TTX restored the R_{in} and τ_m as the artificial I_{nap} did. On the other hand, the injection of an artificial leak current with a positive conductance in the presence of TTX had no effect on the R_{in} and τ_m. We conclude that I_{NaP} increases the R_{in} and τ_m by the negative slope conductance observed in its non-monotonic I-V relationship. These results demonstrate that the effect of I_{nap} on R_{in} and τ_m is stronger in potentials near the firing threshold, which could potentiate the temporal summation of the EPSPs increasing their temporal integration and facilitating action potential firing. Because of its negative slope conductance, I_{NaP} is more effective in increasing excitability near threshold than a depolarizing leak current.

Title: Pyrethroid insecticide effects on spontaneous electrical activity in neural networks are consistent with effects on voltage gated sodium channels (VGSCs) and dependent on time, concentration, and structure

Authors: J. D. STRICKLAND[1,2], C. GRANT[4], J. ROSS[1], *W. D. ATCHISON[3], T. J. SHAFER[4];
[1]Axion Biosystems, Atlanta, GA; [3]Dept Pharmacol & Toxicol, [2]Michigan State Univ., East Lansing, MI; [4]US Envrn. Protection Agency, Research Triangle Park, NC

Abstract: Pyrethroid (PYR) insecticides are used in a wide range of commercial products to control insect pests. They induce insecticidal and toxicological effects by disrupting VGSC kinetics thus altering neural excitability. Effects on VGSC function are related to the presence or absence of a cyano group on the PYR. Previous studies examined effects of 2 PYRs, deltamethrin and permethrin, on neural network function. However, characterization of effects on network function by other PYRs is lacking, and examination of changes across time and concentration are limited. Here, changes in spontaneous neural network function following exposure to 13 PYRs and 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (p,p'-DDT) were monitored over 10 min intervals for 40 min using multi-well microelectrode array (mwMEA) plates. Baseline activity (40 min) of mixed cultures (neurons and glia) from rat cortex on mwMEAs was recorded prior to exposure to non-cytotoxic concentrations (0.03-40 μM) of PYRs. After 40 min, all compounds except allethrin decreased neural network mean firing rates (MFR) at 40 μM. However, effects on MFR were time- and concentration-dependent, and generally aligned with chemical structure. Cyano-containing (deltamethrin, β-cyfluthrin, fenpropathrin, esfenvalerate, cypermethrin) PYRs generally decreased MFR in a time-dependent manner, completely inhibiting MFR at 40 μM. Resmethrin, permethrin, allethrin, bifenthrin, tetramethrin, prallethrin, and p,p'-DDT, which lack a cyano group, generally increased MFR in a time- and concentration-dependent manner to 2-3 fold over control values at 3-10 μM. Increases in MFR were either present at 0-10 min (bifenthrin, permethrin, prallethrin, and p'p'-DDT) or at 20-30 min (tetramethrin, allethrin, S-bioallethrin, and resmethrin). Tefluthrin, which lacks a cyano group, caused a response similar to cyano-containing compounds. Further, although they decreased MFR at higher concentrations, esfenvalerate (0.1-0.3 μM) and cypermethrin (0.3-1.0 μM) also increased MFR 2-3 fold. The results demonstrate that PYR effects on neural networks are both time- and concentration-dependent, and differ based on the presence of a cyano group, consistent with their effects on VGSCs (This abstract does not reflect EPA policy.)

Title: Effect of dietary salt intake on ENaC in vasopressin synthesizing neurons in the rat supraoptic nucleus

Authors: *K. SHARMA, M. HAQUE, R. GUIDRY, R. TERUYAMA;
Biol. Sci., Louisiana State Univ., Baton Rouge, LA

Abstract: An accumulating body of evidence suggests that epithelial Na^+ channels (ENaCs) in the brain play a significant role in the regulation of blood pressure. All three ENaC subunits (α, β, and γ) were demonstrated in vasopressin (VP) synthesizing magnocellular neurons in the hypothalamic supraoptic (SON) and paraventricular nuclei, indicating ENaC affects blood pressure by modulating VP release. Our previous study showed that ENaC mediates a Na^+ leak current that affects the steady state membrane potential of VP neurons. The present study was conducted to assess the effect of dietary NaCl intake on ENaC regulation and activity in VP neurons. Male rats were fed either a high NaCl, a NaCl deficient diet, or a control diet for 7-10 days, and the relative difference in ENaC subunit mRNAs in the SON was assessed by real-time RT-PCR. A high NaCl diet caused a significant increase in β- and γENaC mRNAs in the SON, while expression of αENaC did not change. A change in the subcellular distribution of αENaC immunoreactivety in magnocellular neurons in response to dietary NaCl intake was also observed using confocal microscopy. The labeling in the magnocellular neurons from the high NaCl diet group was distinctively concentrated towards the plasma membrane in all rats tested, while those from the NaCl deficient and control groups were mainly dispersed in the cytoplasm with no distinct labeling at the plasma membrane. These findings imply that high dietary NaCl intake induces not only gene expression of ENaC subunits, but also translocation of ENaC to the plasma membrane. Electrophysiological experiments were performed to assess the effect of dietary salt intake on ENaC activity in VP neurons. The ENaC current was obtained from the difference in the steady state currents before and after the application of the ENaC blocker, benzamil. The mean amplitude of whole-cell ENaC currents and the current density were significantly larger in VP neurons from the high NaCl diet group than those from the control diet group. Collectively, these findings suggest that the regulation and activity of ENaC in VP neurons are modulated by dietary salt intake. Moreover, the modulation of ENaC in VP neurons in response to dietary salt intake is likely to have a significant contribution to the regulation of blood pressure.

Title: system xc (xct) glutamate transport is dynamically regulated in glioma cells

Authors: ***L. WANG**[1], Y. ZHOU[1], N. JIA[1], Q.-F. LU[1], T.-T. SHI[1], Z.-Q. WANG[1], B. R. RANSOM[2], Z. YE[2];
[1]Ctr. for Neurosci. Res., Fujian Med. Univ., Fujian, China; [2]Neurol., Univ. of Washington, Seattle, WA

Abstract: Glioma cell lines may exhibit significant differences in glutamate transport and metabolism. For example, some glioma cells can transition between net glutamate release and net glutamate uptake. Net glutamate transport is determined by the balance of glutamate release and glutamate uptake, and the two main systems for these opposed functions are EAAT1-mediated glutamate uptake and system Xc (xCT)-mediated glutamate release. System Xc exchanges cystine and glutamate, and normally exports glutamate. In contrast, EAAT1 is a Na^+-dependent glutamate transporter and normally imports glutamate. The variability seen in glutamate management in glioma cells related to changes in both xCT and EAAT1. We found that xCT expression was highly variable among glioma cell lines. Expression and function further varied due to other factors including cell density (cell-cell contact),and culture medium pH. Intracellular redox status and PKC activity levels played key roles in regulating expression of both EAAT1 and xCT. While PKC activation (by PMA) inhibited EAAT1 expression, it dramatically increased xCT mRNA transcription and increased the expression of xCT and related proteins. Exposure to N-acetylcysteine (NAC) increased EAAT1 expression while it simultaneously decreased xCT expression, thus facilitating the conversion from net glioma cell glutamate release to net glutamate uptake. Redox status and glutamate handling status also significantly affected glutathione (GSH) levels and GSH synthetic enzymes. Our results indicated complex and bi-directional regulation of xCT and EAAT1 expression and function in glioma cells. These factors may prove important in refining clinical management of gliomas.

Title: Neuroprotective properties of novel positive allosteric modulators of EAAT2

Authors: R. FALCUCCI, O. MEUCCI, J. M. SALVINO, *A. C. FONTANA;
Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Excitatory amino acid transporters (EAATs) play a crucial role in the removal of synaptic glutamate to maintain extracellular concentrations below excitotoxic levels. Glutamate-mediated excitotoxicity has been associated with a number of diseases/conditions, including traumatic brain injury (TBI), stroke, Amyotrophic Lateral Sclerosis, HIV-associated neurocognitive disorders (HAND) among others. Compounds that increase the activity of EAAT2, the major glutamate transporter in the brain, could have therapeutic potential for neuroprotection. Previous work has identified molecular determinants implicated in EAAT2 transport stimulation. Additionally, a hybrid structure based approach has identified selected hit structures that interact with this region. Some of these novel compounds were shown to be selective positive allosteric modulators (PAMs) of the function of EAAT2, in glutamate transport assays in transfected COS-7 cells and in glial cultures. In this work, we have characterized the effects of novel PAMs of EAAT2 in a bilaminar culture model, in which rat cortical neurons are cultured in the presence of a glial feeder layer. To examine potential neuroprotective effects of these PAMs, cultures were subjected to excitotoxic and oxidative stress insults. Specifically, excitotoxic insults were performed with the application of 1, 10, 50 or 100μM L-glutamate, and oxidative stress with the application of 10, 50 or 100μM H_2O_2. Prolonged insults were carried out for 24 h, while acute insults were carried on for 20 min, in the presence or absence of a glial layer. Compounds were applied after the insults and neuronal survival was assessed by MAP-2 staining 24 h after the treatments. Our results indicate that the PAMs are neuroprotective in several conditions, including prolonged and acute excitotoxic insults, but not in oxidative stress conditions. Future directions include determining the *in vitro* therapeutic window of the PAMs, and the examination of the PAMs in other *in vitro* models, including oxygen-glucose deprivation and traumatic brain injury (stretch injury), among others. We also aim to profile these PAMs for ADME/ drug-like properties to assess potential neuroprotection in in *in vivo* neuroprotection studies. In conclusion, these novel PAMs of EAAT2 have neuroprotection potential for translation in *in vivo* neurological diseases and conditions.

Title: Lack of interaction between aquaporin-4 (AQP4) and glutamate transporter-1 (GLT1)

Authors: *J. A. HUBBARD, D. K. BINDER;
Ctr. for Glial-Neuronal Interactions, Div. of Biomed. Sci., Univ. of California, Riverside, Riverside, CA

Abstract: Aquaporin-4 (AQP4) and glutamate transporter-1 (GLT1) are astrocyte-specific molecules that regulate water and glutamate homeostasis, respectively. AQP4 modulates bidirectional fluid movement in response to osmotic gradients and GLT1 is responsible for the majority of glutamate uptake in the brain. It has been reported that AQP4 knockout ($AQP4^{-/-}$) mice have reduced levels of GLT1 and, consequently, slowed glutamate uptake (Zeng *et al.*, 2007). This finding has been used to explain altered neurobiological differences in $AQP4^{-/-}$ mice, including increased neuronal activity and impaired long-term potentiation (Szu and Binder, 2016). If GLT1 levels are reduced in $AQP4^{-/-}$ mice, then they may physically interact with one another. We therefore wanted to (1) determine if there is a physical interaction between AQP4 and GLT1 and (2) define GLT1 protein levels in $AQP4^{-/-}$ mice. We used co-immunoprecipitation, Western blot, and immunohistochemistry in both CD1 and C57 wild-type and $AQP4^{-/-}$ mice. We found that GLT1 does not co-immunoprecipitate with AQP4. Furthermore, GLT1 protein levels were not altered in the CD1 or C57 $AQP4^{-/-}$ mice brains compared to their wild-type counterparts. Finally, the immunoreactivity expression patters of GLT1 and AQP4 were drastically different and these two molecules only occasionally co-localized. Therefore, GLT1 and AQP4 likely do not physically interact and a reduction in GLT1 expression cannot explain the altered neurobiology observed in $AQP4^{-/-}$ mice.

Title: Clinical and central outcomes of peripheral inflammation: what is the role of system xc-?

Authors: *G. ALBERTINI[1], L. DENEYER[1], N. AOURZ[1], E. BENTEA[1], T. DEMUYSER[1], L. VERBRUGGEN[1], H. SATO[2], D. DE BUNDEL[1], A. MASSIE[1], I. SMOLDERS[1];
[1]Vrije Univ. Brussel, Brussel, Belgium; [2]Niigata Univ., Niigata, Japan

Abstract: A variety of pathological stimuli is able to induce systemic inflammation. When systemic inflammation occurs, soluble mediators released from peripheral immune cells are able to reach the central nervous system (CNS) leading to defective brain homeostasis and activation of central immune cells, further exacerbating brain inflammation. Moreover, peripheral inflammation also leads to acute and chronic effects on cognition and behavior. System xc-, with xCT as specific subunit, exchanges intracellular glutamate for extracellular cystine and is the main source of extracellular glutamate in mouse hippocampus and striatum. *In vitro*, it has been shown that several pro-inflammatory stimuli increase the expression of xCT. Besides leading to excessive release of glutamate, increased expression and/or activity of system xc- can directly influence microglia phenotypes towards a pro-inflammatory/neurotoxic state. Modulation of system xc- could therefore be beneficial in inflammation-related disorders in two ways: attenuate the glial release of toxic amounts of glutamate and directly influence microglial polarization towards a protective phenotype. In this study we induced peripheral inflammation via a single injection of 5 mg/kg bacterial lipopolysaccharide (LPS) i.p. and we sought to: i) investigate the consequences of peripheral inflammation on glutamate transporters, ii) unveil the central effects of peripheral inflammation in xCT+/+ and xCT-/- mice and iii) evaluate if deletion of xCT dampens acute clinical implications induced by peripheral inflammation. We demonstrated that LPS strongly impairs glutamate homeostasis *in vivo* leading to significant changes in xCT and GLT1 glutamate transporter protein expression levels in the hippocampus 1 week p.i. Those changes may potentially trigger enhanced hyperexcitability and neuronal death due to toxic extracellular levels of glutamate. We observed that in xCT-/- mice several LPS-induced clinical implications, such as hypothermia, depressive-like behavior in the forced swim and tail suspension tests and increased seizure susceptibility in the pentylenetetrazole model, were

significantly attenuated. Our results highlight the importance of system xc- under inflammatory conditions and bring us one step closer in better understanding its potential relevance in neurological disorders characterized by neuroinflammation.

Title: Resolution of an anion permeation pathway in glutamate transporters using molecular dynamics simulations and cysteine-scanning analysis.

Authors: ***D. TORRES-SALAZAR**[1], M. H. CHENG[2], A. A. D. GONZALEZ-SUAREZ[1], S. G. AMARA[1], I. BAHAR[2];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Excitatory amino acid transporters (EAATs) maintain extracellular glutamate homeostasis in the brain by clearing glutamate through a coupled transport mechanism. They also work as substrate-gated anion channels. In the last decade, structure-function data have advanced our understanding of the substrate transport mechanism. Less is known regarding the structural features responsible for anion permeation. A recent study by Machtens *et al.* combining molecular dynamics (MD) simulations and electrophysiology elegantly showed that channel opening occurs during transitions from intermediate conformations tightly coupled to the transport cycle, an observation that we recently corroborated using different approaches. In addition, they identified a series of residues likely to contribute to the permeation pathway. Here, using molecular modeling and trajectory analysis tools, we visualize the asymmetric transition of substrate-loaded Glt_{Ph}, an archaeal ortholog of the EAATs, into a conformation where one of the subunits assumes an intermediate structure, and we identify a chloride channeling pore intermittently formed at the interface between the trimerization and transport domains of that subunit. The minimum pore size at its constriction zone is around 2.4 Å, close to the value in the

crystal structure of an open chloride channel. The constriction zone is lined by hydrophobic residues (e.g. F50, V51 and L212 in Glt_{Ph}), in broad agreement with those proposed by Machtens *et al*. We have now extended these findings to confirm this permeation pathway in a human isoform (EAAT1) using the substituted cysteine accessibility method. In oocytes expressing several single cysteine substitutions at residues predicted to be within the pathway, we observe an approximately 50% reduction in the macroscopic current amplitude after application of MTSES, a negatively charged sulfhydryl-reactive reagent. We observed comparable results with MTSACE, a similar, but non-charged reagent, ruling out that the observed current reductions were caused by electrostatic interactions. Moreover, our results consistently show that most of the modifications that affect anion permeation do not affect transport currents or glutamate uptake, indicating that substrate translocation is not altered by these modifications. Our results here corroborate a well-defined and evolutionary conserved anion permeation pathway formed mostly by residues in TM2 and TM5. In addition, we demonstrate that despite the well stablished tight coupling between anion channel gating and the transport cycle, anion permeation occurs through a pore independent of the substrate translocation pathway.

Title: AAV-mediated upregulation of GLT-1 does not prevent cocaine relapse

Authors: *C. N. LOGAN, L. A. KNACKSTEDT;
Psychology Dept., Univ. of Florida, Gainesville, FL

Abstract: Cocaine addiction is a serious and highly prevalent issue in the United States. Cocaine addiction treatments are complicated by high rates of relapse after treatment. Animal models of relapse such as the operant self-administration extinction reinstatement paradigm can be used to study relapse prevention. In this model the operant response is extinguished and then reinstated using cues previous paired with the cocaine stimulus during self-administration or a dose of the stimulus drug itself. Previous research has shown several neurobiological changes occur in the nucleus accumbens with repeated exposure to cocaine such as the dysregulation of extracellular

nonsynaptic glutamate, downregulation of the cystine-glutamate exchanger and downregulation of GLT-1 transporters. Along with these alterations in the nucleus accumbens, an increase in synaptically released glutamate has been shown to play a role in reinstatement to drug seeking behaviors. The antibiotic ceftriaxone has been shown to upregulate the cystine-glutamate exchanger, upregulate GLT-1 transporters and restore glutamate homeostasis after cocaine use, ultimately preventing reinstatement of drug-seeking behaviors. In efforts to attempt to narrow down which neurobiological alteration from ceftriaxone leads to the prevention of reinstatement of drug seeking behaviors, we used an adeno-associated virus (AAV) to upregulate GLT-1 transporters to investigate whether this would prevent reinstatement of drug seeking. The animals received AAV-GFAP-GLT1 into the nucleus accumbens immediately after the conclusion of two weeks of cocaine self-administration. The animals then underwent three weeks of extinction training before undergoing a cue-primed reinstatement test. In a separate group of animals, prior to drug- and cue-primed reinstatement testing, the animals were probed with microdialysis cannula to enable us to measure glutamate levels. In the presence of AAV-mediated GLT-1 upregulation, animals reinstated cocaine-seeking. These results indicate that ceftriaxone likely induces other protective adaptations in addition to the upregulation of GLT-1 transporters to prevent the reinstatement of cocaine-seeking.

Title: Role of pkc signaling in glioma cells: glutamate transport and metabolism

Authors: *Y. ZHOU[1], R.-Y. LIN[1], Q.-F. LU[1], N. JIA[1], Z.-Q. WANG[1], L. WANG[1], B. R. RANSOM[2], Z. YE[2];
[1]Fujian Med. Univ., Fujian, China; [2]Neurol., Univ. of Washington, Seattle, WA

Abstract: The transport and metabolism of glutamate in glioma cells is surprising flexible. We reported earlier that under proper circumstances, glioma cell glutamate release could reverse direction and become net glutamate uptake, a phenomenon we termed ‘glioma glutamate release reversal’ or GGRR. GGRR has been observed in several human glioma cell lines. The major mechanism of GGRR appears to be dramatic up-regulation of EAAT1 membrane expression that

converts net glutamate release into net glutamate uptake. However, the signaling mechanisms responsible for GGRR remain unknown. We now report that PKC signaling plays a pivotal role in regulating GGRR in a manner significantly different from PKC's role in normal astrocytes. PKC activation by PMA blocks GGRR. Activated PKC eliminated EAAT1 expression, thus preventing GGRR. In addition to decreasing the stability of EAAT1 on glioma cell membranes, PMA treatment inhibited the transcription of EAAT1 mRNA as measured by qPCR. The PMA effect on EAAT1 was completely blocked by the PKC antagonist GF109203X. Besides PMA, other factors activated PKC and negated GGRR. For example, ouabain at nanomolar concentration caused PKC activation and could act synergistically with PMA.

Title: Conditional deletion of the glutamate transporter GLT-1 in dopaminergic neurons attenuates amphetamine-induced behavioral activation

Authors: ***P. A. ROSENBERG**[1], K. D. FISCHER[1], A. C. W. HOUSTON[1], M. MIAN[1], N. W. HODGSON[1], M. R. DOYLE[2], R. I. DESAI[2], J. BERGMAN[2], A. BECHTHOLT[3], S. CHOI[4], D. L. SULZER[4], E. V. MOSHAROV[4], T. CHOWDHURY[5], A. SHERPA[5], C. AOKI[5];

Hosp., Belmont, MA; [3]Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [4]Neurol., Columbia Univ., New York, NY; [5]New York Univ., New York, NY

Abstract: GLT-1 is the major glutamate transporter in the brain, and is primarily expressed in astrocytes. Although we and others have demonstrated GLT-1 protein expression in excitatory terminals, its function in this location remains unknown. We generated a conditional GLT-1 knockout and inactivated GLT-1 in neurons using synapsin-Cre (synGLT-1 KO). We previously reported [Petr et al., (2015) *J Neurosci.* 35: 5187; Fischer et al., *SfN Abstract* 127.17, (2014); Fischer et al., *SfN Abstract* 386.01, (2015)] that although basal functions, including locomotion, were normal, synGLT-1 KO mice show a blunted locomotor response to acute and chronic administration of amphetamine (AMP). In the present work, we wanted to determine the neuronal type in which deletion of GLT-1 produces a damped response to AMP. Targeted inactivation of GLT-1 specifically from dopamine (DA) neurons using DAT-Cre mimicked the effect of synapsin-cre driven inactivation of GLT-1 on the acute (27% reduction) and sensitized (38% reduction at challenge) locomotor response to AMP. Control experiments showed no effects on responses to AMP of DAT-Cre expression. These observations provide genetic evidence for the expression of GLT-1 in dopamine neurons. Using dual electron microscopy immunocytochemistry (EM-ICC) to detect GLT-1 in axons expressing tyrosine hydroxylase (TH), we found that GLT-1 was co-expressed with TH within DA axons in the NAc shell. Our behavioral and EM results suggested that GLT-1 expressed in DA neurons may promote DA signaling by a vesicular synergy mechanism: GLT-1 might provide the substrate for vGLUT2 mediated transport of glutamate into DA vesicles. However, we found no change in AMP stimulated extracellular DA in the NAc shell by microdialysis, no change in electrically stimulated or AMP-induced DA release in slices using cyclic voltammetry, and no change in DA tissue content. These data suggest that the AMP resistance phenotype in the synGLT-1 KO is unlikely to be due to vesicular synergy or other presynaptic mechanisms. An alternative explanation (see Rimmele et al., poster this meeting) is a change in the expression of proteins involved in DA signaling. Other explanations are possible and will be explored. In summary, genetic and ultrastructural evidence suggests that GLT-1 is expressed in DA neurons, and, in this location plays an important, yet uncharacterized role, in the behavioral response to AMP. Given the significance of AMP as a drug of abuse, and of the AMP sensitized state as a model for the positive features of schizophrenia, it becomes critical to understand the mechanisms underlying the involvement of neuronal GLT-1 in the cellular and circuit effects of AMP.

Title: Expression of the EAAT2 glutamate transporter in axon-terminals is more widespread than previously recognized

Authors: *Y. ZHOU, N. DANBOLT;
Inst. of Basic Med. Science, Univ. of Oslo, Oslo, Norway

Abstract: It has been clear since the 1970s that both astrocytes and neurons express glutamate transporters, but the relative contribution of neuronal and glial transporters to the total glutamate uptake activity has been hotly debated ever since. There are five glutamate transporter subtypes (EAAT1-5) in the mammalian CNS. EAAT2 (GLT-1; slc1a2), which is the most important, is predominantly expressed in astroglia although functional EAAT2 protein has been detected in axon-terminals of CA3 hippocampal pyramidal cells and of retinal bipolar cells. However, EAAT2 mRNA is more widespread being detected in most neurons albeit at low levels. Here we investigated whether there is EAAT2 expression in other neuron populations as well. To do this, we generated mice where EAAT2 was selectively deleted in neurons. This was done by crossing our EAAT2-flox mice (B6.Cg-Slc1a2$^{tm1.1Ncd}$/J; Stock no. 026619; Jackson Laboratory; Zhou et al., 2014 J Biol Chem 289:1329-44) with synapsin I-Cre mice (B6.Cg-Tg(Syn1-cre)671Jxm/J; Stock no. 003966; Jackson Laboratory). We then prepared crude synaptosome containing homogenates from various brain regions. Deletion of EAAT2 in neurons did not affect uptake of GABA and did not cause significant reductions in total tissue content of EAAT2 protein as determined by immunoblotting. However, glutamate uptake activity was reduced to about half in synaptosomes from the hippocampus, neocortex, striatum and thalamus. We next tested the efficiency of the synapsin I-Cre driver by crossing these mice with Ai9 reporter mice (B6; 129S6-Gt(ROSA)$^{26Sortm9(CAG-tdTomato)Hze}$/J; Stock no. 007905; Jackson Laboratory). Cells in the latter mice turn red when Cre is expressed. To our surprise Cre had not been expressed in a substantial numbers of neurons. This means that EAAT2 was still present in many of them and that the measured reductions in uptake activities represent underestimations of the true contributions of neuronal EAAT2.

Title: Analysis of effects by repetitive Transcranial Magnetic Stimulation (rTMS) on glutamate transporters, GABA tranporters and glycine transporters on the mouse brain

Authors: ***T. IKEDA**[1,2], N. NUKINA[3,2];
[1]Kochi Univ., Kpchi, Japan; [2]RIKEN, Wake, Japan; [3]Doshisha Univ., Kyoto, Japan

Abstract: rTMS is a noninvasive technique to induce electric current in the brain and is supposed to be beneficial for the treatment of patients with depression, schizophrenia and neurodegenerative disorders. We reported previously that rTMS modulates monoamine tranporter. However, the mechanisms underlying the effects of rTMS are still unclear. We analyzed the changes in mRNA expression in mouse brain that occurred after rTMS with real time PCR. Following 20days of rTMS, many genes were differentially expressed in the mouse brain. Up-regulation of Glutamate transporters (EAAT4, GLAST and GLT1), GABA tranporters (GAT1 and GAT4) and Glycine transporters (GYLT1 and GLYT2) mRNA expression levels were observed. GRP78 (Bip) mRNA expression levels were up-regulated after transient and chronic rTMS. In PC12 cells, an up-regulation of GRP78 (Bip) mRNA and subsequent cell-protective effects were observed after acute and chronic rTMS. These results indicated that the modulation of several genes may be involved in the therapeutic mechanisms of acute and chronic rTMS for patients with neuropsychiatric disorders.

Title: Neuronal EAAT2b expression alters excitatory synaptic transmission

Authors: *S. M. O'DONOVAN[1], M. L. BACCEI[2], R. E. MCCULLUMSMITH[1];
[1]Psychiatry and Behavioral Neurosci., [2]Anesthesiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: The excitatory amino acid transporter (EAAT2) is expressed primarily on astrocytes and is responsible for the buffering and transport of over 90% of glutamate from the synapse. Reduced expression of the glutamate transporter EAAT2 is found in several neurocognitive disorders including schizophrenia. EAAT2 localization can significantly impact glutamatergic signaling and transport function. Altered localization of astrocytic EAAT2 shapes excitatory postsynaptic current (EPSC) kinetics and contributes to the regulation of glutamatergic synaptic transmission by controlling the concentration of glutamate at the synapse. Multiple variants of EAAT2 have been identified. EAAT2b has an alternate 11-amino acid long C-terminus which contains a PDZ binding domain. The unique structure of EAAT2b allows for highly regulated localization of the transporter at the synaptic membrane. In schizophrenia, we have found increased expression of the primarily astrocytic EAAT2b in enriched populations of thalamic relay neurons and pyramidal neurons in the anterior cingulate cortex (ACC). We hypothesize that EAAT2b overexpression in pyramidal neurons will increase neuronal glutamate uptake and accelerate decay of EPSCs, diminishing NMDAR activation. These studies will identify the effects of aberrant neuronal EAAT2b expression on glutamatergic signaling within a brain region known to be important for cognitive function, supporting a working model of synaptic dysfunction in chronic schizophrenia. Sprague-Dawley rats will receive an intracerebral injection of AAV1-synapsin-GFP-EAAT2b or control vector AAV1-synapsin-GFP into prelimbic cortex at 7-weeks old. Two weeks after injection, coronal slices (300 μm) will be cut on a vibrating microtome and whole-cell patch clamp recordings of GFP-labelled pyramidal neurons in the prelimbic cortex will be obtained at physiological temperatures. Spontaneous EPSCs (sEPSCs) mediated by AMPARs will first be recorded (from a holding potential of -70 mV) in these EAAT2b-overexpressing pyramidal cells to determine the effect of increased EAAT2b expression on glutamatergic transmission. sEPSC amplitude (pA), frequency (Hz), rise times (ms) and decay times (ms) will be compared between the AAV1-synapsin-GFP-EAAT2b and control groups. In summary, our results will offer insight into the role of enhanced neuronal

EAAT2b in disease states and contribute to our understanding of its effects on glutamatergic synaptic transmission, simulating changes observed in schizophrenia in an effort to understand the consequences of aberrant localization of this glutamate transporter splice variant in the brain.

Title: Biochemical phenotyping of the neuronal GLT-1 knockout mouse

Authors: *T. S. RIMMELE[1], K. D. FISCHER[1], R. B. LAPRAIRIE[2], E. M. DENOVAN-WRIGHT[2], P. A. ROSENBERG[1];
[1]Dept. of Neurol. and the F.M. Kirby Neurobio. Ctr., Boston Children's Hosp., Boston, MA;
[2]Dept. of Pharmacol., Dalhousie Univ., Halifax, NS, Canada

Abstract: To reveal cell-type-specific functional roles of the brain's major glutamate transporter, GLT-1, we generated a conditional GLT-1 knockout mouse with which to inactivate GLT-1 in neurons using synapsin-Cre (synGLT-1 KO) and in astrocytes using inducible human GFAP-CreERT2 [Petr et al., (2015) *J Neurosci.* 35: 5187]. We found that GLT-1 in astrocytes protects against fatal epilepsy, whereas the loss of neuronal GLT-1 significantly diminishes glutamate uptake into synaptosomes. As previously reported [Fischer et al., *SfN Abstract* 127.17, (2014); Fischer et al., *SfN Abstract* 386.01, (2015)], we sought to understand the functional significance of GLT-1 expression in neurons and discovered that pan-neuronal GLT-1 knockout resulted in a phenotype of amphetamine (AMP) resistance. We used Cre-drivers to determine whether this phenotype could be associated with a specific population of neurons, and found that dopamine transporter (DAT)-Cre driven deletion of GLT-1 specifically in dopamine (DA) neurons

replicated the phenotype of pan-neuronal knockout of GLT-1 (see poster this meeting). In that study, we found no evidence for a change in DA dynamics, arguing against an effect on vesicular synergy or other presynaptic mechanisms. Another possibility we considered was that there might be a constitutive change in expression of genes involved in DA signaling in the synGLT-1 KO causing a change in response to AMP. Using gene microarray to assay changes in gene expression in the striatum, we found no changes of expression attained at a significance level of $p<0.01$; however, there was a suggestion of a decrease in D1 receptor expression and DARPP-32 (Ppp1r1b) in the synGLT-1 KO mice at the $p<0.05$ level. Using *in situ* hybridization we detected decreased D2 receptor expression in the prefrontal cortex of 12 week old synGLT-1 KO mice compared to WT (12.2 ± 1.2 in WT, 3.2 ± 0.9 in synGLT-1 KO, $p<0.01$), but no changes in other brain areas or in D1 receptor expression. No change in D2 receptor expression was found in 6 week old synGLT-1 KO mice. In summary, we have obtained evidence that postsynaptic changes in DA receptors, in particular in D2 receptors, occur in the synGLT-1 KO. This downregulation of D2 receptors might contribute to the phenotype of AMP resistance seen in this mutant. Other possible mechanisms underlying the observed phenotype include mGluR modulation of DA release or reduced glutamate signaling by DA neurons.

Title: Pre- and postsynaptic changes at excitatory synapses in xCT deficient mice

Authors: *A. MASSIE[1], E. BENTEA[1], C. MOORE[2], M. J. CHURCHILL[2], R. L. HOOD[2], L. DENEYER[1], L. VERBRUGGEN[1], H. SATO[3], C. K. MESHUL[4];
[1]Vrije Univ. Brussel, Brussels, Belgium; [2]Veterans Affairs Med. Ctr., Portland, OR; [3]Niigata Univ., Niigata, Japan; [4]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: System xc- is a plasma membrane amino acid antiporter, of mainly glial origin, that couples the import of cystine with the export of glutamate. System xc- (specific subunit xCT) contributes substantially to ambient extracellular glutamate levels in various regions of the brain, including the striatum and hippocampus. Despite the fact that system xc- is highly expressed in the brain and is a proposed therapeutic target for various neurological disorders, including Parkinson's disease, Alzheimer's disease, multiple sclerosis and epilepsy, its function under physiological conditions in the central nervous system remains poorly understood. By acting as a source of glial extrasynaptic glutamate, system xc- might modulate synaptic transmission as a mechanism of neuro-glial communication. Previous electrophysiological findings indicate that system xc- delivered glutamate can inhibit excitatory synaptic neurotransmission in the cortico-accumbens pathway (Moran et al. J Neurosci. 2005; 25:6389-93) and at hippocampal CA3-CA1 synapses (Williams et al. J Neurosci. 2014; 34:16093-102). In order to gain further insight into the proposed function of system xc- as modulator of synaptic transmission, we carried out single section electron microscopy analyses of excitatory axospinous synapses at the level of the dorsolateral striatum and motor cortex of adult xCT knockout (xCT-/-) and xCT wildtype (xCT+/+) mice. Our findings accommodate the hypothesis that system xc- negatively modulates neurotransmission, as morphological changes in the excitatory synapses in the dorsolateral striatum of xCT-/- mice reflect increased synaptic activity. In particular, we could observe depletion of glutamate immunogold labeling from presynaptic terminals of xCT-/- mice, an increase in the head diameter and area of spines contacted by asymmetric synapses, an increase in the length, thickness and area of the postsynaptic density, an increased occurrence of spinules, and an increase in the average area of synaptic vesicles. The ultrastructural changes observed in xCT deficient mice suggest the involvement of both presynaptic and postsynaptic forms of synaptic strength regulation via system xc-. In the future we would like to extend our findings on excitatory synapses in the motor cortex, as well as evaluate the expression of AMPA and NMDA receptor expression as a possible contributor to the increased size of the postsynaptic density in xCT deficient mice. Together, these findings shed new light on the re-organization of the glutamatergic system after genetic deletion of system xc-, and confirm the involvement of this antiporter in the control of synaptic strength *in vivo*.

Title: The trace amine receptor 1 and amphetamine induced internalization of the dopamine and glutamate transporters

Authors: *S. M. UNDERHILL, P. HULLIHEN, J. CHEN, S. AMARA;
Lab. of Mol. and Cell. Neurobio., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Amphetamine (AMPH) and its derivatives are useful therapeutic agents, but also pose a danger as a consequence of their addictive properties. Acute AMPH exposure elevates extracellular dopamine by a variety of mechanisms including an increase in the rate of internalization of the plasma membrane dopamine transporter (DAT) and of the excitatory amino acid transporter 3 (EAAT3). We found that AMPH-mediated trafficking requires activation of the small GTPase RhoA that is regulated by protein kinase A (PKA) phosphorylation. PKA phosphorylation of RhoA takes it out of the active pool and, effectively stops activation of the GTPase as well as neurotransmitter transporter internalization. The trace amine receptor 1 (TA1) is a G-protein coupled receptor (GPCR) known to couple through Gs and activate PKA signaling. TA1 also has been shown previously to contribute to the actions of psychostimulants in dopamine neurons and thus these observations led us to examine the potential role of TA1 in RhoA and PKA activation.

We used CRISPR-Cas9 gene editing technology to disrupt the TA1 gene in HEK293 cells. We hypothesized that the actions of AMPH on transporter trafficking in TA1 knockout cells would be potentiated because without TA1- mediated PKA signaling the activation of RhoA would be sustained. Unexpectedly, in cells that lack TA1, AMPH did not induce DAT or EAAT3 internalization. We also could not detect Rho activation despite robust AMPH-induced Rho activation in wildtype TA1-expressing cultures. AMPH-induced Rho activation and DAT/EAAT3 internalization could also be restored in the knockout cell line by transfecting with a modified TA1. TA1 was initially characterized as a Gs-coupled GPCR, however these data suggest that alpha-subunits that couple to other signaling pathways can interact with the receptor. Using mini-genes that interfere with various alpha-subunits we determined that TA1 also couples with the alpha-13 G-protein, well-established as an activator of RhoA signaling.

These observations show that TA1 serves as the intracellular target that mediates the effects of AMPH on RhoA and cAMP signaling and suggest new pathways to target in order to better understand the mechanisms of action of AMPH.

Title: Habit learning induced by natural reward involves molecular adaptations of the glutamate transporter 1 in the dorsolateral striatum

Authors: *A. J. BOENDER, R. TONINI;
Neurosci. and brain technologies, Inst. Italiano di Tecnologia, Genova, Italy

Abstract: Uncovering the mechanistic similarities and differences between drug-induced habits and naturally induced habits should explain why these two types of habit acquisition differ in their ability to be reversed. Habitual drug seeking is associated with downregulation of the glutamate transporter 1 (GLT1) and xCT, the catalytic subunit of the constitutive cysteine/glutamate exchanger, which leads to imbalances in the glutamate homeostasis. This results in decreased extrasynaptic glutamate levels and a reduced inhibitory tone on corticostriatal synapses via metabotropic glutamate receptors, ultimately increasing the release probability of synaptic glutamate. Whether xCT and GLT1 are also involved in the formation of habits that occurs naturally after repeated practice remains to be established. To address this question, mice were overtrained to nose poke for food rewards, a form of operant conditioning that promotes habitual behavior. Upon habit formation, xCT mRNA levels were unaffected, whilst levels of GLT1 mRNA and protein were upregulated in the dorsolateral striatum (DLS); a brain region critical for the expression of habitual behavior. Since GLT1 protein is predominantly expressed by astrocytes, this points toward astrocytic involvement in habit learning. The apparent discrepancy between the downregulation of GLT1 by drug-induced habits and the upregulation of GLT1 upon the acquisition of a habit induced by food rewards could be explained by the differential regulation of GLT1 isoforms, for which we have found proof using PCR-based techniques. In sum, we provide evidence that habit learning by repeated practice affects the glutamate homeostasis in the DLS through increased GLT1 expression.

Title: System x_c^- null mice are resistant to pentylenetetrazole kindling.

Authors: *S. M. SHAHIDZADEH, J. A. HEWETT, S. J. HEWETT;
Syracuse Univ., Syracuse, NY

Abstract: Kindling, the time-dependent sensitization of neuronal circuitry to an electrical or chemical stimulus, serves as a model of epileptogenesis. This neuroplasticity is associated with aberrant activation of the glutamatergic system. System x_c^- is an antiporter known to contribute to basal extracellular glutamate levels. Thus, in this study, we tested the contribution of system x_c^- to epileptogenesis using a chemical kindling model. Kindling in male and female wild-type or system x_c^- null littermates was induced by giving a subconvulsant dose of pentylenetetrazole (PTZ) once daily (i.p.) for 21 days. Animals were observed for 30 min and seizure activity scored according to a slightly modified Racine scale. Animals were considered kindled after exhibiting a convulsive seizure on three consecutive days. Our data demonstrate the incidence of kindling was significantly decreased in system x_c^- deficient mice as compared to wild-type littermates. Specifically, in response to a daily injection of 35 mg/kg PTZ, 74% (17/23) of wild-type male mice kindled, as compared to only 43% (6/14) of their system x_c^- null male littermates. A similar result was found in females. When subjected to a daily injection of 28 mg/kg PTZ, the incidence of kindling in wild-type female mice was 31% (4/13), whereas it was only 14% (1/7) in system x_c^- null female littermates. Furthermore, persistence of the kindled state was decreased in mice lacking system x_c^- compared to their wild-type littermate controls. To wit, 81% (17/21) of wild-type and only 57% (4/7) of system x_c^- null mice exhibited a convulsive seizure when re-challenged with PTZ 10 days post-kindling. Altogether, these data suggest that system x_c^- contributes to the enhancement of excitatory transmission that is responsible for the kindled phenotype, thereby suggesting that system x_c^- may play a permissive role in epileptogenesis. Supported by NS051445-06 (SJH and JAH) and NS082982 (JAH).

Title: Thrombin decreases expression of GLT-1 via the rho kinase pathway in astrocytes

Authors: *A. HOLLOWAY[1], C.-S. PIAO[2], M. WAINWRIGHT[3];
[1]Neurol., Ann and Robert H Lurie Children's Hosp., Chicago, IL; [2]Neurol., [3]Pediatrics, Neurology, Critical Care, Ann and Robert H Lurie Children's Hosp. of Chicago, Chicago, IL

Abstract: Background: Traumatic brain injury (TBI) can cause decrease in the expression of glutamate transporters (EAAT1/GLAST and EAAT2/GLT-1), which may contribute to glutamate excitotoxicity and secondary brain injury. TBI also causes compromise of the blood brain barrier and extravasation of macromolecules, such as thrombin, into the brain parenchyma. The mechanism by which TBI leads to a reduction in expression of astrocyte glutamate transporters is not known. The Rho/Rho kinase (ROCK) pathway has previously been implicated as a mediator of glutamate transporter expression. Here, we used an in vitro model of TBI to test the hypothesis that mild mechanical stretch injury would exacerbate subsequent thrombin exposure, causing decreased expression and impaired function of GLAST and GLT-1 in hippocampal astrocytes via the ROCK pathway. Methods: Primary hippocampal astrocytes were isolated from Sprague Dawley rat pups and plated on flexible-bottom cell culture plates. Astrocytes were subjected to a mild stretch injury and exposed to thrombin or vehicle one hour later. To elucidate the role of ROCK in regulation of glutamate transporters, we tested the effect of the ROCK inhibitors, Y-27632 and Fasudil, on glutamate transporter expression and function under the same conditions. Cells were assessed for expression of glutamate transporters and activation of the Rho kinase pathway by Western Blot, or were subjected to a glutamate uptake assay. Media samples were evaluated for lactate dehydrogenase (LDH) content to confirm injury. Results: Exposure to thrombin or stretch injury alone caused down-regulation of GLAST and GLT-1. Exposure to thrombin after stretch injury caused significantly greater down-regulation of both transporters compared to control cells and stretch injury alone. Glutamate uptake was also significantly decreased at 24 hr recovery following exposure to thrombin, consistent with the down-regulation of both transporters. Stretch injury did not alter glutamate uptake and there was no additive effect of stretch injury when combined with exposure to thrombin. Exposure to thrombin activated the ROCK pathway and inhibition of ROCK activation reversed the thrombin-induced down-regulation of GLT-1. Conclusion: These results suggest that thrombin contributes to the regulation of the expression of astrocyte glutamate transporters and glutamate

uptake, acting via the ROCK pathway and that these responses are altered following stretch injury during TBI.

Title: Glutamate-dependent glut3-glast association in cultured bergmann glia cells

Authors: O. G. MENDEZ-FLORES[1], *L. C. HERNANDEZ[2], E. SUAREZ-POZOS[1], M. NAJIMI[3], A. ORTEGA[1];

Abstract: Glutamate (Glu), the main excitatory neurotransmitter in the vertebrate brain, exerts its actions through specific membrane receptors present in neurons and glial cells. Over-stimulation of glutamate receptors results in neuronal death, unless glial sodium-dependent glutamate uptake transporters, remove the amino acid from the synaptic cleft.
The sustained Na^+ influx associated to Glu uptake in glial cells, activates the Na^+/K^+ ATPase to restore the ionic balance, additionally Glu entrance activates glutamine synthetase. Both biochemical processes are energy demanding and therefore, activate glucose uptake. In order to gain insights into the molecular mechanisms underlying the Glu and glucose uptake interaction we performed [^{3}H]-2-deoxy-D-glucose ([^{3}H]2DOG) uptake assays, immunoprecipitation, biotinylation and western blot in the well-known model of Bergmann Glia cell primary (BGC) culture.
Glu stimulation, presumably through Glu transporters, as indicated by the ability of D-Asp to increase [^{3}H]2DOG uptake, augments global glucose transporters expression, as well as their plasma membrane trafficking. Additionally a physical interaction between GLUT3 and GLAST was noted upon Glu and D-Asp treatment. The present study shows a rapid response of glial cells

to Glu neurotransmitter exposure, which entails a likely dialogue between neuronal and glial cell population in the vicinity of glutamatergic synapses.

Title: Phogrin, a novel vesicle marker in the CNS, is expressed in hippocampal parvalbumin-positive interneurons

Authors: *S. JURADO[1], R. LUJAN[2], F. MUNOZ-CUEVAS[1], J. RAMIREZ-FRANCO[1]; [1]Univ. of Maryland, Baltimore, MD; [2]Synaptic Structure Laboratory, Inst. de Investigación en Discapacidades Neurológicas (IDINE), Univ. de Castilla La Mancha, Albacete, Spain

Abstract: Hippocampal interneurons comprise a diverse family of inhibitory neurons which function is critical for fine information processing. Along with gamma-aminobutyric acid (GABA), interneurons secrete a myriad of neuroactive substances via secretory vesicles which molecular composition and regulatory mechanisms remain unknown. In this study, we have combined immunohistofluorescence, electron microscopy and transgenic mice to describe the molecular content of vesicles in distinct populations of hippocampal neurons. Our results indicate that chromogranin B, a canonical large dense core vesicle marker, is excluded from inhibitory cells in the hippocampus but highly expressed in excitatory CA3 pyramidal neurons and dentate gyrus granule cells. Surprisingly, phogrin, an integral protein of secretory vesicles in neuroendocrine cells, is highly enriched in parvalbumin-positive interneurons. Consistently, immunoelectron microscopy revealed phogrin staining in axon terminals of symmetrical synapses establishing inhibitory contacts with cell bodies of CA1 pyramidal neurons. Furthermore, phogrin is highly expressed in CA3 and dentate gyrus interneurons that also contain neuropeptide Y. Our results provide the first evidence of phogrin expression in

hippocampal interneurons and suggest the existence of molecularly distinct populations of secretory vesicles in different neuronal types.

Facility, The Westmead Inst. for Med. Res., The Univ. of Sydney, Westmead, Australia

Abstract: Bulk endocytosis is the internalization of large amounts of membrane observed in various cell types. In neuronal synapses activity dependent bulk endocytosis (ADBE) occurs during high activity to compensate for large amounts of internal membrane that fuse with the plasma membrane. ADBE is more rapid than constitutive clathrin mediated endocytosis and is triggered by high activity. New synaptic vesicles (SVs) derived from the bulk endosomes primarily refill the recyclable pool of vesicles yet the intervening steps from BEs to SVs are unknown. Our aim is to identify the proteins localised to BEs as the first step towards understanding ADBE regulation. To achieve this we developed a purification method to isolate BEs from SVs for subsequent mass spectrometry (MS) analysis. Methods: Percoll synaptosomes obtained from whole rat brains were treated with control or high K^+ stimulation, at a level known to predominantly induce BE formation, in the presence of HRP as a fluid phase uptake marker. The synaptosomes were lysed and organelles separated on a density gradient. The protein content of each fraction was isolated on beads and digested for MS analysis, or processed for Western blots (WB). Digested peptides from control and stimulated fractions were differentially labelled

by dimethylation and analysed by LC-MS on an ABSciex Triple TOF 5600. Digested peptides from select density fractions of control treated synaptosomes were labelled using 10-plex TMT and analysed by LC-MS on a Thermo Q Exactive. Organelles were collected from combined density fractions of synaptosomes stimulated in the presence of HRP. The presence of HRP in the organelles was detected by electron microscopy (EM) using DAB/H_2O_2. Results/Conclusion: Analysis of HRP and overall protein changes down the gradient indicate 3 distinct regions of newly endocytosed organelles suggesting 2 populations of BEs. Localisation of organelle proteins by isotope tagging (LOPIT) analysis of the TMT data dissociated the continuous gradient of proteins into distinct organelle clusters. Tracking proteins moving into the putative BE regions and relating them to the LOPIT analysis reveals the organelles likely involved in BE formation. EM images confirm the presence of large HRP labelled structures in a putative BE region.

Title: Molecular mechanisms of ultrafast endocytosis

Authors: *S. WATANABE[1], L. E. MAMER[2], T. TRIMBUCH[2], M. CAMACHO-PÉREZ[3], I. MILOSEVIC[4], P. DE CAMILLI[5], C. ROSENMUND[3], E. JORGENSEN[6];

Abstract: Synaptic vesicles are recycled locally at synapses. Using 'flash-and-freeze' time-resolved electron microscopy, we have discovered a novel endocytic pathway, ultrafast endocytosis, that retrieves vesicle membrane within 100 ms after vesicle fusion. Despite its fast kinetics, this pathway requires dynamin for the fission reaction. However, little is known about the molecular mechanisms that mediate maturation of endocytic pits from the planar membrane. Here, we have used a candidate approach to test the involvement of molecules that directly or indirectly interact with dynamin in this process. Endophilin is a membrane-bending protein that interacts with dynamin directly through its Src homology 3 (SH3) domain. Genetic knockout of endophilin A results in an accumulation of clathrin-coated vesicles in the synaptic terminals. Following a single stimulus, ultrafast endocytosis is triggered in these neurons, but endocytic structures are stalled on the membrane due to the delayed formation of the neck. These observations indicate that endophilin is likely required at a late step of ultrafast endocytosis rather than for the initiation of membrane curvature. Synaptojanin is a phosphoinositide phosphatase that interacts with endophilin through its proline-rich domain. It contains two phosphatase domains: Sac1 like phosphatase and inositol 5-phosphatase. Synaptojanin and endophilin function together during clathrin-mediated endocytosis. To test its role in ultrafast endocytosis, we stimulated mouse hippocampal neurons lacking synaptojanin 1. Similar to the endophilin knockout neurons, endocytic structures are stalled on the membrane with a significant delay in the neck formation. This phenotype is rescued by expressing full-length synaptojanin in these neurons. However, when 5-phosphatase activity, but not the Sac1 activity, is blocked by a point mutation, the neck formation is delayed, suggesting that the removal of a phosphate group from the 5-postion of inositol is required for shape transition during ultrafast endocytosis. Taken together, these results suggest that endophilin and synaptojanin mediate the neck formation during ultrafast endocytosis.

Title: Clathrin is essential for vesicle endocytosis at mammalian central synapses

Authors: *S. LEE, S. VILLARREAL, X.-S. WU, H. LIU, Y. JIN, L.-G. WU;
NIH/NINDS, Bethesda, MD

Abstract: Synaptic vesicle endocytosis retrieves fused vesicles from the plasma membrane to sustain synaptic transmission crucial for brain function. It has been hypothesized to be mediated primarily by the classical clathrin-dependent mechanism for decades. However, recent test of clathrin hypothesis with manipulation of clathrin and electron microscopy suggests surprisingly that clathrin is dispensable for synaptic vesicle endocytosis at mammalian central synapses. Here we determined whether clathrin is required for synaptic vesicle endocytosis by performing a conditional knockout of clathrin heavy chain and pHluorin imaging. We found that endocytosis of synaptic vesicle protein synaptophysin and VAMP2 at cultured mouse hippocampal synapses is slow and clathrin-dependent after 1-800 action potentials at 0.03-80 Hz. Also, these results suggest that clathrin is essential for synaptic vesicle endocytosis in hippocampal synapses.

Title: Activity- and temperature-dependent facilitation of membrane endocytosis at nerve terminals by a non-canonical mechanism

Authors: H.-Y. YUE, *J. XU;
Dept. of Neurosci. and Regenerative Med., Med. Col. of Georgia, Augusta Univ., Augusta, GA

Abstract: In nerve terminals, endocytosis follows immediately after exocytosis to recover membrane homeostasis of terminals and recycle vesicle membrane for future exocytosis. Endocytosis typically retrieves membrane by an amount equivalent to the exocytosed, while

membrane capacitance from various cells has revealed excess endocytosis retrieving extra membrane that pre-exists at surface. To advance understanding of endocytosis of pre-existing membrane, we performed membrane capacitance measurements at the rat calyx of Held. We found that endocytosis of pre-existing membrane was ATP-independent, distinguishing it from the well-recognized clathrin-mediated endocytosis, bulk endocytosis and ultrafast endocytosis. This non-canonical form of endocytosis played a minor role and required intense activity to trigger at room temperature, but became significant at near physiology temperature. These results suggest that endocytosis of pre-existing membrane is a unique, important mechanism to ensure efficiency of endocytosis.

Title: Synaptojanin phosphorylation by the minibrain/DYRK1A kinase regulates synaptic vesicle endocytosis

Authors: L. WANG[1], J. GENG[1], J. LEE[2], C.-K. CHEN[1], *K. T. CHANG[3];
[1]Zilkha Neurogenetic Inst., [2]Zilkha Neurogenetic Inst. and Neurosci. Grad. Program, [3]Zilkha Neurogenetic Inst. and Dept. Cell & Neurobio., USC, Los Angeles, CA

Abstract: The rapid recycling of synaptic vesicles during neuronal activity is critical for maintaining communication between neurons. Defects in synaptic vesicle recycling can therefore have severe consequences, ranging from neurodegeneration to lethality. Synaptojanin (Synj), a phosphoinositide phosphatase, is known to play an important role in synaptic vesicle endocytosis by facilitating the uncoating of clathrin following synaptic vesicle uptake. Previous work from our lab demonstrated that Synj is a substrate of the minibrain (Mnb) kinase, a homolog of human dual-specificity tyrosine phosphorylation-regulated kinase 1A (DYRK1A) in *Drosophila*; however, the target sequence on Synj phosphorylated by Mnb has not been identified and the functional impacts of Synj phosphorylation by Mnb are not well understood. We find that Ser1029 is a target site on Synj that is phosphorylated by Mnb *in vivo*. In addition,

phosphorylation of Synj at Ser1029 is required to maintain normal synaptic vesicle recycling *in vivo* but surprisingly is not necessary to sustain neurotransmission during high frequency stimulation. Additional experiments will be performed to distinguish mechanisms underlying synaptic vesicle recycling by phosphorylated and dephosphorylated Synj. Since both Mnb and Synj are upregulated in DS, and Synj is mutated in Parkinson's disease, an understanding of mechanisms that modulate Synj function will provide valuable insights into basic mechanisms affecting neuronal communication and lead to strategies to treat neurological disorders.

Title: A supported tubulated bilayer system for evaluating synaptotagmin effects on membrane curvature

Authors: ***P. DAHL**[1], J. VASQUEZ[2], J. KNIGHT[2], A. ANANTHARAM[1];
[1]Biol. Sci., Wayne State Univ., Detroit, MI; [2]Chem., Univ. of Colorado, Denver, CO

Abstract: The proper execution of Ca^{2+}-triggered exocytosis requires extreme changes in bilayer shape to be precisely regulated. Because membranes alone are unlikely to undergo the required changes, proteins are necessary to mediate events. However, the identity of these proteins and the conditions under which they act are not well understood. Within this context, our studies focus on membrane targeting C2 domains from synaptotagmin-7 (Syt-7) – an isoform of the Syt protein family that is important for secretion in neuroendocrine cells. To define how Syt-7 drives changes in membrane morphology, we have used recombinant C2AB protein fragments, supported lipid bilayers (SLBs), and total internal reflection fluorescence microscopy (TIRFM). We have developed conditions for forming SLBs under which the membrane spontaneously forms long tubule-like structures extending away from the support surface. Using this Supported Tubulated Bilayer System (STuBS), we find that addition of purified Syt-7 C2AB, but not Syt-1 C2A, leads to disappearance of the tubules in a Ca^{2+} dependent manner; the mechanism of this

dramatic change is currently under investigation. These studies demonstrate that Syt-7 can alter membrane morphology, ostensibly by driving changes in membrane curvature. They also demonstrate the utility of STuBS as a novel experimental system in which protein-mediated changes in membrane topology can be studied in aqueous media and in real-time.

Title: Two major synaptotagmin isoforms cooperate to drive release at a fast inhibitory synapse

Authors: *B. BOUHOURS, O. KOCHUBEY, E. GJONI, R. SCHNEGGENBURGER; EPFL, Lausanne, Switzerland

Abstract: Fast transmitter release at synapses is enabled by the C2-domain protein Synaptotagmin (Syt). Syt1 is the major Ca^{2+} sensor for fast release at excitatory forebrain synapses whereas Syt2, a Syt isoform with high sequence homology to Syt1, is the Ca^{2+} sensor for phasic release at excitatory hindbrain synapses. The role of Syt isoforms at inhibitory synapses is, however, less well known. Although inhibitory synapses in cortical neuron cultures were shown to use Syt1 (Maximov and Südhof, 2005), the calcium sensor at defined inhibitory synapses of more intact preparations has remained elusive, with only a minor role for Syt1 at GABAergic output synapses of fast-spiking hippocampal interneurons (Kerr et al., 2008).
Here we studied the role of the two major Syt isoforms, Syt1 and Syt2, at a strong and fast-releasing inhibitory synapse in the auditory brainstem, the MNTB to LSO synapse. To overcome the perinatal lethality of the conventional Syt1 KO mice, we used a novel floxed allele of Syt1, bred together with a conventional Syt2 KO mouse. To produce either single- or double KO inhibitory synapses amenable to optogenetic stimulation, we virally expressed Cre-recombinase and the Channelrhodopsin variant oChIEF in presynaptic neurons of the different genotype combinations. This method allowed us to limit synaptic stimulation to molecularly perturbed presynaptic elements.
We found that both Syt1- and Syt2 must be deleted to produce strongly asynchronous release typical for Syt KO synapses. In contrast, single KO synapses had only small deficits in phasic release, but we observed an increased spontaneous release in Syt2 KO synapses. The redundant action of two major Syt isoforms might guarantee high rates of fast release at these inhibitory

synapses, a mechanism with possible relevance also for fast-releasing inhibitory synapses in other brain areas.

Title: Chromaffin cell synaptotagmin isoforms form functionally but not spatially separable granule pools

Authors: *T. C. RAO[1], M. W. SCHMIDTKE[1], E. R. CHAPMAN[2], D. R. GIOVANNUCCI[3], A. ANANTHARAM[1];
[1]Dept. of Biol. Sci., Wayne State Univ., Detroit, MI; [2]Dept. of Neurosci., Univ. of Wisconsin, Madison, WI; [3]Dept. of Neurosci., Univ. of Toledo Med. Sch., Toledo, OH

Abstract: Current models for the adrenal chromaffin cell secretory response rely on the assumption that secretory granules are functionally homogenous. However, there is growing evidence that heterogeneity may define fundamental properties of granules, including their kinetics and Ca^{2+}-dependence of fusion. In this context, a key difference between granules appears to be whether they express synaptotagmin-1 (Syt-1) or synaptotagmin-7 (Syt-7). To understand the implications of this difference for the secretory response, we first investigated the morphological distribution of Syt-bearing granules within cells. Despite the fact that isoforms are rarely co-expressed (<10%), Syt-1 and Syt-7-bearing granules are homogenously distributed within cells and lack obvious evidence of spatial segregation with respect to the plasma membrane or distinct coupling to Ca^{2+} channel subtypes. We next investigated functional differences between granules with Syt-1 or Syt-7 in cells depolarized with elevated K^{+}. First, we found that with mild depolarization, the Syt-7 granule population shows far greater fusion efficacy. However, strong depolarization is equally effective at driving fusion of both types of Syt-bearing granules. When cells are challenged to secrete again immediately following a strong depolarization, Syt-1 granules require less time to transition to a “fusion-ready” state.

Irrespective of the fusion efficacy, Syt-7 granules fuse with faster kinetics across all stimulation conditions tested. These findings were validated in cells permeabilized with digitonin and exposed directly to high intracellular Ca^{2+}. While Syt-7 granules fuse with greater efficacy at low $[Ca^{2+}]_{in}$, higher $[Ca^{2+}]_{in}$ is equally effective at activating isoforms. Overall, our results show that Syt-1 and Syt-7 are sorted to functionally, but not spatially, distinguishable granule pools. We posit that the heterogeneity in chromaffin granule fusion modes and release kinetics may therefore arise from intrinsic differences in granules themselves.

Title: Calcium binding to Synaptotagmin III regulates the kinetics of fusion pores and the interaction with SNAP-25

Authors: Y.-H. TSAI[1], Y.-T. HUANG[1], *C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Calcium-dependent exocytosis is initiated by calcium binding to a calcium sensor protein, triggering a number of interactions with molecular targets, including the fusion machinery SNAREs. Synaptotagmins (Syts) function as calcium sensors that regulate the kinetics of exocytosis in neurons and neuroendocrine cells. At least 17 Syt isoforms have been found in mammals and share a similar structure, consisting of an N-terminal transmembrane domain, a variable linker, and two highly conserved C-terminal C2 domains (C2A and C2B), possessing variable calcium-binding affinities. A particular isoform Syt III localizes to plasma membrane with six calcium-binding sites. Our previous studies found that Syt III is significantly up-regulated in P4-P6 rat retinal ganglion cells, suggesting that Syt III may play a unique role in regulating synaptic activity in the developing nervous system. However, the molecular mechanism underlying Syt III's regulation of vesicle release remains elusive. In this study, we overexpressed Syt III and Syt III-C2AB* (a mutant harboring the abolished calcium binding

sites) in PC12 cells. At 3 days post transfection, we harvested the cell lysates and performed endogenous co-immunoprecipitation. We found that abolishing the calcium binding sites in Syt III mainly regulated its interaction with SNAP-25 (a t-SNARE), consistent with the localization of Syt III to plasma membrane. Moreover, by comparing with control and Syt III-C2AB*, overexpressing Syt III shortened the duration of fusion pores leading to full dilation, suggesting that calcium binding to Syt III may destabilize fusion pores. These results suggest that Syt III regulates the kinetics of fusion pores and the interaction with SNAP-25 through calcium binding to its C2AB domains.

Abstract: Inositol pyrophosphates such as 5-IP_7 (5-diphosphoinositol pentakisphosphate) are highly energetic inositol metabolites containing phosphoanhydride bonds. While inositol pyrophosphates are known to regulate various biological events, including growth, survival and metabolism, the molecular sites of 5-IP_7 action in vesicle trafficking have remained largely

elusive. We here report that elevated 5-IP_7 levels, caused by overexpression of IP_6 kinase (IP6K1), suppressed depolarization-induced neurotransmitter release from PC12 cells. Conversely, IP6K1 depletion decreased intracellular 5-IP_7 concentrations, leading to increased neurotransmitter release. Consistently, knockdown of IP6K1 in cultured hippocampal neurons augmented action potential-driven synaptic vesicle exocytosis at synapses. Employing a fluorescence resonance energy transfer (FRET)-based in vitro vesicle fusion assay, we found that 5-IP_7, but not 1-IP_7, exhibited significantly higher inhibitory activity toward synaptic vesicle exocytosis than did inositol hexakisphosphate (IP_6). Synaptotagmin 1 (Syt1), a Ca^{2+} sensor essential for synaptic membrane fusion, was identified as a molecular target of 5-IP_7. Notably, 5-IP_7 showed a 45-fold higher binding affinity for Syt1 compared with IP_6. In addition, 5-IP_7-dependent inhibition of synaptic vesicle fusion was abolished by increasing Ca^{2+} levels. Thus, 5-IP_7 appears to act through Syt1 binding to interfere with the fusogenic activity of Ca^{2+}. These findings reveal a role of 5-IP_7 as a potent inhibitor of Syt1 in controlling the synaptic exocytotic pathway and expand our understanding of the signaling mechanisms of inositol pyrophosphates.

Title: The transmembrane domain of synaptobrevin influences synaptic fusion pore flux in mouse hippocampal neurons

Authors: *C.-W. CHIANG, C.-W. CHANG, M. B. JACKSON;
Dept. of Neurosci., Univ. of Wisconsin Madison, Madison, WI

Abstract: The fusion pore is the first stable intermediate of exocytosis that mediates release, and is believed to be a bifurcation point between full-fusion and kiss-and-run. Studies in endocrine cells have shown that transmembrane domain (TMD) mutations in the SNARE proteins syntaxin and synaptobrevin (Syb) influence flux through the fusion pore. These results suggest that a proteinaceous fusion pore composed of both SNARE protein TMDs connects the vesicle and plasma membrane. To test this model in synaptic transmission we cultured hippocampal neurons

from Syb/cellubrevin double knockout mice and expressed Syb mutants with single tryptophan substitutions in its TMD (residues 97 through 108). Miniature excitatory synaptic currents (mEPSC) were recorded using whole cell patch clamp. Transmitter flux was inferred from the kinetics evaluated with the aid of careful fits to individual events. We identified mutations at position 99, 101, 103, 104, and 105 that reduced the maximum slope during the rising phase of mEPSCs, which represents the highest velocity of efflux through the initial fusion pore. Residues 101 and 103 also have increased rise time. Except for residue 104, these residues had been shown previously to influence flux through endocrine fusion pores. Our results suggest that the Syb TMD forms part of the fusion pore during synaptic vesicle exocytosis, and substitutions in the pore lining residues for amino acid with higher volume hinder the passage of neurotransmitter and slow down release. The comparison with previous studies indicates that endocrine and synaptic release employ very similar molecular machinery in forming fusion pores.

Title: A chimeric approach to studying the Syntaxin Habc domain uncovers roles in exocytosis and Syntaxin trafficking

Authors: *L. A. PARRA, M. T. PALFREYMAN, E. M. JORGENSEN;
Univ. of Utah, Salt Lake City, UT

Abstract: Synaptic vesicle fusion is mediated by the concerted action of Munc18 and SNARE proteins. Munc18 has multiple binding modes with syntaxin. Key to understanding this interaction is the highly conserved three-helix bundle (known as the Habc domain) that is present on the SNARE protein syntaxin. This domain is the major interaction interface between Munc18 and the SNARE proteins. To test the role of the Habc domain and Munc18 proteins *in vivo*, we are analyzing different Habc domain variants using the nematode *C. elegans*. Specifically, we are exchanging the Habc domain of the worm with the respective Habc domains of other species. Using this chimeric approach we hope to identify key components that will help to mechanistically characterize the interaction between the SNAREs and the Munc18 proteins. Previous evidence suggests the interaction of Munc18 and the SNAREs serves a role in trafficking and in exocytosis. Our evidence shows that replacing the worm Habc with the

choanoflagellate *Monosiga brevicollis* (MoBr) Habc does not disrupt trafficking whereas the yeast *Saccharomyces cerevisiae* (SaCe) Habc domain does result in partial trafficking defects. Despite the correct localization, the choanoflagellate Habc chimera animals are still uncoordinated and have dramatic decrease in synaptic vesicle fusion -thus, demonstrating the important role for the Habc domain downstream of trafficking. Interestingly, the roles downstream of trafficking might result from specific interactions between the Habc domain and Munc18. Specifically, the inviability of yeast Habc chimeras can be rescued by expression of Sec1p, the yeast homolog of Munc18. In this combination the viability is restored independent of an observable restoration of wild-type syntaxin localization. I am currently performing further chimeric analyses to understand the physiological implication of syntaxin Habc domain interaction with Munc18. These experiments will parse the roles of Munc18 in the trafficking of syntaxin and the exocytosis of synaptic vesicles.

Title: The role of Auxilin in neurosecretion in NGF-treated PC12 Cells.

Authors: *W. LIM;
Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Endocytosis are important transportation of molecules outside to inside of a cell. One of the endocytosis is Clathrin-mediated endocytosis (CME). In neuron CME is an important mechanism for the formation of new vesicles at the presynaptic-terminal and synaptic vesicles recycling. CME starts from assembly proteins then bind to the synaptic vesicle proteins (SNAREs) and phosphoinositides; later recruiting clathrin a protein which will surround and coat the vesicle. After the vesicle fission into the cell de-coating of clathrin layer is required for the content inside of the vesicles to release or uptake into early endosome. Early studies indicated that Hsc70 and Auxilin facilitate in the process of de-coating clathrin layer. Auxilin was shown to be a J cochaperone which—like DnaJ, contains a J domain which binds on Hsc70. Auxilin also contains a clathrin-binding domain it bind to clathrin coat and recruiting Hsc70 this provides the mechanism to drive clathrin-caot disassembly. In this study we focus on expressing auxilin and its mutation forms into NGF-treated PC12 cell to study their effect on endocytosis. To monitor the effect of endocytosis, we use perforated-patch to record the cell capacitance changes,

when cell undergoes more exocytosis the surface areas of the cell membrane will increase and the capacitance will also increase, in contrast when endocytosis is more than exocytosis, the cell membrane surface area will decrease and so the capacitance. By this method we can monitor the living cell capacitance changes and verify the role of different Auxilin domain in endocytosis.

Title: Spontaneous neurotransmission driven by non-canonical vesicular SNAREs modulates synaptic plasticity

Authors: *D. C. CRAWFORD, D. M. O. RAMIREZ, B. TRAUTERMAN, L. M. MONTEGGIA, E. T. KAVALALI;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Most presynaptic vesicles fuse with the plasma membrane after the arrival of an action potential, but some vesicles fuse spontaneously in the absence of such stimulation. Recent studies suggest that stimulus-evoked and spontaneous neurotransmitter release processes are molecularly distinct, so it is possible that these forms of neurotransmission differentially signal to the postsynaptic neuron. To test this hypothesis, we targeted the non-canonical synaptic vesicle SNARE proteins Vps10p-tail-interactor-1a (vti1a) and vesicle-associated membrane protein 7 (VAMP7) to specifically impair spontaneous release events and probe whether loss of these proteins alters synaptic plasticity. In cultured neurons, loss of vti1a and VAMP7 impaired spontaneous high-frequency glutamate release and augmented unitary event amplitudes by reducing postsynaptic eukaryotic elongation factor 2 kinase (eEF2K) activity. In hippocampal

brain slices, loss of vti1a and VAMP7 reduced spontaneous neurotransmitter release, as measured via uptake of antibody against the luminal domain of synaptotagmin 1. Presynaptic, but not postsynaptic, loss of vti1a and VAMP7 in hippocampal slices occluded N-methyl-D-aspartate receptor (NMDAR) antagonist-induced synaptic potentiation in an intact circuit, confirming the role of these vesicular SNAREs in setting synaptic strength. Long-term potentiation, which depends on stimulus-evoked neurotransmission for induction, was not impaired by presynaptic loss of vti1a and VAMP7. Collectively, these results demonstrate that spontaneous neurotransmission signals independently of stimulus-evoked release and is a key regulator of postsynaptic efficacy.

Title: An improved event-driven model of presynaptic dynamics for large-scale simulations

Authors: *J. W. GARCIA[1,2], T. M. BARTOL[1,2], D. J. SPENCER[1,2], T. J. SEJNOWSKI[1,2]; [1]Salk Inst., La Jolla, CA; [2]Howard Hughes Med. Inst., La Jolla, CA

Abstract: Chemical synapses play a central role in neural computation in the brain: the dynamics of probabilistic vesicle release, facilitation, and depression at these synapses strongly determine how information is transferred between neurons. However, the precise computational role of these presynaptic dynamics remains under investigation. To elucidate their role in biological networks, computational simulations with many neurons and synapses require synaptic models with strong realism, efficiency, and versatility. Our model aims to replicate the phenomenology of both biological synapses and validated molecular models of presynaptic function through an efficient event-driven framework that tracks action potential, vesicle release, priming, reuptake, and recycling event times. The model includes multiple mechanisms of asynchronous vesicle release, facilitation, and depression and easily allows features to swap in and out for controlled modelling experiments. It overcomes numerous limitations of previous

models, achieving high realism with minimal sacrifice in computational efficiency, which makes it ideal for studying the role of presynaptic dynamics in large network simulations.

Title: Comparing models of synaptic release by combined experimental recordings and neuronal simulation

Authors: *D. SPENCER, J. W. GARCIA, T. M. BARTOL, T. J. SEJNOWSKI;
Salk Inst. CNL-S, La Jolla, CA

Abstract: Computational neuroscience today is moving toward larger and more heterogeneous networks of neurons. These simulations are modeling neurons and their interconnections in greater detail to match improvements in experimental neurophysiology. Inclusion of detailed modeling of synapses in network simulations, however, is lagging due to their large numbers, complex behavior and diversity. Relatively few network simulations today incorporate individual synapses and those that do use simplified facilitation/depression models that release synchronously with the input axonal spikes. Newer synaptic models are emerging that encompass multiple presynaptic release mechanisms and produce asynchronous releases over time spans greater than one second from a single input spike. A problem in these new synaptic models is how to tune their many parameters and how to compare and rate the models for their fidelity. Traditionally, the comparisons have been with in vitro experiments encompassing presynaptic spikes stimulating axons that synapse onto a postsynaptic neuron from which facilitation, depression, and release probability can be calculated and compared. Here we use a simulated postsynaptic neuron and input axons that model in vivo experiments of a controlled behavioral stimulation with simultaneous recording of pre synaptic and postsynaptic neurons. A typical experiment would be simultaneous recordings of mammalian LGN neurons and V1 cortical neurons during stimulation of the eyes by either natural or artificial scenes. We evaluate different synaptic models by driving them with the same experimental presynaptic spike trains and statistically measuring the difference of the simulated postsynaptic output with the in vivo

neuron recordings. This paradigm can also be use to “tune” a synapse model. Using different sets of experimental data, we compare synapse models of varying computational complexity. They are compared for their closeness to the in vivo cortical neuron output as well as for their facilitation, depression, and release profiles.

Title: Dmnoa1 function at the *Drosophila* neuromuscular junction

Authors: *R. HABETS;
Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Neurotransmitter release is a process that is critically dependent on mitochondria due to the high energy demand of the vesicle recycling machinery. We isolated mutants in the *Drosophila* homologue of NOA1, which we called DmNOA1, in a screen for mutants with synaptic defects. NOA1 is a circularly permutated GTPase that is conserved from yeast to man and we find DmNOA1 localized at the mitochondria of muscles and neuromuscular junctions. Rescue experiments indicate that DmNOA1 needs to be expressed in all tissue to rescue lethality in the mutants. Interestingly, mutant animals are developmentally delayed, meaning that the larval stage is prolonged to up to 20 days. We find that mitochondrial morphology is normal in mutant animals, but to our surprise found that levels of complex I of the electron transport chain are elevated in *DmNOA1* mutants. Basic synaptic transmission at the larval neuromuscular junction was not altered, yet upon high frequency stimulation excitatory junctional potentials depressed to a greater extend in *DmNOA1* mutant animals. We conclude that DmNOA1 is necessary for correct assembly of complex I and that failure to do so results in synaptic defects in *DmNOA1* mutants.

Title: Distinct functions of cGMP-dependent protein kinase in synaptic function

Authors: *J. S. DASON, A. M. ALLEN, M. B. SOKOLOWSKI;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The *foraging* gene in *Drosophila* encodes a cGMP-dependent protein kinase (PKG). PKG is thought to regulate several aspects of synaptic function, including synaptic plasticity, synaptic vesicle exocytosis and endocytosis, and neurite outgrowth. However, the mechanisms by which PKG regulates these processes are not fully understood. In addition, much of the evidence for its putative role in these processes is based on the use of pharmacological inhibitors. Pharmacological approaches can be limiting because of their non-specific effects and the inability to distinguish between presynaptic, postsynaptic and glial effects. To overcome these limitations, we used a genetic approach to understand the role of PKG in synaptic function. Here, we used a newly created *foraging* null mutant to characterize the synaptic effects of PKG at the *Drosophila* larval neuromuscular junction. We found that the *foraging* null mutant displayed increased nerve terminal growth, increased neurotransmitter release in response to low frequency stimulation and impaired synaptic vesicle endocytosis. Next, we used RNAi to knockdown *foraging* selectively in neurons, glia or muscles to determine where PKG was required for these synaptic effects. We found that glial PKG regulated synaptic growth, presynaptic or postsynaptic PKG regulated neurotransmitter release and presynaptic PKG regulated synaptic vesicle endocytosis. Finally, we used FIAsH-FALI to acutely inactivate PKG and separate its roles in synaptic vesicle exocytosis and endocytosis. Overall, we found that presynaptic, postsynaptic and glial PKG have distinct roles in regulating synaptic growth and synaptic vesicle cycling.

Title: Role of D2 auto-receptors in neurotransmitter modulation

Authors: *H. S. DHILLON[1], R. FORMISANO[1], J. CAPLAN[2];
[1]Biol. Sci., Delaware State Univ., Dover, DE; [2]Biol. Sci., Univ. of Delaware, Newark, DE

Abstract: The neurotransmitter dopamine influences a variety of neural processes ranging from reward, cognition and locomotion, both in vertebrate and invertebrate. Several neuropsychiatric disorders including Parkinson's disease, schizophrenia, depression and bipolar disorders are associated with dopamine imbalances. Dopamine signaling is mediated via two sub-types of G-protein coupled receptors (GPCR) receptors, D1-like and D2-like receptors. Dopamine autoreceptors are a sub-type of D2 receptors that are found at both somatodendritic and axonal sites and are suggested to mediate the amount and the timing of dopamine release. In contrast to the complexity of the mammalian CNS, the 302-neuron nervous system of *Caenorhabditis elegans* provides a powerful as well as simpler biological system that has been successfully used to link genes, individual neurons, and neural circuits to specific behaviors. The phylogenetic conservation of *C. elegans* genes involved in DA signaling provides a pragmatic model to unravel DA regulatory mechanisms. There are 8, clearly identifiable DA neurons in the *C. elegans* hermaphrodite and 4 confirmed *C. elegans* DA receptors. We are characterizing its D2-like receptor DOP-2 to understand the role of autoreceptors in modulation of dopamine signaling in movement control and non-associative learning. Previously, we have shown that DOP-2, which is expressed in all eight *C. elegans* dopaminergic neurons, physically interacts with GPA-14, an inhibitory G-alpha subunit (Pandey et al., 2012, *J Mol Signal 7: 3*). We have also shown that both *dop-2* and *gpa-14* deletion mutants habituate at a significantly faster rate as compared to wild-type worms (Mersha et al., 2013, *Behav Brain Funct. 9:16*). Our current work is focused towards analyzing synaptic vesicles release in *dop-2* mutants using fluorescence recovery after photobleaching (FRAP) to monitor neurotransmitter vesicle release activity at specific synapses in live animals. Our preliminary results indicate that loss of *dop-2* directly influences the rate of synaptic vesicle fusion potentially suggesting that the basal excitation of dopaminergic neurons may be elevated in *dop-2* animals. In parallel we are also studying the effect of *dop-2* deletion on movement control using swimming induced paralysis assay (Hardaway et al., 2012, *G3 Bethesda 2:961*), in efforts towards understanding the functional contribution of D2 auto-receptors on

motor activity. Results from our experiments have the potential to provide basic science foundations towards understanding disorders of movement control.

Title: Activity dependent vesicle recycling at the CA3-CA1 synapse contributes to synaptic plasticity

Authors: ***V. MUDIGONDA**, S. NADKARNI;
Dept. of Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: In the hippocampal CA3-CA1 synapse, a well studied synapse for plasticity mechanisms, the pool of vesicles available for immediate release (readily releasable pool, or RRP) is typically limited to a small number (7-10). Recruitment of vesicles to RRP takes place via two distinct reservoirs. Each of these have a characteristic time scale of refilling and an associated number of vesicles. In a high frequency regime of activity, usually required to induce plasticity in these synapses, the RRP may quickly run out of its vesicle resource. Given that the vesicle recycling timescales (order of seconds) are much slower compared to the ongoing electrical activity, how do small synapses cope up with high activity demands? Recent experimental studies suggest that the recycling rates are indeed modulated in order to keep up with vesicle release needs. One of the ways vesicles achieve faster recycling rates is exocytosis sans loss of vesicle membrane identity (kiss and run mechanism). This enabling mechanism has specifically been observed to play a role for high frequency stimulus at CA3-CA1 synapse. The identity of several molecular players which coordinate these processes at the presynaptic terminal have been elucidated, however a quantitative framework to model the dynamics and its effect on plasticity thus far does not exist. Here, we develop a detailed kinetic model with 3 distinct pools for synaptic vesicles at the CA3-CA1 synapse. Our model takes into account kiss and run and full fusion forms of vesicle recycling. We include a frequency and calcium dependence for the recycling rates in accordance with reported results. We elucidate synaptic

vesicle dynamics under various plasticity protocols. Furthermore, we explore how changes in vesicle pool sizes can alter synaptic plasticity. The computational framework developed here could be generalized to other synapses like the calyx of Held and allow us to have better quantitative understanding of mechanisms implicated in presynaptic plasticity.

Title: Fatigue in rapsyn-deficient zebrafish reflects defective transmitter release

Authors: *H. WEN[1], M. MCGINLEY[2], J. M. HUBBARD[3], W.-C. WANG[1], P. BREHM[1]; [1]The Vollum Inst., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Texas Children's Hosp., Houston, TX; [3]Inst. du Cerveau et de la Moelle épinière, Paris, France

Abstract: Generally associated with a drop in release probability among release sites, synaptic depression at the zebrafish neuromuscular junction results instead from the dropout of a subset of slow release sites that require seconds to recover. This determination was based on multinomial variance analysis of evoked endplate current (EPC) amplitudes obtained with paired motor neuron-muscle recordings. Our analysis indicated a release probability near unity at frequencies <0.2 Hz and an average of 14 functional release sites. These consisted of two kinetically distinct groups that are >60 fold different in their recovery rates, with each accounting for approximately half of the total release site number. At frequencies above 1 Hz the number of functional release sites dropped to half due to the inability of the slow sites to reload. The midpoint of steady state depression was resistant to change between 20 and 100 Hz due to the fast time constant of recovery of the remaining sites. The steady state level of transmission was maintained solely by the fast release sites, which recovered within <45 ms. We applied the analysis to a mutant line of zebrafish which serves as a model for human rapsyn deficient myasthenic syndrome. As with most myasthenic syndromes in human, the fish underwent rapid use-dependent muscle fatigue, the basis for which has remained unresolved. We now show that the fatigue results from exaggerated synaptic depression compared to wild type fish. As with wild type there are two

groups of kinetically distinct release sites, but in the mutant line the recovery rate specifically for the fast sites is greatly compromised. Thus, the postsynaptic mutation in rapsyn leads to lowered receptor density but also impacts the presynaptic release. The collective actions of defective presynaptic release and postsynaptic responsiveness lead to fatigue onset that is frequency dependent.

Title: Behavioral consequences of point mutations in the vesicular acetylcholine transporter

Authors: *D. WHITE, JR, A. WALLACE, O. AKRINSOLA, S. BOPPANA, H. LAWAL; Biol. Sci., Delaware State Univ., Dover, DE

Abstract: The neurotransmitter acetylcholine (ACh) is involved in critical organismal functions as locomotion, learning and memory. Therefore, decline in this neurotransmitter system is a key underlying factor in movement and cognitive deficits. The vesicular acetylcholine transporter (VAChT) is responsible for packaging ACh into synaptic vesicles for exocytotic release. Mutations in this protein ultimately diminish locomotion whereas complete loss of function of VAChT is fatal. The direct role of altered acetylcholine release and its association with impairment or enhancement of cognitive functions is still not fully understood**.** We hypothesize that point mutations in VAChT will cause age-related deficits in cholinergic-mediated behaviors such as locomotion and learning and memory. Using *Drosophila melanogaster* as a model system, we have generated several mutations within VAChT and observed its effect on behaviors such as lifespan and locomotion. Here we report that VAChT point mutants show age-dependent defects in locomotion ability; and certain mutant alleles display a shorter lifespan. Moreover, we present preliminary studies on the effect of these mutants on courtship conditioning, a well-described assay for learning and memory in *Drosophila*. We also show the expression pattern of VAChT in both wildtype and VAChT point mutants. Together, these results demonstrate that central cholinergic release is important for the regulation of behavioral performance in *Drosophila*. In future studies, we will test methodologies to effectively rescue these deficits with

implications for intervention strategies to treat cholinergic deprived disorders such as Alzheimer's disease.

Title: How does synaptotagmin 7 contribute to synaptic facilitation?

Authors: ***S. L. JACKMAN**, J. TURECEK, W. G. REGEHR;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Many neuronal synapses exhibit facilitation, a form of short-term enhancement in which the amount of neurotransmitter release increases with each subsequent presynaptic action potential. While synchronous neurotransmitter release is triggered during action potentials when local, high-concentrations of Ca^{2+} bind to the fast synaptotatgmin (Syt) isoforms Syt1 and Syt2, facilitation is driven by the smaller, longer-lasting Ca^{2+} signals between action potentials known as residual Ca^{2+}. Thus it was proposed that a specialized Ca^{2+} sensor, distinct from the fast synaptotagmin isoforms, binds residual Ca^{2+} to produce facilitation. We recently showed that Syt7 is required for facilitation at several central synapses. In Syt7-knockout mice, facilitation is eliminated even though the initial probability of release and the presynaptic residual calcium signals are unaltered. Yet how Syt7 produces facilitation remains a mystery. To explore the mechanism by which Syt7 contributes to facilitation, we constructed a biophysical model that incorporates the measured Ca^{2+}-affinities and lipid binding properties of Syt1 and Syt7. Our model recapitulates the behavior of several well-characterized synapses, and may also provide insight into the mechanism by which synaptotagmins trigger neurotransmitter release.

Title: The presynaptic protein Mover regulates frequency facilitation at hippocampal mossy fibre terminals

Authors: J. S. VIOTTI, H. POFANTIS, A. K. AKULA, M. ARNDT, *T. DRESBACH;
Univ. of Goettingen Med. Sch., Goettingen, Germany

Abstract: Few proteins in the neurotransmitter release machinery escape the evolutionary conservation that makes synapses among nematodes, flies, mice and man quite similar. Mover is one of these rare exceptions. Mover is a vertebrate-specific, synaptic vesicle-bound phosphoprotein. It binds both the highly conserved Calmodulin and the vertebrate-specific active zone scaffolding protein Bassoon. Moreover, Mover is highly expressed at some and below detection limit at other synapses, indicating that it may regulate synaptic function at subsets of synapses. In addition, Mover is strongly upregulated in the anterior cingulate cortex in post-mortem brains of schizophrenic patients, raising the possibility that it is upregulated in response to - or as a cause of - aberrant neuronal activity. Knock-down of Mover at the calyx of Held increases the rate of vesicle reloading after synaptic depression, as well as the calcium sensitivity and probability of release, revealing a role for Mover in regulating transmitter release at this synapse.
In this study, we have used a Mover knockout mouse line in combination with imaging and electrophysiology to understand the role of this protein in synaptic transmission. Knockout of Mover increases frequency facilitation, paired-pulse ratio and high-frequency facilitation in the hippocampal mossy fiber - to CA3 synapse, but not in the Schaffer collateral - to CA1 synapse. These data suggest that Mover boosts release probability and dampens frequency facilitation in hippocampal mossy fibre terminals.
In cultured neurons, Mover is upregulated when global activity is increased and downregulated when activity is decreased.
These discoveries, together with its role in the Calyx of Held, suggest that Mover is an activity-dependent, synapse-specific regulator of presynaptic plasticity. Moreover, they suggest that a) Mover has distinct roles at different synapses; b) generally acts to dampen the extent of

presynaptic events; c) acts as a brake that can be released during low activity. At the hippocampal mossy fibre terminal, activity-dependent regulation of Mover could increase the dynamic range for the induction of frequency facilitation and working memory.

Title: Sex difference in the requirement of different Ca^{2+} sources to initiate estradiol-induced excitatory synaptic potentiation in the hippocampus

Authors: ***A. JAIN**[1], C. S. WOOLLEY[2];
[2]Neurobio., [1]Northwestern Univ., Evanston, IL

Abstract: 17β-estradiol (E2) acutely modulates neuronal physiology in the hippocampus. One acute effect of E2 is to potentiate excitatory synaptic transmission at CA3-CA1 synapses. Whole-cell recordings in hippocampal slices from rats show that bath application of E2 (100nM) potentiates excitatory postsynaptic currents (EPSCs) in ~60% of CA1 pyramidal cells in both females and males. However, this occurs through distinct underlying mechanisms in each sex. Preliminary results show that protein kinase A (PKA) is required to initiate E2-induced synaptic potentiation in females but not in males. Because increased intracellular Ca^{2+} can activate kinases to initiate synaptic potentiation, here we investigated whether either of two principal sources of increased intracellular Ca^{2+}, L-type Ca^{2+} channels or Ca^{2+} release from internal stores, are required for E2-induced synaptic potentiation, and whether this differs by sex. We used nifedipine (10μM) to block L-type Ca^{2+} channels and thapsigargin (1μM) to deplete internal Ca^{2+} stores.
Nifedipine by itself had no effect on EPSCs in either sex. Thapsigargin produced a transient increase in EPSC amplitude in both sexes and E2 was applied after EPSC amplitude returned to baseline. We found that, in females, E2-induced synaptic potentiation was inhibited completely by either nifedipine (13 of 13 cells) or thapsigargin (9 of 9 cells). In contrast, in males, neither

nifedipine nor thapsigargin alone was sufficient to inhibit this potentiation. In males, E2 potentiated EPSCs in nifedipine by 68±7% in 9 of 15 cells and in thapsigargin by 56±6% in 6 of 10 cells, both statistically similar compared to potentiation by E2 alone (81±4%, 11 of 18 cells) (unpaired t-test, nifedipine: p=0.26, thapsigargin: p=0.16). However, when L-type Ca^{2+} channels were blocked and internal Ca^{2+} stores were depleted together in males, E2-induced synaptic potentiation was completely inhibited (9 of 9 cells). Thus, while both L-type Ca^{2+} channels and Ca^{2+} release from internal stores are involved in initiation of E2-induced potentiation in both sexes, one Ca^{2+} source can compensate the other in males, whereas in females, both are required to initiate synaptic potentiation. Further experiments will investigate whether the requirement for both L-type Ca^{2+} channels and Ca^{2+} release from internal stores in females is related to the female-specific requirement of PKA in E2-induced synaptic potentiation. Understanding differences between males and females in E2-induced synaptic modulation may provide insight into mechanisms that underlie sex differences in the prevalence and/or symptoms of neuropsychiatric disorders that vary by sex.

Title: Inter-hemispheric modulation of TMS-evoked potentials following intermittent theta burst stimulation to motor cortex

Authors: *M. GANNON, S. LONG, N. PARKS;
Univ. of Arkansas, Fayetteville, AR

Abstract: Transcranial magnetic stimulation (TMS) produces a transient magnetic field that is capable of activating cortical tissue through induction. Repetitive TMS (rTMS) uses repeated administration of TMS pulses and has been reliably shown to produce changes in the state of cortical excitability outlasting the time of stimulation. One such protocol that has demonstrated states of increased excitability is intermittent theta burst stimulation (iTBS). This method applies high-frequency bursts (50Hz) of pulses every 200 ms in trains of ten bursts. Protocols such as these have found use in clinical domains for the treatment of a variety of neurological and psychological disorders. However, there are still many unknowns regarding the

neurophysiological changes that accompany this plasticity. Here, we sought to investigate neurophysiological mechanisms of iTBS-induced plasticity in motor cortex using EEG simultaneously recorded with TMS pulses. Further, we sought to examine inter-hemispheric changes in motor cortex excitability attributable to iTBS. That is, we examined if iTBS conducted over right motor cortex would lead to measureable changes in excitability indices of left motor cortex. We administered a standard iTBS protocol to subjects' right motor cortex and examined changes in cortical excitability immediately following application and thirty minutes later. We quantified changes in right and left motor cortex excitability with measurements of TMS-evoked potentials (TEPs) and motor-evoked potentials (MEPs) elicited through blocks of single pulse TMS. We compared the effects of the iTBS condition to those found in a control condition where a sham version of iTBS was administered. Results indicate differential modulations of cortical TEPs between hemispheres. The N100 component was enhanced in the iTBS condition across time in the right hemisphere, while there was suppression of the P30 component across time in the left hemisphere.

Title: Isoflurane inhibits excitatory neurotransmission in the anesthetic hypersensitive mouse mutant, Ndufs4(KO)

Authors: *P. I. ZIMIN, C. B. WOODS, P. G. MORGAN, M. M. SEDENSKY;
Ctr. for Developmental Therapeut., Seattle Children's Res. Inst., Seattle, WA

Abstract: INTRODUCTION: Mitochondrial complex I dysfunction is linked to volatile anesthetic sensitivity in nematodes, mice and children[1-3]. Mice with loss of a mitochondrial complex I subunit, NDUFS4, are very hypersensitive to volatile anesthetics (VAs).[1] Limiting NDUFS4 loss to a subset of glutamatergic neurons recapitulated the total knock-out (KO) VA hypersensitivity phenotype. Exposure to 0.6% isoflurane, which anesthetizes KOs but not controls, selectively depressed spontaneous excitatory neurotransmission in KO CA1 neurons

(submitted for publication). Here we investigated excitatory neurotransmission under conditions of high energetic demand caused by high frequency stimulation (HFS).
METHODS: All studies were approved by our IACUC. Evoked field excitatory postsynaptic potentials (fEPSPs) were recorded from CA1 region of coronal mouse brain slices. Fibers were stimulated every 30s for baseline activity and for at least 60min following HFS, which consisted of 3 trains of 100Hz delivered at 20s intervals. In some experiments isoflurane-containing solution was superfused for 40min prior to HFS, and for the duration of the experiment.
RESULTS: HFS failed to induce potentiation in KO slices within 2min, while control slices showed potentiation to ~150%. By ~10min, KO and control slopes of fEPSPs displayed very similar potentiation, of ~140%, which gradually decreased to ~120% at 60min. 0.6% isoflurane exposure initially decreased slopes of fEPSPs in the KO to only 20% of baseline, gradually increasing to match potentiation in control slices of about 120% over 20min. There were no differences between KO and control in the slopes of fEPSPs during HFS in the absence of isoflurane. In 0.6% isoflurane the KO preparations displayed much lower slopes in the first 50msec in the second and third train of HFS. 0.6% isoflurane corresponds to ~1.5 MAC for the KO. We tested 1.5 MAC isoflurane (1.8%) in controls. Isoflurane reduced fEPSPs to ~25% of baseline at 30s post-HFS, recovering to ~80% by 15min, without further changes.
CONCLUSIONS: Under energetically demanding conditions, isoflurane markedly inhibited the ability of a mitochondrial mutant to recover excitatory synaptic transmission. HFS in our model uncovered selective differences in *Ndufs4(KO)* neuronal function that are consistent with whole animal data for both the global KO and cell specific loss of this protein. Depression of mitochondrial function by isoflurane may limit effective neurotransmission in key circuits responsible for responses to VAs in both normal animals and mitochondrial mutants.

Title: Physiological role of bk channels in synaptic plasticity associated with cognitive function

Authors: ***T. ZAMAN**[1], M. SMOKA[2], S. SCHMID[1];
[1]Anat. and Cell Biol., Schulich Sch. of Med. & Dent., London, ON, Canada; [2]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Effective sensory filtering is critical for the healthy brain as it is believed to reduce the processing demands placed on advanced circuitry. Disruption of sensory filtering, as observed in autism and schizophrenia, can be measured as a deficit in habituation of acoustic startle response. In recent years, evidence has accumulated that mechanisms that influence synaptic transmission are involved in habituation. The aim of this study is to investigate the physiological role of calcium and voltage-activated potassium channel (BK channel) in the synaptic plasticity underlying acoustic startle habituation using immunofluorescence, electrophysiological and voltage-sensitive dye imaging tools. We hypothesize that activation and possibly phosphorylation of BK channels in auditory afferents that synapse onto startle mediating caudal pontine reticular nucleus (PnC) giant neurons may play a critical role in the synaptic depression related to startle habituation. Our immunofluorescent staining revealed that BK channels are located on glutamatergic terminals synapsing on PnC neurons. Patch-clamp recordings in rat brainstem slices show that repeated activation of auditory synapses on PnC neurons by short trains of action potentials leads to synaptic depression that is significantly reduced by bath perfusion of both BK channel blocker paxilline and CaMKII phosphorylation inhibitor KN93. Voltage sensitive dye imaging of the brain slice that shows directional flow, magnitude of neuronal activity and consequent plasticity in the PnC region further strengthens the association of BK channels with synaptic depression. In summary, this study provides compelling evidence that BK channels are critical for synaptic plasticity underling sensory filtering that is linked to cognitive function.

Title: Differential regulation of short-term presynaptic plasticity by calcium channels and calcium sensor proteins in excitatory and inhibitory synapses in the hippocampus

Authors: *E. NANOU, W. A. CATTERALL;
Pharmacol., Univ. of Washington, Seattle, WA

Abstract: Regulation of $Ca_V2.1$ channels by specific calcium sensor (CaS) proteins mediates different patterns of synaptic facilitation vs. rapid synaptic depression in cultured neurons that transiently express $Ca_V2.1$ and CaS proteins. Introducing the mutation IM-AA into the CaS binding site (IM motif) in the C-terminus of $Ca_V2.1$ channels in mice blocks synaptic facilitation in excitatory synapses in single-neuron microcultures. Here we compare the effects of this mutation in three synapses in hippocampal slices: Schaffer Collaterals (SC) to CA1, SC to parvalbumin (PV)-expressing interneurons, and PV interneurons to CA1. In excitatory SC-CA1 synapses, the IMAA mutation reduced synaptic facilitation in response to paired-pulse stimuli by 50%, without an effect on miniature postsynaptic currents, and shifted the pattern of synaptic plasticity in response to trains of stimuli such that both synaptic facilitation and rapid depression were slowed. In excitatory SC-PV synapses, we also found that paired-pulse facilitation was reduced by 50% and both facilitation and rapid depression were slowed in trains of stimuli. Thus, the IM-AA mutation in presynaptic $Ca_V2.1$ channels affected these two different excitatory synapses formed by SC presynaptic nerve terminals in a similar manner. In contrast, the IM-AA mutation affected only rapid synaptic depression in inhibitory PV-CA1 synapses. Synaptic depression dominated at all inter-stimulus tested (20-200 ms). Surprisingly, we found that the IM-AA mutation abolished rapid synaptic depression at inter-stimulus intervals from 50 to 200 ms. We also examined synaptic plasticity in response to trains of action potentials at different frequencies (5-50 Hz). WT synapses exhibited synaptic depression in response to trains at all frequencies tested. Surprisingly again, rapid synaptic depression was abolished in IM-AA synapses at frequencies of 5-20 Hz and significantly slowed at 50 Hz**.** Altogether, our studies show that $Ca_V2.1$/CaS regulation is important for the balance of excitatory and inhibitory circuits, because prevention of CaS regulation slowed development of both facilitation and depression in these excitatory synapses while it only slowed depression in these inhibitory synapses.

Title: Pkc is not the ca sensor for ptp at ca1 synapses

Authors: *C.-C. WANG[1], C. WEYRER[1,2], M. PATURU[1], D. FIORAVANTE[1,3], W. REGEHR[1];
[1]Dept. of Neurobio., Harvard Med. Sch., Boston, MA; [2]Develop. & Neurosci., Univ. of Cambridge, Cambridge, MA; [3]Ctr. for Neurosci., Univ. of California at Davis, Davis, CA

Abstract: Post-tetanic potentiation (PTP) is a widespread form of short-term synaptic plasticity in which a period of elevated presynaptic activation leads to synaptic enhancement that lasts tens of seconds to minutes. A leading hypothesis for the mechanism of PTP is that tetanic stimulation elevates presynaptic calcium that in turn activates calcium-dependent Protein Kinase C (PKC) isoforms to phosphorylate targets and enhance neurotransmitter release. Previous pharmacological studies have implicated this mechanism in PTP at hippocampal synapses, but the results are controversial. Here we combine genetic and pharmacological approaches to determine the role of classic PKC isoforms in PTP. We find that PTP is unchanged in PKC triple knockout (TKO) mice in which all calcium-dependent PKC isoforms have been eliminated (PKCα, PKCβ, and PKCγ). We confirm previous studies and find that in wildtype mice 10 μM of the PKC inhibitor GF109203 eliminates PTP and the PKC activator PDBu enhances neurotransmitter release and occludes PTP. However, we find that the same concentrations of GF109203 and PDBu have similar effects in TKO animals. We also show that 2 μM GF109203 does not abolish PTP even though it inhibits the PDBu-dependent phosphorylation of PKC substrates. We conclude that at the CA3 to CA1 synapse Ca^{2+}-dependent PKC isoforms do not serve as calcium sensors to mediate PTP.

Title: Plasticity-dependent, full detonation at hippocampal mossy fiber-CA3 pyramidal neuron synapses

Authors: N. P. VYLETA[1,2], *C. BORGES-MERJANE[2], X. ZHANG[2], P. JONAS[2];
[1]Oregon Hlth. & Sci. Univ. - Vollum Inst., Portland, OR; [2]Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: “Detonator” or “teacher” synapses directly control the activity of postsynaptic targets in the absence of spatial summation. The hippocampal mossy fiber synapse on CA3 pyramidal neurons is thought to be a “conditional detonator” that discharges postsynaptic targets after repetitive activity (Henze et al., 2002, Nat. Neurosci. 5:790-795). The “conditional” status implies that burst activity in granule cells is strictly required for detonation. Whether a single action potential in a single mossy fiber bouton can trigger spikes in CA3 pyramidal neurons remains unknown. Presynaptic facilitation has been identified as a mechanism underlying conditional detonation. However, mossy fiber synapses also exhibit short-term synaptic enhancement with uniquely large and persistent post-tetanic potentiation (PTP). Here we investigated whether PTP could convert mossy fiber synapses from subdetonator into full detonator mode. In order to determine the efficacy of individual connections, we used our recently developed technique to selectively and noninvasively stimulate single mossy fiber presynaptic terminals (Vyleta et al., 2014, Science 343:665-670). Single mossy fiber terminals were stimulated in the tight-seal bouton-attached configuration and postsynaptic CA3 pyramidal neurons were simultaneously recorded in the whole-cell mode at ~33°. Bouton-attached stimulation enabled precise control of electrical activity, as verified by action currents in the presynaptic terminal. We first examined the properties of synaptic transmission evoked by single presynaptic action potentials. Single unitary EPSPs failed to reliably induce action potential initiation in postsynaptic CA3 pyramidal neurons under control conditions, with a mean probability of only 0.12 ± 0.08. We then measured the probability of postsynaptic action potential initiation before and after high-frequency stimulation (HFS, 100 stimuli delivered at 100 Hz), a paradigm that reliably induces PTP. Intriguingly, HFS substantially increased the probability of spiking for the first stimulus, from 0.14 ± 0.09 under control conditions to 0.71 ± 0.18 at the peak and to 0.51 ± 0.16 in a 100-s time window following HFS (22 to 122 s; 7 pairs; P = 0.03). The enhanced detonation decayed with a time constant of 67 s. Thus, PTP converted mossy fiber synapses from subdetonator into full detonator mode for an extended time period. In vivo recordings from awake head-fixed mice revealed that granule cells occasionally fire bursts of >10 action potentials during spatial navigation. Thus, plasticity-induced full detonation may play a role for information processing in the hippocampal network in vivo.

Title: State-dependent alteration in $K_v3.4$ channel availability drives flexible synaptic signaling dependent on somatic subthreshold depolarization

Authors: ***M. J. ROWAN**[1], M. LEITGES[2], J. M. CHRISTIE[1];
[1]Max Planck Florida Inst., Jupiter, FL; [2]The Biotech. Ctr. of Oslo, Univ. of Oslo, Oslo, Norway

Abstract: In many classes of neurons, electrotonic spread of subthreshold depolarizing potentials can reach distant presynaptic specializations in the axon resulting in enhancement of action potential (AP) evoked synaptic transmission. This analog-to-digital facilitation may involve modulation of voltage-gated channels involved in shaping the presynaptic AP, but has also been suggested to result from altered vesicular priming. Thus the molecular mechanisms contributing to analog facilitation of AP-evoked release remain unresolved. We used two-photon (2P) voltage-sensitive dye imaging, patch-clamp recordings from presynaptic boutons, overexpression of tagged voltage-gated channels and genetically modified mice to examine mechanisms contributing to analog signaling in the unmyelinated axons of molecular layer interneurons (MLIs) in the cerebellum. We find that subthreshold somatic depolarization spreads throughout a large extent of the axon arbor resulting in rapid broadening of APs at *en passant* boutons. However subthreshold depolarization did not alter AP duration at the axon initial segment (AIS), indicating a subcellular locus for this form of plasticity within MLI axons. We found that pharmacological blockade of K_v3 channels occluded AP broadening following subthreshold depolarization and, furthermore, that AP broadening was completely abolished in mice lacking rapidly inactivating $K_v3.4$ subunits. Nonuniform expression of axonal AP broadening was due to the segregated expression of $K_v3.4$ channels at presynaptic specializations and their absence in the AIS. Interestingly AP broadening varied considerably between nearby boutons within the same axon, likely due to heterogeneous densities of $K_v3.4$ among nearby

boutons. Following depolarization, wider presynaptic spikes resulted in greater AP-evoked Ca^{2+} influx at boutons and enhanced synaptic transmission. Previous work suggested analog enhancement of release was due to Ca^{2+}-dependent activation of PKC. However, analog enhancement of synaptic transmission was completely abolished in $K_v3.4$ KO mice but unaffected in mice lacking the three classical Ca^{2+}-dependent PKC isoforms (triple KO). Together our results indicate that analog-to-digital facilitation is due to changes in the presynaptic AP waveform in MLIs, and introduce a novel mechanism necessary for analog-to-digital facilitation in a GABAergic interneuron.

Title: Short-term synaptic depression can increase the information rate at a release site

Authors: *M. SALMASI[1,2,3], A. LOEBEL[6,4], S. GLASAUER[5,2,3,1,6], M. STEMMLER[6,4]; [1]Ctr. for Sensorimotor Res., [2]German Ctr. for Vertigo and Balance Disorders, [3]Grad. Sch. of Systemic Neurosciences, [4]Dept. of Biol. II, [5]Dept. of Neurol., Ludwig-Maximilian Univ., Munich, Germany; [6]Bernstein Ctr. for Computat. Neurosci., Munich, Germany

Abstract: Short-term synaptic depression is a ubiquitous feature of neuronal activity. A central functional role of depression is hypothesized to be the modulation of the synaptic information rate [1-3]. However, quantifying the mutual information rate of the overall synaptic transmission process in the presence of short-term dynamics is challenging. We consider therefore a bottom-up approach, and analytically calculate the information rate of a single synaptic release site in the presence of depression. The release site's response dynamics is captured by a general multi-state model, in which each state corresponds to a distinct binary asymmetric channel that depends on the previous *L* time steps of the release site's history (Fig. 1A). With each successful release, the spike-evoked and spontaneous release probabilities depress fractionally more; and in the quiescent intervals, in which no vesicle is released, the probabilities recover gradually back to their default values.
We prove that the mutual information rate of the release site with depression is equal to the statistical average over the information rates of all of its constituent states. We also calculate an

energy-normalized information rate measure, which considers the amount of energy consumed by each vesicle release. We show that depression can increase both the mutual and energy-normalized information rates of the release site, if the spontaneous release depresses more than the spike-evoked release. An additional regime of synaptic parameters exists for which depression increases the energy-normalized information rate, while the mutual information rate decreases (Fig. 1B). However, if spontaneous and spike-evoked release depress equally, depression *invariably* impairs the energy-normalized information rate of the release site. Equal depression would be the default assumption for the synapse. But this assumption implies that the biological system does not fulfill energy-efficient information transfer.

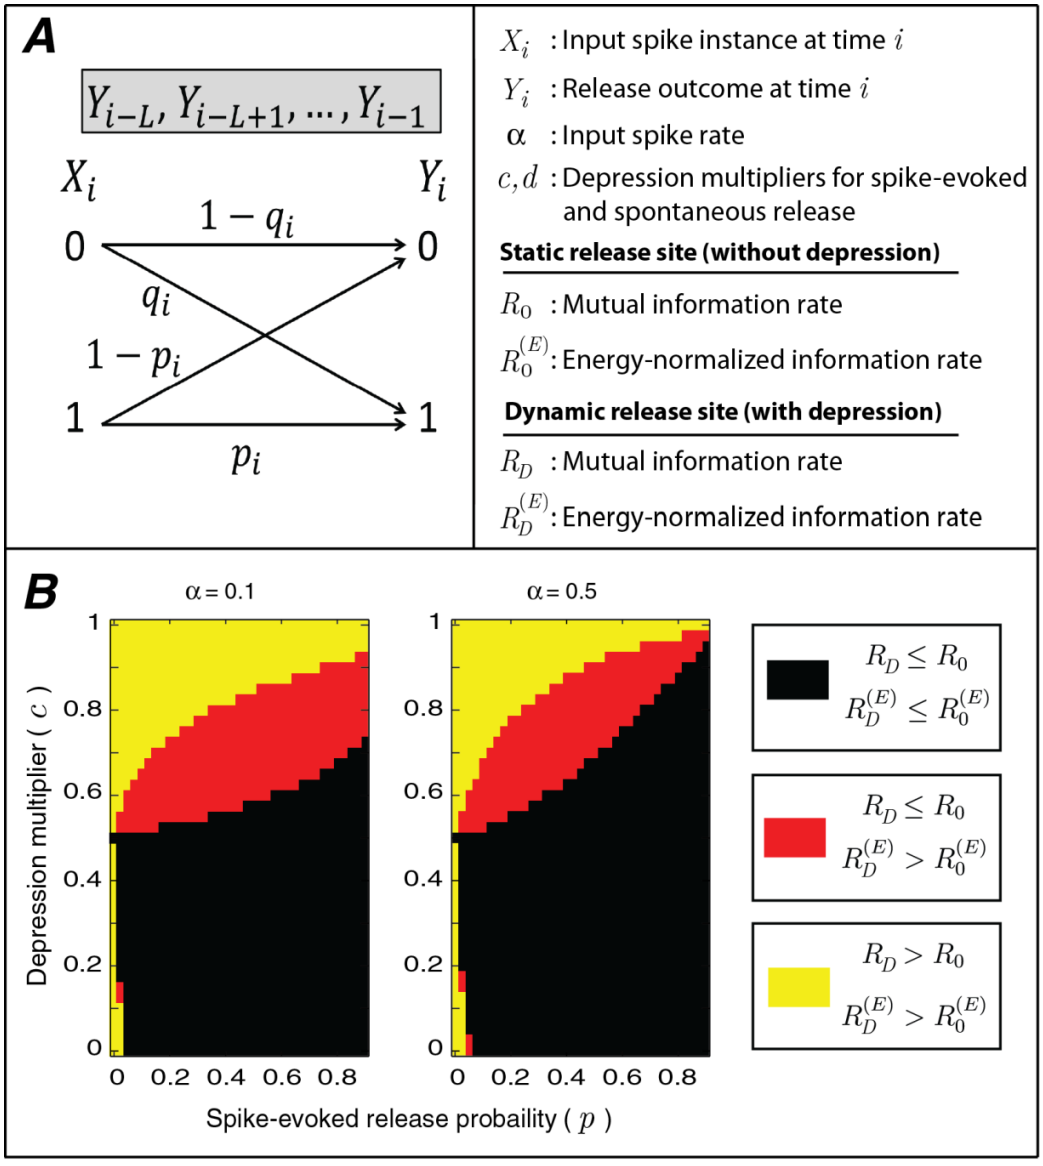

Figure 1: A) The dynamic release site (with depression) modeled by a binary asymmetric channel with memory. B) The impact of depression on the information rate and energy-normalized information rate of the release site. The depression multiplier of spontaneous release is fixed at d=0.5.

Title: Activity-dependent postsynaptic potentiation studied at the *Drosophila* larval neuromuscular junction

Authors: *A. S. POWERS, G. A. LNENICKA;
Dept. of Biology, SUNY Albany, Albany, NY

Abstract: Repetitive stimulation has been shown to produce various forms of synapse strengthening at the neuromuscular junction (NMJ). Early studies showed that these synaptic enhancements involved an increase in the quantal content of transmitter release and subsequent studies examined the role of presynaptic residual Ca^{2+} in NMJ plasticity. This differs from the CNS where long-term potentiation involves increased postsynaptic glutamate sensitivity and increased quantal current amplitude; these changes are triggered by an elevation in postsynaptic intracellular calcium concentration $[Ca^{2+}]_i$. We have found that the *Drosophila* larval NMJ also shows an activity-dependent increase in quantal current amplitude resulting from greater postsynaptic glutamate sensitivity and this plasticity is elicited by increased postsynaptic $[Ca^{2+}]_i$. Two-electrode voltage clamp was used to record spontaneous miniature excitatory postsynaptic currents (mEPSCs) before and after nerve stimulation. Experiments were performed on muscle fibers 5, 6 and 7 in wandering 3rd instar larvae. For these 3 fibers, nerve stimulation at 20 Hz for 1 minute resulted in a 70 to 150% increase in mEPSC charge transfer and 25 to 30 % increase in mEPSC amplitude . This increase in mEPSC size was expressed about 1 minute after nerve stimulation and persisted for at least 10 minutes. Ca^{2+} has been shown to enter through the postsynaptic glutamate receptors and we found that the increase in quantal currents was dependent upon an increase in postsynaptic $[Ca^{2+}]_i$. BAPTA was injected into muscle fiber 7 to buffer intracellular Ca^{2+}; a lower BAPTA concentration delayed the increase in mEPSC size and

a higher concentration eliminated it.
We iontophoresed glutamate at the NMJ to determine whether the increase in quantal currents was due to greater sensitivity of the postsynaptic membrane to glutamate. Using rapid perfusion, 15 ms glutamate pulses were applied at synaptic boutons on muscle fiber 4 and the pulse amplitude was adjusted to give glutamate evoked excitatory postsynaptic potentials (gEPSPs) of approximately 10 mV. Test pulses were applied at 0.2 Hz then conditioning pulses were delivered at 10 Hz for 1 minute followed again by test pulses. As a result of conditioning, the gEPSP amplitude increased by 70% and there was no increase in postsynaptic membrane resistance. The increase in gEPSP amplitude resulted from an increase in postsynaptic $[Ca^{2+}]_i$ since adding EGTA to the bath blocked the increase in gEPSP amplitude . These results demonstrate an activity-dependent postsynaptic potentiation at the NMJ that has features in common with synapse strengthening seen in the CNS

Abstract: PURPOSE Associative stimulation, or synchronized input from different pathways, induces long-term potentiation and long-term depression in a manner consistent with Hebbian plasticity. We have reported that kinesthetic illusion induced by visual stimulation (KiNVIS) increases corticospinal tract excitability via association fibers. The present study investigated whether the associative stimuli of KiNVIS and peripheral nerve stimulation (PENS) could induce sustained excitability changes in the corticospinal tract. METHODS Ten healthy young subjects participated in this experiment. The subjects were instructed to be fully relaxed during the

intervention. PENS was applied to the ulnar nerve as the interventional stimulus during KiNVIS. To induce KiNVIS, a movie of index finger movement was presented on the display which covered the subject's actual hand. The spatial position on the display was adjusted until the subject reported feeling as though the on-screen hand was their own. PENS was applied at the point at which the index finger flexed maximally in the movie. PENS was delivered to the right ulnar nerve at the wrist at 300% of the perceptual threshold; however, we altered intensity to 90% of the motor threshold if the perceptual threshold exceeded the motor threshold. The associative stimulation of KiNVIS and PENS was delivered for 15 minutes (3 sets x 5 minutes). Paired-pulse transcranial magnetic stimulation (TMS) and Single-TMS (SgTMS) were used to assess corticospinal excitability and short-interval intracortical inhibition (SICI). We recorded MEP from the right first dorsal interosseous (FDI) muscle and the abductor digiti minimi (ADM) muscle. TMS was applied at the optimal site for eliciting MEP from the right FDI. The intensity of SgTMS and the test intensity of paired-pulse TMS were adjusted to elicit a MEP of approximately 1 mV in amplitude. The conditioning stimulus intensity was 80% of the active motor threshold. The paired-pulse TMS inter-stimulus interval was 2 and 3 ms. MEP was measured twice before the intervention, immediately after the intervention, and 20, 40, 60, and 80 minutes after stimulation. MEP amplitude and SICI were presented as relative values based on before. RESULTS MEP amplitude of the FDI was significantly larger until 60 minutes after stimulation, whereas there were no significant differences in the ADM. There were no significant differences in SICI. CONCLUSIONS These findings indicated that associative stimulation of KiNVIS and PENS can induce a sustained enhancement of corticospinal tract excitability.

Title: Depolarization-induced suppression of inhibition in the lateral septum

Authors: *J. M. POWER, K. MOODLEY, A. HARASTA, M. KLUGMANN;
Translational Neurosci. Facility & Dept. of Physiol., UNSW Australia, Sydney, Australia

Abstract: The lateral septum (LS) provides context dependent regulation of mood and motivated behaviour. The majority of neurons in the LS are GABAergic projection neurons that integrate excitatory inputs from hippocampus and send feedforward inhibitory projections to a host of limbic, diencephalic and midbrain regions that control goal-directed, stress, and consumption

behaviours. LS neurons also provide strong feedback inhibition of other LS neurons through extensive local circuit connections. In many brain regions, inhibitory synaptic transmission is transiently suppressed by endocannabinoids released by depolarization-induced calcium influx in post synaptic neurons. Cannabinoid type 1 (CB1) receptors are highly expressed in the LS, however depolarisation-induced suppression of inhibition (DSI) has not been demonstrated in the LS. To resolve this, whole cell patch clamp recordings were made from LS neurons in brain slices prepared from C57Bl/6J mice (4-6 weeks). Pharmacologically isolated inhibitory postsynaptic currents (IPSCs) were readily evoked by a stimulating electrode positioned locally in the LS. Brief depolarization of the post-synaptic neuron (3.5s step from -70 mV to 0 mV) transiently suppressed the IPSC by 18 ± 10% (n=10). DSI was associated with an increase in the paired pulse ratio, indicative of a decrease in the transmitter release probability. No DSI was observed in presence of CB1 cannabinoid receptor antagonists AM251 (4 ± 3%; n=9) or SR141716A (-2 ± 4 %; n=7). These data confirm the existence of cannabinoid-mediated DSI in the LS.

Abstract: Lysine-specific demethylase 1 (LSD1) is a flavin adenine dinucleotide-dependent histone demethylase and participates in gene repression or activation. Recent studies reported that LSD1 inhibition by chemical inhibitors blocked memory consolidation and LSD1 phosphorylation by PKCα was implicated in circadian rhythmicity independently of its demethylase activity. However, the effect of LSD1 phosphorylation by PKCα on learning and

memory is largely unknown. In this study, we examined the roles of LSD1 in cognition using LSD1 knock-in (KI) mice, in which a PKCα phosphorylation site was mutated. LSD1 KI mice showed partially decreased anxiety and increased locomotion. Interestingly, short-term and long-term contextual fear memory as well as spatial learning and memory in the Morris water maze were impaired in LSD1 KI mice. Extracellular field recordings from Schaffer collateral-CA1 pathways showed that short-term synaptic plasticity such as paired pulse ratio and post-tetanic potentiation was significantly reduced in LSD1 KI mice compared to wild-type littermates whereas long-term synaptic plasticity including long-term potentiation and long-term depression were normal. Moreover, the frequency of miniature EPSC was significantly increased but the amplitude was not changed in LSD1 KI mice, suggesting presynaptic dysfunction in LSD1 KI mice. Consistently, RNA-seq analysis showed that gene expression related to the presynaptic vesicle release was significantly upregulated in LSD1 KI mice. These results suggest that LSD1 plays an important role in hippocampus-dependent learning and memory through presynaptic dysfunction. C.-S. Lim and J. Lee contributed equally to this work.

Title: Time and intensity determine the effect of downslope walking on soleus but not tibialis anterior H-reflexes

Authors: *M. SABATIER[1], E. ARNOLD[2], T. RIGEL[2], D. LEE[2], B. FARMER[2], M. KEIGHTEY[2], M. HOQUE[2];
[1]Rehabil. Med., [2]Emory Univ., Atlanta, GA

Abstract: We recently found that a 20-min bout of downslope walking (DSW) at 2.5 mph and -15% slope results in acute soleus (Sol) H-reflex depression. The purpose of this study was to determine if 1) DSW-mediated H-reflex depression, previously found only in the Sol, also occurs

in the tibialis anterior (TA), and 2) the effect of DSW on H-reflexes depends on walking time (i.e., duration) or intensity (i.e., slope steepness). Sol and TA H-reflexes were measured before and after DSW at 2.5 mph in fourteen healthy adults on four days. Four DSW time-intensity combinations were used: 10 and 20 mins at -15%, 10 and 20 mins at -25%. Ten participants completed level walking (LW) for 20 mins at 2.5 mph. Sol and TA H-reflex and M-wave recruitment curves were collected while participants maintained EMG background activity at 20% of max. The H-reflex was expressed as H_{max}/M_{max}. Sol H_{max}/M_{max} depression after 10 mins of DSW at -15% was not significantly different from depression after 20 mins of LW (P=0.61), but Sol H_{max}/M_{max} depression after DSW for 20 mins at -15% (-30 ± 21%), 10 mins at -25% (-31 ± 22%), and 20 mins at -25% (-32 ± 23%) was significantly greater than Sol H_{max}/M_{max} depression after both LW for 20 mins (9 ± 15%, $P \leq 0.02$) and DSW for 10 mins at -15% ($P \leq 0.04$). Therefore, more H-reflex depression resulted from DSW than from LW if the duration was at least 20 mins at -15% slope, or if the slope was -25%. Neither LW nor DSW had an effect on TA H-reflexes. Thus, 10 mins of DSW is insufficient, if the slope is -15%, to cause more H-reflex depression than LW for 20 mins, but both 10 and 20 mins at -25% DSW cause significantly more H-reflex depression than LW for 20 mins. However, H-reflex depression found after LW and DSW for the Sol does not extend to the TA. Therefore, DSW-mediated H-reflex depression is muscle-group specific and determined by walking time and intensity. These findings further our understanding of how to tailor DSW as a neuromodulatory methodology to target spinal plasticity, and could guide future efforts in rehabilitation science to induce durable spinal plasticity.

Title: Kainate Receptors gating modulates the receptor diffusion at glutamatergic synapses

Authors: ***A. I. POLENGHI**[1], P. GOROSTIZA[2], A. BARBERIS[1];
[1]Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [2]Inst. of Bioengeneering of Catalonia, Barcelona, Spain

Abstract: The lateral mobility of neurotransmitter receptors is a crucial determinant for the fine tuning of the number of the receptors at the post-synaptic site and, consequently, for the

modulation of synaptic strength. Although a considerable effort has been made to characterize the role of lateral diffusion in the control of neuronal network activity, the relation between the conformational state and the mobility of the receptors is poorly investigated. To address this issue, we manipulated the conformational states of glutamate receptors with light by using Photoswitched Tethered Ligands. In particular, we took advantage of engineered glutamate receptors (LiGluK2Rs) in which a molecular photoswitch operates the glutamate binding and unbinding upon azobenzene *cis/trans* photoisomerization, obtained by illumination with 380 nm and >460 nm light, respectively. By combining the use of LiGluK2 with the single particle tracking technique, we studied the receptor lateral diffusion in controlled LiGluK2 conformational states. We report that transition into desensitization of LiGluK2 receptors markedly and reversibly immobilized receptors at excitatory synapses. In contrast, desensitization did not alter the lateral mobility of extrasynaptic LiGluK2Rs, thus suggesting that this phenomenon is selective for synaptic receptors. Next, we assessed whether the light-induced immobilization of desensitized LiGluK2Rs might be due to the increase of intracellular Ca^{2+} induced by LiGluK2Rs activation. Interestingly, the suppression of the Ca^{2+} permeability of LiGluK2 and the block of the principal sources of intracellular calcium increase did not affect the immobilization of desensitized LiGluK2Rs at synapses. We hypothesized that the trapping of synaptic LiGluK2Rs could be due to altered interactions between scaffold proteins at excitatory synapses and receptors in the desensitized state. To this end, we generated two mutant forms of LiGluK2, lacking of the PDZ binding domain or the β-catenin/N-Cadherin interaction domain. Interestingly, we found that the deletion of the β-catenin/N-Cadherin domain completely abolished the desensitization-induced trapping of LiGluK2 at synapses. To further confirm this result, the use of a dominant-negative form of Delta-N-cadherin prevented the immobilization of synaptic LiGluK2Rs in the desensitized state. We propose here that the conformational changes occurring during transition into desensitization may strengthen the interactions between receptors and specific scaffold proteins, thus leading to the trapping of LiGluK2Rs at excitatory synapses.

Title: Short-term synaptic plasticity within rat thalamocortical circuitry

Authors: *K. R. LOUIS, J. A. BEATTY, C. L. COX;
Michigan State Univ., East Lansing, MI

Abstract: It is well established that information transfer within thalamocortical circuits is dynamically regulated. Considering that tetanic activation of afferent pathways can lead to alterations in synaptic efficacy in many brain regions (i.e., long-term potentiation, long-term depression, and spike-timing dependent plasticity), we carried out a series of experiments to determine if similar forms of plasticity occur in thalamocortical circuits. Whole-cell recordings were obtained from thalamocortical relay neurons in the ventrobasal nucleus (VB). The induction protocol involves tetanic electrical stimulation of corticothalamic afferents (5 pulses at 100Hz, repeated 400 times at 2Hz). This stimulation protocol produced a short-term (10-15 minutes) facilitation of the excitatory postsynaptic current (EPSC) amplitude in 31 of 42 neurons. Using paired-pulse stimulation (100 ms interval), the induction protocol produced a decrease in the paired-pulse ratio, consistent with a presynaptic mechanism. In addition, the potentiation is calcium-dependent, because the enhancement was absent in calcium-free physiological solution. Activation of adenylyl cyclase by forskolin mimicked the potentiation and occluded the subsequent train-induced potentiation indicating the role of the adenylyl cyclase pathway. The adenylyl cyclase inhibitor, SQ22536, significantly reduced the potentiation. Furthermore, the K^+ channel blockers tetraethylammonium chloride (TEA) and 4-aminopyradine (4-AP) attenuated the potentiation, indicating the role of K^+ channels in the potentiation. These data suggest that tetanic activation of corticothalamic afferents activates the adenylyl cyclase pathway, leading to alterations in K^+ conductances that ultimately enhances neurotransmitter release. This potentiation could provide a mechanism through which corticothalamic activity could impact and regulate information processing through thalamocortical circuits.

Title: Activation of $GABA_A$-receptors by high-frequency stimuli causes paired burst facilitations in area CA1 of the hippocampal slice

Authors: *T. TOMINAGA, Y. TOMINAGA;
Inst. of Neuroscience, Tokushima Bunri Univ., Sanuki, KAGAWA, Japan

Abstract: The cross-frequency interaction of oscillatory brain activity is thought to have a critical role in animal behavior. In particular, the gamma (25-100 Hz) - theta (4-8 Hz) coupling is considered to have an important computational role in the hippocampus system. During in vitro preparation, a stimulation protocol that mimics the coupled oscillation theta burst stimulation (TBS) is used to induce long-term potentiation (LTP). However, little is known about the mechanism and role of the coupling. Using electrophysiology and voltage-sensitive dye imaging (VSDI), we found that TBS induces the augmentation of spike firing. The augmentation can be induced with only the first pair of TBS, i.e., a pair of short 100 Hz bursts of stimulation intermitted with 170 ms. In this study, we focused on the characteristics of the augmentation caused by a pair of brief bursts of stimulation (paired burst stimulation, or PBS). We found that PBS enhanced membrane potential responses on VSDI signals and intracellular recordings when it was absent in the current recording under whole-cell clamp conditions. The enhancement of the response accompanied the augmentation of the excitatory postsynaptic potential (epsp) to spike firing (E-S) coupling. The paired-burst facilitation (PBF) reaches a plateau when the number of the first burst stimulations (priming burst) exceeds three. Also, the augmentation was seen only after the third and fourth stimulus in the following test burst. Thus, the augmentation always needs a pair of bursts. The interval between the bursts of 150 ms resulted in the maximum PBF. Gabazine (a GABAA receptor antagonist) abolished the PBF. The threshold for the spike generation of the postsynaptic cells measured with a current injection to cells was not lowered by the priming burst of PBS. These results indicate that PBS activates the GABAergic inhibitory system to cause short-term E-S augmentation without raising postsynaptic excitability. The whole cell current of the GABAergic current shows a longer time constant when the stimulation is applied in the bursting form. We propose that a GABAergic inhibitory system of area CA1 of the hippocampus produces the short-term E-S plasticity that could cause exaggerated spike-firing upon a theta-gamma activity distinctively, thus making the neural circuit of the CA1 act as a specific transmitter of the specific oscillation signal.

Title: Influence of single session aerobic exercise on trafficking of receptors involved in neuroplasticity

Authors: *J. S. THACKER[1], W. R. STAINES[1], J. G. MIELKE[2];
[1]Kinesiology, [2]Sch. of Publ. Hlth. and Hlth. Systems, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: The priming of motor cortex to facilitate plasticity is an approach that may improve motor rehabilitation following injury. Emerging evidence supports the possibility that aerobic exercise may offer one means to achieve priming, however, the mechanisms whereby priming may occur following an acute bout of aerobic exercise are not clear. Although one popular hypothesis stems from data displaying robust increases in neurotransmitter and neurotrophic factor release in brain during and after exercise, this phenomenon appears broadly, and may not alone explain changes occurring within specific regions, such as motor cortex. An alternate explanation may be related to the migration of receptors towards synaptic densities, which has been shown to play a key role in plasticity. Possibly, aerobic exercise may prime neuroplasticity through both increased neurotransmitter/neurotrophic release and the reorganization of the synaptic receptor population, and we sought to investigate the latter option. Specifically, we hypothesized that a single session of exercise would promote the trafficking of plasticity related receptors (AMPA receptor/NMDA receptor/TrkB; BDNF receptor) to synaptic terminals, and that this change in their cellular distribution would act as a molecular mechanism for priming of motor cortex. Young, male Sprague-Dawley rats (n = 18) on a reverse light cycle (12h/12h) were exposed to a gradual treadmill acclimatization procedure lasting 8 days (10 m/min up to 25 m/min) for 10 minutes at the same time (10 am) each day. Acclimatization was followed by 2 days of rest to reduce any carryover effects. On testing day, rats were separated into either exercise (exhaustion/steady state moderate), or non-exercising groups. Immediately following exercise, rats were sacrificed and tissue slices prepared from both the motor cortex and hippocampus. Surface proteins were labelled by incubating slices in biotin. After homogenization, synaptoneurosomes were prepared (to enrich pre/post-synaptic terminals), and then proteins at the synaptic membrane were isolated by incubation with neutravidin beads. We plan to probe all surface synaptic fractions for proteins of interest by Western blotting analysis. The work in progress aims to establish that a single session of aerobic exercise is sufficient to promote a “primed” state within motor cortex by influencing the trafficking of a particular set of plasticity-related receptors.

Title: Synapse labelling by PSD95FingR-GFP intrabody does not affect LTP induced by glutamate uncaging in single spines

Authors: *N. OTMAKHOV, J. LISMAN;
Biol. Department, Volen CCS, Brandeis Univ., Waltham, MA

Abstract: Labeling of synaptic proteins by fluorescent expressible proteins is a valuable tool for investigation of synapse growth during synaptic plasticity in real time in living cells. Previous work, however, showed that overexpression of synaptic proteins such as PSD95 fused with fluorescent proteins (GFP) can by itself produce synapse/spine growth, a growth that can preclude further induction of LTP. Recently a new approach was developed for labelling PSD95 by antibody-like expressible proteins such as PSD95FingR-GFP intrabodies (Gross et al., 2013). This approach was shown to accurately mark localization of the endogenous PSD95 without altering spine density or the amplitude/frequency of mEPSPs. What has not been tested is whether this type of labeling alters synaptic plasticity processes such as LTP. Here we expressed PSD95FingR-GFP intrabody together with mCherry (as cell volume marker) in hippocampal pyramidal CA1 neurons in slice cultures. Structural LTP (sLTP) in single dendritic spines was induced by 2-photon glutamate uncaging and estimated by a sustained increase in spine volume measured by two-photon imaging of mCherry. As a control, single spine sLTP in neurons expressing untagged GFP was measured in interleaved experiments. PSD95FingR-GFP intrabody expression was strongly enriched in spines. Glutamate uncaging produced significant initial spine growth which was stabilized at steady state level of 180% at 60 min after induction ($n = 20$) which was not significantly different from sLTP induced in GFP labelled cells ($n = 5$, $P > 0.05$). Interestingly, total PSD95FingR-GFP fluorescence in spines transiently increased (40% for < 15 min) with the initial phase of spine growth and remained slightly above the baseline during the steady state phase of LTP. The calculated bound pool of the PSD95FingR-GFP, however, transiently decreased (20% for < 10min) after uncaging and remained at the baseline

for at least 60 min after sLTP induction. We conclude that synaptic labelling by PSD95FingR-GFP intrabody does not alter sLTP for at least 60 min. Currently, we exploring a possibility to use PSD95FingR-GFP labelling for measuring synapse growth during late phase of sLTP.

Title: Measuring cannabinoid-induced presynaptic structural plasticity by 3D 2-color STORM nanoscopy

Authors: M. H. MCFADDEN[1], C. LETERRIER[2], *D. ZALA[1], Z. LENKEI[1];
[1]Brain Plasticity Unit, ESPCI ParisTech, PSL, UMR8249, Paris, France; [2]Crn2m cnrs umr 7286, Aix Marseille Univ., Marseille, France

Abstract: The endocannabinoid system is an important regulator of functional plasticity within the mammalian brain and has now long been associated to both long and short term forms of synaptic plasticity, both essential for learning and memory. Recent findings have suggested, using electron microscopy, that this functional plasticity may be a direct effect of structural reorganization of the presynaptic compartment following activation of the cannabinoid type 1 receptor (CB1R), the main cannabinoid receptor in the mammalian brain. Given these findings, we are currently investigating the structural relationship between the different presynaptic elements that may be affected by CB1R activation. As presynaptic boutons are relatively minute in size, measuring on average about 1μm^3, the structural changes expected to occur under CB1R activation are on the nanometer scale. For this reason, we have chosen to resort to STORM nanoscopy, one of the most resolved microscopy techniques currently available. Using 3D 2-color STORM and immunostaining for different vesicle markers and synaptic scaffolding proteins, we are now able to measure the nanoscale relationship between synaptic vesicles, the presynaptic active zone and the postsynaptic scaffold and observe cannabinoid-induced nanoscale reorganization of these elements. Furthermore, given the computationally intensive nature of STORM localization measurements, we are developing a user-friendly technique for

rapidly measuring spatial relationships within chosen ROIs of 3D 2-color STORM images by integrating currently available STORM data processing ImageJ plugins.

Title: Using the lipophilic dye DiI to study dendritic spine alterations in hippocampal slices

Authors: *J. S. TRIVINO PAREDES[1], P. C. NAHIRNEY[1,2,3], B. R. CHRISTIE[1,2,3];
[1]Div. of Med. Sci., [2]Dept. of Biol., Univ. of Victoria, Victoria, BC, Canada; [3]Dept. of Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The hippocampus is a key brain structure involved in learning and memory, and has been used as a model structure for studying synaptic plasticity, a biological model for learning and memory processes. In many studies, hippocampal slices are widely used for *in vitro* electrophysiological experiments to study the cellular mechanisms involved in synaptic transmission and plasticity. To optimize slice viability and hopefully recapitulate *in vivo* physiological conditions *in vitro*, a number of variables, including: age of the animal; composition of the artificial cerebrospinal fluid (aCSF); temperature; and slice cutting methodology are taken into consideration. However, previous studies using electron microscopy and two-photon microscopy approaches have reported that dendritic spines, neuronal structures crucial to the process of excitatory synaptic transmission, are dramatically altered as compared to those normally observed in perfusion-fixed slices. These alterations in dendritic spines could represent a serious confound for *ex vivo* work, and lead to the results that vary markedly from *in vivo* electrophysiological experiments. In these experiments, we employed the lipophilic carbocyanine dye 1,1'-Dioctadecyl-3,3,3',3'-Tetramethylindocarbocyanine Perchlorate (DiI) in combination with confocal microscopy to compare dendritic spine density in the *Cornu Ammonis 1* and *Dentate Gyrus* areas in perfusion-fixed slices and slices prepared for *in vitro* recordings. We found that in both young and adult Sprague-Dawley rats there was an increase in dendritic spine density in slices prepared for *in vitro* recordings. These results in conjunction with observations in previous studies highlights the fact that slicing-induced spinogenesis is an important factor to take into consideration when studying functional and structural plasticity.

Title: The k63 linkage-specific deubiquitinase cyld regulates synapse formation, remodeling, and plasticity

Authors: ***E. M. ZAJICEK**, Q. MA, H. RUAN, W. BURNETTE, W.-D. YAO;
SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Lysine-63 (K63) linked ubiquitin chains are primarily non-proteasomal, and their exact role is not well understood in the mammalian brain. However, they are known to play a key role in various immune signaling functions and diseases. CYLD is a K63-linkage-specific deubiquitinase that has been extensively studied in the immune system for its role in NFκB signaling and the development of cylindromatosis (turban tumor syndrome) in humans. Recent evidence, however, has shown that CYLD is abundant in the brain, especially in the postsynaptic density (PSD) of excitatory synapses, and is recruited to the PSD following neuronal activity. We propose that K63 ubiquitin chains, as well as their ubiquitin and deubiquitinating enzymes, play a role in the regulation of synaptic development, maintenance, and plasticity. To test this hypothesis, we employed a series of molecular, behavioral, and electrophysiology experiments. Preliminary results indicate that CYLD plays an important role in the regulation of synaptic receptor subunits and morphological remodeling of dendritic spines in cultured hippocampal neurons. Preliminary experiments also suggested alterations in learning, memory, reward and other behaviors in mice lacking CYLD. Further work will be done to confirm the functional role of CYLD and K63 linked ubiquitin chains and to identify the mechanism of action.

Abstract: The PNN is a specialized form of extracellular matrix, initially deposited around selected neurons during critical periods of development in specific parts of the brain, interrupted by holes where synapses occur. We postulate that the PNN comprises a longer-lived structural template and that new memories are created by cutting new holes in the PNN or by expanding existing holes to enable formation of new synapses or to strengthen existing ones. A basic premise of this hypothesis is that the PNN, should undergo very low metabolic renewal from the first age at which memories are retained until senescence, whereas the active constituents of synapses turn over much more frequently and would therefore be poorer substrates for permanent information storage, unless they are equipped with incredibly accurate copying mechanisms (R.Y.Tsien PNAS 2013). We continue to examine this hypothesis using several experimental approaches: 1. Using ^{15}N Spirulina diet for Stable Isotope Labeling in Mammals (SILAM) we compare the lifetimes of PNN proteins vs. intra-synaptic components in Enriched Environment (EE) vs. Conventional Cages (CC), ending the pulse-case by changing to ^{14}N diet at P45 vs. P21, in four different brain areas. Analysis by Multidimensional Protein Identification Technology (MudPIT) indicate: a. Low turnover rate for PNN proteins while synaptic proteins were at the noise level of $^{15}N/^{14}N$ ratio. b. Higher turnover of PNN proteins in EE vs. CC cages c. Lower $^{15}N/^{14}N$ ratio when the pulse chase was terminated at P21 vs. P45 (i.e. before vs. after the closure of many critical periods). d. Variability in the retention of ^{15}N in PNN proteins between brain areas. 2. 2D EM and 3D volumes of Serial Block Face Scanning EM reveal that neurons engulfed in PNN labeled with WFA have more than 95% of their plasma membrane surface occupied by PNN or synapses. 3. The role and timing of matrix metalloproteinase (MMP) activity in memory consolidation using pharmacological inhibitors in a fear-conditioning

paradigm. Our results demonstrate that MMP inhibition during fear conditioning training: a. Does not affect acquisition. b. Significantly impairs long-term memory (30 days). c. Is dose dependent. d. Memory impairment increases with time. 4. Mapping PNN location in mouse brain tissues to test correlation between regions that are known to take a role in very-long-term memory and high density of PNN engulfed neurons.

Title: sAPPα and sAPPβ increase structural complexity and synapse generation in primary hippocampal neurons by altering Ca^{2+} homeostasis

Authors: ***R. HESSE**[1], D. FERNÁNDEZ-FERNÁNDEZ[2], K. J. FOEHR[3], K. KROKER[2], D. SCHWANZAR[1], H. ROSENBROCK[2], C. A. F. VON ARNIM[1];

Abstract: Amyloid-β (Aβ) generation from its precursor (APP) is either prevented or promoted, depending on the APP cleavage pathway. In Alzheimer's disease (AD) patients APP cleavage is shifted towards the amyloidogenic pathway. Aβ is known to have severe impact on synaptic function, however much less is known about the physiological functions of APP. The neurotrophic properties of sAPPα are well-established, whereas only few and conflicting studies on sAPPβ function exist. The cellular mechanisms of sAPP functions are largely unknown. Since the main domains involved in neurotrophic functions of sAPPα are also present in sAPPβ we performed a head-to-head comparison of both mammalian recombinant peptides in primary hippocampal neurons (PHN). Binding assays revealed a co-localisation of exogenous applied sAPP with MAP-2 in PHN. We found that sAPPα significantly increase axonlength (p=0.0002) and that sAPPα and sAPPβ increase neurite number (p<0.0001) of PHN at DIV7 but not at DIV4. Moreover both sAPPα and sAPPβ treated neurons showed a higher neuritic complexity in Sholl analysis. Number of glutamatergic synapses (p<0.0001), as well as layer thickness of

PSDs, are significantly increased upon sAPP overexpression in PHN. Although sAPP pre-treatment of PHN elevated glutamate sensitivity of PHN (p<0.05) analysed by Calcium-Imaging, glutamate-induced currents are not affected by sAPP overexpression. Taken together our results indicate that sAPPα as well as sAPPβ have critical stage-dependent roles in neuronal development by increasing glutamate sensitivity, but do not alter synaptic activity.

Title: Rapid postsynaptic cAMP signaling regulates structural and functional potentiation underlying learning and memory

Authors: *T. LUYBEN[1,2], J. BOROVAC[2], M. VALENCIA[2], M. KHAN[1], T. TOMINAGA[3], K. OKAMOTO[1,2];

Abstract: Functional and structural modifications of dendritic spines are tightly correlated and play an essential role in synaptic plasticity. Postsynaptic cAMP signaling is crucial for an enhancement of synaptic function such as the protein synthesis-dependent late phase of long-term potentiation (L-LTP). However, the role of cAMP in the structural change of synapses remains elusive. Here we provide evidence for a rapid postsynaptic cAMP/PKA function in structural potentiation of dendritic spines (sLTP) without protein synthesis signaling. By monitoring postsynaptic cAMP dynamics during LTP using two-photon FRET microscopy, we detected NMDA receptor-dependent transient cAMP production in dendritic spines and the dendrite during L-LTP induction, but not the early-phase (E-LTP). This demonstrated the presence of postsynaptic cAMP signaling in L-LTP but not E-LTP. Next, to address the function of cAMP in structural plasticity, we induced L-LTP by tetanic stimulation and generated sLTP at a neighbouring unaffected spine on the same neuron. We found a prolonged spine enlargement during sLTP following neighboring synapse L-LTP induction that could be blocked by a PKA inhibitor, suggesting a role for cAMP in sLTP. We also mimicked cAMP production by two-photon photoactivation of photoactivatable adenylyl cyclase (PAC) at single spines, and found the cAMP/PKA function in sLTP did not require either new protein synthesis or

hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. It was necessary to produce cAMP within a 1 min time window after sLTP induction, suggesting rapid cAMP signaling is involved in the regulation of sLTP. In addition to the structural function, we also found that the rapid postsynaptic cAMP enhanced synaptic function after LTP induction by employing voltage-sensitive dye (VSD) imaging and field recording methods. We will discuss rapid and new protein synthesis independent cAMP function and mechanism in structural and functional plasticity underlying learning and memory.

Title: Imaging the activity of classic protein kinase C isozymes during single spine structural plasticity

Authors: *L. A. COLGAN, P. PARRA-BUENO, R. YASUDA;
Max Planck Florida Inst., Jupiter, FL

Abstract: Synaptic plasticity is mediated by complex signaling cascades that transduce short-lived calcium inputs into long-lasting changes of synaptic strength. Classic protein kinase C (PKC) isozymes, which are activated by both calcium and lipid signaling to phosphorylate downstream targets, are well suited to play a role in this process. However, limitations in current approaches have impeded our understanding of the specific role of these PKC isozymes in plasticity. To determine whether classic PKC isozymes are required for plasticity, isozyme-specific PKC knockout animals were screened for plasticity deficits. Only disruption of PKCa function resulted in structural plasticity deficits which could be rescued by expression of PKCa, but not by other classic isozymes PKCb or PKCg, suggesting specificity of isozyme signaling even amongst these closely related isozymes. To further study the role of PKCa signaling in plasticity, we developed optical sensors to measure the isozyme-specific activity of classic PKCs during the induction of plasticity in single spines. In response to glutamate release PKCa was

robustly activated in a rapid and transient manner, with kinetics that differed from PKCb and PKCg activity. With each release of glutamate, PKCa translocated to the membrane and bound substrate. Maximal activation required both NMDAR activation as activation of PLC lipid signals, suggesting that PKCa serves as a coincidence detector of these canonical plasticity pathways. Consistent with these findings, PKCa KO animals show impaired long-term potentiation and deficits in spatial learning.

Title: A novel *Drosophila* protein regulates apposition of the active zones and postsynaptic densities.

Authors: *A. M. BUCKLEY-SHAW, R. NATARAJAN, Y. WAIRKAR;
Neurol., Univ. of Texas Med. Br., Galveston, TX

Abstract: The synapse is the fundamental link for communication amongst neurons. Formation and function of neural circuitry, learning, as well as storage and retrieval of memories are all dependent on transfer of information via the synapses. Indeed, synaptic dysfunction may underlie many of the neurodevelopmental and neurodegenerative disorders, including Autism Spectrum disorder (ASD) and Alzheimer's disease. One of the key aspects of efficacious synaptic transmission is the apposition of presynaptic active zones with the postsynaptic densities. Therefore, understanding how normal apposition of the presynaptic active zones and the postsynaptic densities is crucial to understand how fast neurotransmission at the synapse is accomplished. However, very few molecules are known that regulate the apposition of active zones and postsynaptic densities. To seek more molecules and to thereby, better understand the process of synaptic apposition, we performed a large-scale screen at the *Drosophila* NMJ synapses. Using the marker for active zones (BRP) and postsynaptic densities (DGLURIII), we

screened a collection of P-element mutations and found one gene that showed a change in the apposition of synapses. Our preliminary data with this novel gene will be presented.

Title: Ultrastructural examination of synapses following channelrhodopsin2-induced long-term potentiation

Authors: ***M. KUWAJIMA**[1], G. CAO[1], B. L. KAJS[1], K. M. HARRIS[2], B. V. ZEMELMAN[2]; [1]Ctr. for Learning & Memory, [2]Ctr. for Learning & Memory, Dept Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: A longstanding question in neuroscience concerns the cellular mechanisms of learning and memory. Addressing this question requires substantial improvement in our ability to identify the synapses involved. It is then possible to examine the functional, cellular, and molecular processes that have been engaged by learning or cellular models of learning such as long-term potentiation (LTP). Unequivocal detection of changes in synapses and their subcellular components requires (1) confidence that specific synapses have been potentiated, and (2) their three-dimensional reconstruction from serial section electron microscopy (3DEM). We re-engineered a genetically encoded EM tag based on the plant ascorbate peroxidase (APEX2; Lam et al., 2015, Nat Methods 12:51-4) to optimize its expression and targeting in neurons, leading to enhanced contrast for 3DEM. (We refer to our re-engineered enzyme as mAPEX2.) An adeno-associated virus (AAV) vector was constructed to co-express mAPEX2 with Chr2-EGFP

(channelrhodopsin2, ET/TC variant) as two proteins separated by the self-cleaving 2A peptide (P2A) from porcine teschovirus. The virus was injected unilaterally into the hippocampal area CA3 of adult mice. One group of AAV-injected mice was used to test mAPEX2 function. After perfusion-fixation with 2.5% glutaraldehyde and 2% formaldehyde, AAV-infected neurons were visualized successfully with nickel-enhanced diaminobenzidine (Ni-DAB), which resulted in electron-dense deposits in mAPEX2-expressing axons. Their visualization through serial section electron micrographs reveal well-preserved tissue for 3DEM analyses. In another group of animals, LTP was induced at CA3 → CA1 synapses in acute hippocampal slices using high-frequency light pulses. Our light stimulation protocol consisted of 3 trains of 100 pulses at 50 Hz, with each pulse lasting 1 ms and 15 s intervals between 100-pulse trains (λ = 473 nm at ~13.5 mW). This was sufficient to induce LTP lasting for 2 hrs, as measured by changes in the slope of field excitatory postsynaptic potential. At end of recording, the slices were chemically fixed (enhanced by a brief microwave irradiation), then stained with (Ni-DAB) to visualize the mAPEX2-expressing axons in the area CA1. 3DEM analysis of the labeled axons and synapses is currently underway. Our new approach will greatly facilitate the detection of synapse-specific ultrastructural changes associated with long-term synaptic plasticity, a crucial first step in elucidating the cellular mechanisms of learning and memory.

Title: Saturation of structural plasticity at individual dendritic spines

Authors: *O. VIVAS[1], W. C. OH[2], L. PARAJULI[2], K. ZITO[1];
[1]Ctr. for Neurosci., [2]Univ. of California Davis, Davis, CA

Abstract: Long-term potentiation (LTP) of synaptic strength is widely accepted as one of the key cellular modifications that support learning. One interesting property of LTP is that it saturates and that saturation impairs learning. In this project, we are interested in understanding

the saturation of structural and functional plasticity at the level of single dendritic spines. Spines are tiny dendritic protrusions (<0.1 μm^3) that serve as the site of most excitatory synapses in the cerebral cortex. Spine morphology is tightly coupled to spine function: spine volume is highly correlated with the area of the postsynaptic density, the number of vesicles in the presynaptic membrane, the number of AMPA receptors, and the amplitude of excitatory postsynaptic currents. Notably, individual dendritic spines exhibit structural and functional plasticity in response to local glutamatergic stimulation. To study the saturation of structural plasticity, we used two-photon glutamate uncaging to examine the parameters that limit the repetitive induction of LTP at individual dendritic spines of hippocampal CA1 neurons. We also are investigating if spines grow in small increments and if there is a predetermined size volume reached for each spine, beyond which spines do not grow. Indeed, as spines grow in response to LTP stimuli, we found that it is increasingly unlikely that the same uncaging protocol will induce additional growth. We are currently studying the molecular mechanisms that place the upper limit on spine size.

Title: Maturation of sensory networks through homeostatic structural plasticity

Authors: ***J. GALLINARO**, S. ROTTER;
Bernstein Ctr. Freiburg, Dept. of Biology, Univ. of Freiburg, Freiburg, Germany

Abstract: Neurons in the adult visual cortex of mice prefer to make synapses with neurons responding to similar visual features. As such a bias in connectivity is not observed at the time of eye opening, it has been proposed that the functional subnetworks are formed through rewiring of recurrent synaptic connections, induced by visual experience [1]. However, it is not clear according to which rules this structure develops. The emergence of feature specific wiring was recently demonstrated in a balanced network model with appropriate rules of functional synaptic

plasticity [2]. In this model, however, connectivity was evaluated based on the strength of already existing synapses, and the structure of the network remained unchanged throughout the simulation.
Referring to recent findings of homeostatic regulation of cortical activity in rodent visual cortex *in vivo* [3,4], we employ here a structural plasticity rule based on firing rate homeostasis described previously [5] for simulating network restructuring during sensory stimulation. We show that, next to other biologically meaningful properties, feature specific connectivity also emerges in a balanced network of changing structure, using a plasticity rule that does not depend on spike timing.

Title: Dopamine D2 receptors are related to physical fitness and exercise: Evidence from an exercise intervention on older adults

Authors: *L. S. JONASSON[1,2], K. RIKLUND[3,2], A. F. KRAMER[4], L. NYBERG[5,2,3], C.-J. BORAXBEKK[6,2];
[1]Dept. of Radiation Sciences, Diagnos. Radiology, Umeå Univ., Umea, Sweden; [2]Umeå Ctr. for Functional Brain Imaging, Umeå University, Sweden; [3]Diagnos. Radiology, Dept. of Radiation

Sci., Umeå University, Sweden; [4]Beckman Inst., University of Illinois, IL; [5]Dept. of Integrative Med. Biol., Umeå University, Sweden; [6]Ctr. for Aging and Demographic Res., Umeå University, Sweden

Abstract: In the PHysical Influences on BRain in Aging (PHIBRA) study, 60 sedentary elderly individuals (64-78y) completed a randomized physical activity intervention for 6 months, contrasting aerobic exercise with a stretching and toning active control condition. For the first time on human subjects, the relation between physical fitness and *dopamine D_2 receptors* (D2R) was investigated. D2R availability was measured with *positron emission tomography* (PET) and [^{11}C]raclopride before and after the intervention. We focused on striatum, a subcortical structure serving several important motor and cognitive functions. At baseline, higher aerobic capacity (peak oxygen uptake) was associated with higher D2R availability in striatum. If D2R is assumed to decrease with age, one explanation for the cross-sectional analysis is that the aging related reduction of D2R is slowed by maintaining a higher level of physical fitness at an older age. Following training improved aerobic capacity was related to a change in D2R. Specifically increased peak oxygen uptake was related to an increased D2R in left sensorimotor striatum (k = 16, mni coordinates [-30 -15 -2]), and reduced D2R in left limbic and associative striatum (k = 59, mni coordinates [-9 9 4]). The reduced D2R in anterior regions potentially reflects an increase in endogenous dopamine following improved aerobic capacity since increased endogenous dopamine may lead to a lower estimation of D2R availability. The increased D2R in relation to improved aerobic capacity likely reflects, similar to the findings at baseline, either an increase in D2R, or a slowed reduction in D2R. This is the first study to show 1) a relation between physical fitness and the human dopamine D2R, and 2) that human D2R is sensitive to change in aerobic capacity, which is likely one reason as to why staying physically fit reduces the risk of age-related decline in brain health.

Title: Mitral cell dendritic arbors recover morphology after chronic deafferentation in the adult zebrafish olfactory bulb

Authors: *J. M. DICKENS, C. A. BYRD-JACOBS;
Western Michigan Univ., Kalamazoo, MI

Abstract: The dendritic arbors and processes of neurons are complex structures, and their morphologies are critical for proper cellular function. Synaptic connections are essential for development and maintenance of dendritic shape. Using mitral cells, the primary output neurons of the olfactory bulb, we examined the afferent/target interactions necessary for the maintenance of dendritic morphology and the potential for the recovery of these structures following long-term removal of sensory input in a reversible deafferentation model. Disruption of afferent input through repeated chemical ablation of the olfactory organ with detergent results in a significant decrease in total number of major dendritic branches, reduction in length of the branches, and diminished area of the dendritic tuft following eight weeks of chronic treatment. There is also a significant decrease in overall dendritic complexity and prevention of growth-related elaboration of the dendritic arbors. The hypothesis of this study was that the size and complexity of mitral cell dendritic arbors would return after recovery of afferent innervation following long-term deafferentation. The olfactory epithelium of adult male and female zebrafish was chemically ablated with the detergent Triton X-100 every three days for eight weeks, followed by cessation of treatment and recovery for a further three or eight weeks. Mitral cells were labeled using retrograde tract tracing with a fluorescent dextran injected into the olfactory tracts of isolated whole brains in culture and imaged using whole-mount confocal microscopy. Projection images of unidendritic mitral cells from unoperated external control fish and detergent-treated fish allowed a recovery period were examined, and the total number of major dendritic branches, length of major dendritic branches, and area of the dendritic arbor were analyzed. A modified Sholl analysis was used to examine the changes in overall dendritic complexity. Following eight weeks of recovery, there were no significant differences in the number of major dendritic branches ($p>0.05$) or the length of those major branches ($p>0.05$) compared to mitral cells of control fish. Additionally, compared to untreated control cells there was no significant difference in the area of the dendritic tuft ($p<0.05$) or in the overall complexity of the dendritic arbor ($p<0.05$). Thus, eight weeks of recovery following chronic deafferentation allows mitral cell dendrites to return to control morphologies. These results provide us with a model system that allows investigation of the regenerative capabilities of adult brain structures.

Title: The role of structural versus functional potentiation in the stabilization of nascent dendritic spines

Authors: *J. T. LAMBERT, T. C. HILL, K. ZITO;
Univ. of California Davis, Davis, CA

Abstract: Animals have a remarkable capacity to change their behavior to suit a wide range of circumstances. At the cellular level, this behavioral flexibility is made possible because individual neurons modify their connectivity in response to varying patterns of synaptic activity in a process termed experience-dependent plasticity. During experience-dependent plasticity, the selective stabilization of new dendritic spines is linked tightly with functional changes in neural circuits. We have shown previously that high-frequency stimulation that induces long-term potentiation (LTP) increases the stability of new spines. Here, we further investigate the cellular and molecular mechanisms of this activity-dependent structural stabilization. We found that stabilization-inducing activity at new spines increases the enrichment of SAP97, a synaptic scaffolding molecule that binds and clusters AMPARs. High-frequency stimulation at individual spines activates pathways for both functional LTP, through the recruitment of additional AMPARs, and structural LTP, through regulation of the actin cytoskeleton. Our finding that a protein important for recruiting AMPARs accumulates at new spines following an LTP stimulus that induces new spine stabilization raised the questions: Is recruitment of AMPARs to new spines necessary for stabilization and, if so, are AMPARs playing a functional or structural role? We will present the results of our ongoing studies to define the relative role of structural versus functional potentiation in the stabilization of nascent spiny synapses.

Title: Glial TNF regulates dendritic spine density in the nucleus accumbens

Authors: *S. C. KONEFAL, J.-P. CLÉMENT, S. CHIERZI, K. MURAI, D. STELLWAGEN; Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: The nucleus accumbens (NAc) plays an important role in generating motivated behaviors to natural rewards and drugs of abuse. We have previously reported that tumor necrosis factor alpha (TNFα) decreases excitatory synaptic strength in the NAc core following repeated cocaine administration via the endocytosis of AMPA-type glutamate receptors on medium spiny neurons (MSNs). TNFα is produced by glia in the brain, the two main types of which are microglia and astrocytes. Both cell types have been shown to regulate the structural plasticity of dendritic spines on neurons. We propose that glia-derived TNFα regulates the formation and maintenance of dendritic spines on MSNs and plays a role in the cocaine-induced changes in spine density. Repeated exposure to cocaine followed by a period of withdrawal produces an enduring increase in dendritic spine density. We report that adult TNFα -/- mice have an increased baseline spine density in MSNs and, following prolonged withdrawal from cocaine, also show an increase in spinogenesis as compared to wild-type mice. This result suggests a regulatory role for TNFα in dendritic spine formation or maintenance. Our preliminary data further suggest that TNFα derived from astrocytes and microglia have different roles regulating spine density where astrocytic TNFα controls baseline spine density and microglial TNFα regulates cocaine-induced spinogenesis.

Abstract: Retinoic acid (RA) and its receptors are well-known transcriptional regulators involved in neurogenesis and neural differentiation during embryonic development. Recent findings identify RA and its receptor, RARα, as critical molecules that regulate excitatory and inhibitory synaptic transmission in the context of homeostatic plasticity through modulation of activity-dependent dendritic protein synthesis in the adult brain. Dendritic spines are small protrusions on the dendrites of neurons and serve as the postsynaptic sites of the majority of excitatory synapses in the brain. The role of RA and RARα in homeostatic synaptic plasticity suggest that they might also impact spine plasticity. Combining mouse genetics and *in vivo* two-photon imaging, we followed apical dendrites of layer 5 pyramidal neurons in the barrel cortex of RARα conditional knockout (cKO) mice in which RARα is selectively deleted from the excitatory neurons in the brain. We showed that sensory experience-dependent spine elimination was accelerated in adolescent (1 month old) cKO mice, leading to a decreased spine density in adult (3 Months old) cKO mice. We also show that cKO are less responsive to environmental enrichment, compared to wild-type littermates, suggesting a defective homeostatic regulation. Correlated with the synaptic structural abnormality in the barrel cortex, we also found that cKO mice had impaired whisker-barrel function. These results reveal the important functional role of RA signaling in the developing brain, and identify RARα as an important player in experience-dependent spine pruning.

Title: The inhibition of the EphA4/c-Abl signaling pathway promotes the synaptic insertion of the NMDA-NR2B receptor

Authors: *L. VARGAS ROJAS[1,2], N. LEAL[4,3], P. JIMENEZ[5], F. CARVAJAL[5], W. CERPA[5], A. ALVAREZ[6,3];

Católica de chile, Santiago de Chile, Chile

Abstract: In the synaptogenesis and synaptic maturation processes, a functional exchange occurs between the subunits of the NMDAR, NR2B and NR2A. The synaptic proteins SAP-102 and PSD-95 participate of the differential transport of the NR2B and NR2A subunits to de synapsis, respectively. In the development stages the NMDAR-NR2B/SAP102 complex are targeted to the synapsis, while the NMDAR-NR2A/PDS-95 complex are inserted in the synapsis during the synaptic maturation process. However, the molecular mechanisms for the development and maturation of the synapsis have not been determined.
The c-Abl kinase translates the signal from various receptors, such as EphA4. We have established that the activation of c-Abl by the EphA4 receptor is fundamental in the dendritic spines loss induced by Aβ oligomers. Additionally, in a physiological context, the activation of the post-synaptic EphA4 receptor by its ligand ephrin-A3, is involved in the retraction and pruning of dendritic spines. EphB2, another member of the ephrin receptors is activated by its specific ligand and induces the increase of NR2B subunit membrane levels in the surface. The activation of the EphB2 receptor leads to Src kinase-dependent phosphorylation of the NR2B in the tyrosine 1472, which is important for the permanence of NMDAR in the surface and its synaptic localization. The activation of EphB2 and EphA4 promote signals which are opposed but necessary to the correct formation of mature synapses.
Our results show that the inhibition of EphA4/c-Abl signaling pathway increase the NMDAR-NR2B/SAP102 complex in the membrane. When the signaling pathway is inhibited using the specific inhibitor KYL for EphA4 and GNF-2 for c-Abl, a significant increase of the NMDA-NR2B and NR2B-phospho-tyr1472 in the synaptic membrane was observed, in primary culture of hippocampal neurons.
Furthermore, in c-Abl knockout mice (cAbl flox/flox Nestin Cre) we observed: i) an increase of NMDA-NR2B and p-NR2B-tyr1472 in the surface of primary cultures and in different days after birth; ii) an increase in the total NMDA currents and iii) additionally we observed that c-Abl knockout mice show high levels of the scaffolding protein SAP102, which is important for the transport of the NR2B subunit.
Interestingly, by inducing the activation of c-Abl with a system inducible by tamoxifen in 293T cells, the phosphorylation in tyrosine 1472 of the NR2B subunit decreases. Summarizing, the activation of the EphA4/c-Abl would be a negative regulator of the synapsis in physiological conditions, because the inhibition of the basal activity of this pathway promotes the insertion in the membrane of the NMDA-NR2B receptors specifically.

Title: A novel DnaJ domain protein regulates activity-dependent synaptic structural modification via integrin activation

Authors: *J. LEE[1], K. T. CHANG[2];
[1]USC, Los Angeles, CA; [2]Zilkha Neurogenetic Institute, Univ. of Southern California, Los Angeles, CA

Abstract: Synapse is a dynamic structure that actively modifies its morphology during development and in response to stimuli. Cell adhesion molecules (CAM) are known to govern such functions by modulating adhesive forces between synaptic terminals. Integrins, trans-synaptic CAMs, have been shown to function in structural remodeling by mediating adhesion between the cell and extracellular matrix (ECM). Here, we demonstrate that a protein named Shriveled, Shv, plays an important role in regulating synaptic growth and activity-dependent synaptic remodeling at the *Drosophila* neuromuscular junction. Depletion of Shv protein results in synaptic overgrowth whereas upregulation of Shv induces enlargement of the synapse instead, a process generally associated with synaptic maturation. We find that Shv genetically interacts with βPS integrin and that Shv is secreted upon intense stimulation to activate integrin signaling. Our data identifies Shv as a novel activator of integrin signaling at the synapse, and further suggests that Shv may restrict synaptic growth and promote synapse maturation. Additional experiments will be conducted to elucidate the mechanism underlying activity-dependent Shv release and integrin activation. Understanding the functional impact of Shv and integrin signaling in synaptic growth may reveal new insights into mechanisms contributing to abnormal structural plasticity that are commonly associated with neurological disorders.

Title: Activity-dependent synaptic growth and restructuring in *Drosophila* temperature-sensitive seizure mutant

Authors: *C. L. TORRES FERRERIS[1], A. VASIN[2], M. BYKHOVSKAIA[2];
[1]Anat. and Cell Biol., [2]Neurol., Wayne State University, Sch. of Med., Detroit, MI

Abstract: We investigated how seizure activity affects the neuronal structure at the *Drosophila* larval neuromuscular junction (NMJ). We took advantage of the seizure mutant *(sei)*, which demonstrates neuronal hyperactivity when being exposed to restrictive temperatures. We generated the *Drosophila sei* line with fluorescently tagged neuronal membranes (CD8-GFP). Experiments were performed at dissected preparations with severed axons, as well as at intact larvae. In the latter case, the imaging was performed at anesthetized larvae through the cuticulum. All the NMJs were imaged employing confocal stacks to enable 3D reconstructions of all the synaptic boutons and filopodia. Seizure activity was induced by exposing larvae to restrictive temperatures (50 $^{\circ}$C) for one minute. After a ten minute resting period the preparations were imaged again, and 3D reconstructions of all the neuronal structures were performed. Strikingly, we found a significant restructuring in the stimulated preparations that occurred both in intact and in dissected larvae. The restructuring included the growth of new satellite synaptic boutons and fillopodia and the formation of new boutons along nerve brunches, as well as a retraction of boutons, fillopodia, and even small brunches. These results suggest that seizure activity can produce rapid modifications in the neuronal ultrastructure, including growth and retraction of synaptic boutons. Since such modifications occurred on rather short time scales (ten minutes) and in dissected preparations with severed axons, the underlying mechanisms are likely to be local to the nerve terminals and to involve active transport and trafficking.

Title: The relationship between AMPAR levels and spine dynamics in basal conditions and with motor-skill learning in the fmr1 KO mouse

Authors: *A. SURESH, A. DUNAEVSKY;
Developmental Neurosci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Fragile X syndrome (FXS) is the most common inherited form of intellectual disability. Patients with FXS exhibit a range of neurological deficits including motor skill deficits. Previously, we found that fmr1 knockout mice (KO) have an impairment in motor skill learning in a forelimb reaching task and reduced learning-induced synaptic plasticity in the forelimb area of the primary motor cortex (M1). Specifically, KO mice do not exhibit learning induced increases in dendritic spines as seen in the trained hemisphere of wild type mice and show a delay in synaptic insertion of AMPAR subunit GluA1 in the forelimb region of the primary motor cortex. Here we investigated the relationship between spatiotemporal dynamics of AMPAR and dendritic spine structural plasticity. We performed *in utero* electroporation of AMPAR subunit GluA2 tagged to SEP (GluA2) and a morphological marker td-Tomato to label layer 2/3 neurons in M1 of wild type (WT) littermates and KO mice. We then performed repeated *in vivo* multiphoton imaging of dendritic spines and GluA2 both under basal conditions and following motor skill training in adolescent mice. We find that there is a linear relationship between GluA2 levels and spine volume in both KO and WT controls with a relatively small proportion of spines containing very large amounts of GluA2. In both KO and WT mice the levels of GluA2 were dynamic suggesting that the strength of individual spines varies continuously in adolescent mice. Under basal conditions we find that there is a gradual increase of GluA2 levels in stable spines reaching an average increase of 15% over 10 days in both genotypes. This increase was mainly contributed by low GluA2 containing spines which over time both grew in size and accumulated GluA2. We also observed that in both KO and WT mice spines with large amounts of GluA2 were preferentially stable compared to low GluA2 containing spines. Spine destined for elimination showed decreases in GluA2 hours before elimination. In both KO and WT mice, newly formed persistent spines had increased GluA2 levels 24 hours following formation an additional increases later on. To evaluate learning-induced changes in GluA2, we trained KO and WT mice on a forelimb reaching task. Preliminary results suggest that as in dendrites of layer 5 neurons, motor learning results in an

increase in dendritic spines on layer 2/3 neurons in the trained hemisphere. Moreover, an increase in synaptic GluA2 was observed in wild type mice but not in the KO mice. Hence our results suggest that under basal conditions the relationship between AMPAR and dendritic spines is not altered in the fmr1 KO mice but may be affected under activity dependent mechanisms such as learning.

Title: Subchronic low-dose ketamine stimulates formation of dendritic spines in somatosensory cortex of awake behaving mice

Authors: ***L. KHIROUG**[1], E. PRYAZHNIKOV[3], P. CASAROTTO[2], J. KOLIKOVA[3], P. MARSHALL[3], D. TOPTUNOV[3], P. HOTULAINEN[4], V. VOIKAR[2], R. TERRY-LORENZO[5], S. ENGEL[5], E. CASTREN[2];

Abstract: Our primary finding is that subchronic 5-day once-daily treatment with ketamine stimulates spine formation in mouse primary somatosensory cortex, reversing the net loss of spines (synaptic pruning) that is observed in control animals at this age (2-3 m.o.). Ketamine has attracted significant attention as a drug of abuse and, more recently, as a rapidly acting antidepressant. However, the structural synaptic plasticity mechanisms induced by repeated ketamine administration remain unknown. We studied effects of subchronic ketamine injections on spine formation and elimination rates in awake, behaving mice. Young adult female mice expressing YFP in cortical layer 5 pyramidal neurons were head-fixed in the Mobile HomeCage device enabling microscopic imaging in the cortex of awake behaving mice. Ketamine (10mg/kg) or vehicle (PBS) was injected intraperitoneally and spines were imaged at 0h, 6h, 24h, 72h and 120h, with ketamine/vehicle treatment at 1h, 25h, 49h, 73h and 97h. Apical dendrites of layer 5 neurons in primary somatosensory cortex were imaged in layers 1 and 2. Between 150 and 300 spines per animal were tracked individually over time. Ketamine significantly increased the spine formation rate at 72h ($p<0.05$, $n=6$ mice for ketamine group, $n=5$ mice for control group). We also observed a strong trend towards the decrease in the rate of spine elimination, although this effect of ketamine did not reach the significance level. As a

whole, the control group displayed a net loss of spines, and this loss was reversed by ketamine. Effects of ketamine on spine formation in somatosensory cortex correlated with ketamine-induced increase in phospho-Actin and PSD-95 protein level ($p<0.05$ at 72h), consistent with formation of functional synapses. Interestingly, the protein level of NR2B subunit of NMDA receptor was not affected by subchronic 10mg/kg ketamine treatment. However, the ratio between mobile and stable spine fractions was unaffected by ketamine treatment. Behavioral tests revealed that ketamine injections induced a sustained significant improvement in the nest score without affecting the overall activity of the animals.

Title: Environmental enrichment confers resistance to stress-induced abnormal dendritic spine dynamics and cognitive defects in the mouse cerebral cortex

Authors: ***C.-C. CHEN**, Y. ZUO;
Mol. Cell and Dev Biol, Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: It is widely accepted that significant experiences can rapidly cause long-lasting alterations of anatomical, physiological, and behavioral features in the brain. As one of the most prevalent experiences in modern society, stress can have a profound and enduring impact on brain functioning. These functional defects are primarily mediated through the dysregulation of synapses, the communication sites between neurons. Much is known about the deleterious effects of stress on the affective systems mediated through subcortical structures, but less has been explored in the cortical regions, which are the seats for perception, memory, and cognition. Furthermore, it is unclear how positive experiences may counteract or negate the effects of stress. To address these questions, we investigated how various experiences, stressful and/or enriching, can alter cortical functioning and its associated synapse dynamics. Using *in vivo* two-

photon transcranial microscopy, we longitudinally followed the dynamics of postsynaptic dendritic spines of apical dendrites in layer V pyramidal cortical neurons. We found that animals reared in an enriched environment are more resistant to stressful experiences than animals reared in standard cages, measured by a cortex-specific cognitive task. Similarly, enriched environment also counteracts the negative effects of stress on dendritic spines. Understanding how various experiences cooperate or negate one another, provides a framework on how similar or opposing events in life can differentially leave lasting footprints in the neurocircuit, thus impacting cognitive processes through the altered functioning of synaptic structures.

Title: Synaptic pruning in layer 5 of the medial prefrontal cortex of female mice requires $GABA_A$ receptors

Authors: *M. R. EVRARD, S. S. SMITH;
Physiol. and Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: The onset of certain neurodevelopmental disorders, such as schizophrenia, overlaps with the maturation of the prefrontal cortex (PFC), suggesting that it is implicated in their etiology. Unlike other areas of the brain, the PFC is not fully developed until early adulthood. It is well established that before puberty the number of synaptic spines located on the dendrites of cortical pyramidal cells increases dramatically. These synaptic connections that develop before puberty are pruned during adolescence (Huttenlocher, 1979; Koss, et al., 2014); this process, known as synaptic pruning, is thought to be important for normal cognition because dysregulation of this process appears to result in neurodevelopmental disorders. However, the initial mechanisms which trigger synaptic pruning remain largely unknown. It is known that the spines of cortical pyramidal cells receive GABAergic input. We first identified layer-specific pruning in the mPFC using the Golgi-Cox staining method in female mice at puberty (PND 35, confirmed by vaginal opening) and post-pubertally (PND 56). Spine counts were obtained using a Nikon Eclipse Ci-L microscope and manually counted on basilar dendrites. Spine density in layer 5 of the mPFC decreased by 62% from puberty (5.9 spines/10 μm) to post-puberty (3.7

spines/10 μm; $P < 0.0001$) - with the greatest decline occurring in the medial (Puberty, 7.4 spines/10 μm; Post-puberty, 3.6 spines/10 μm, $P < 0.0005$) and distal (Puberty, 7.5 spines/10 μm; Post-puberty, 4.9 spines/10 μm, $P < 0.0005$) regions. To test the hypothesis that synaptic pruning is $GABA_A$ receptor (GABAAR) mediated we injected female mice with picrotoxin (3mg/kg, i.p.), a GABAAR antagonist, once a day for the first 10 days following the onset of puberty (P36-P46); mice were then sacrificed at P56. Spine density in mice injected with picrotoxin had a significantly higher synaptic density in each region (proximal, 5.4 spines/10 μM [$P < 0.0001$]; medial, 8.7 spines/10μm [$P < 0.0001$]; distal, 11.3 spines/10μm [$P < 0.0001$]) and overall (8.5 spines/10μm, $P < 0.0001$) than untreated post-pubertal mice. These data suggest that synaptic pruning occurs in layer 5 of the prefrontal cortex in female mice and is mediated by GABAARs, which prior to this study, has not been shown. Future studies seek to identify specific GABAARs that mediate synaptic pruning.

Title: Pilot clinical trial of transcranial alternating current stimulation (tACS) for the treatment of major depressive disorder

Authors: ***C. E. LUGO**, J. MELLIN, M. ALEXANDER, S. ALAGAPAN, C. LUSTENBERGER, D. RUBINOW, F. FROHLICH;
psychiatry, UNC, Raleigh, NC

Abstract: Major depressive disorder (MDD) is a network disorder characterized by impaired organization of electric activity patterns in the brain. Given the known alterations in alpha oscillations (8-12 Hz) [1] in MDD, we hypothesized that transcranial alternating current stimulation (tACS) can alter alpha oscillations and improve clinical symptoms in people with MDD. To test this hypothesis, we are conducting a double-blind, sham-controlled pilot clinical trial to establish feasibility and to collect initial efficacy data for the use of tACS in MDD patients. The study employs a parallel design with three arms; participants receive daily 40

minutes stimulation for 5 consecutive days (40Hz gamma tACS, 10 Hz alpha tACS or active sham). The stimulation frequencies were chosen due to the emerging evidence that tACS in these frequencies modulate alpha oscillations in healthy controls. Changes in the Montgomery Asberg Depression Rating Scale (MADRS) scores from baseline to the 4 week follow-up visit are the primary outcome. Changes in resting-state alpha oscillation power from high-density EEG are the secondary outcome. In addition, a working memory task (n-back task) is administered during each EEG recording. Data from the Beck Depression Inventory (BDI), Clinical Global Impression (CGI), Hamilton Depression Rating Scale (HDRS), Montreal Cognitive Assessment (MOCA), and Young Mania Rating Scale (YMRS) are also collected. This study is currently enrolling patients (8 patients enrolled, target: 21 by Nov 2016). Here, we report data from the first 6 patients who have completed the stimulation week (all female, mean age 34.7 years). At baseline, the mean MADRS was 23.2 (std: 6.9) and the mean HDRS was 14.2 (std: 5.1). At the completion of the stimulation week, the mean MADRS was 16.3 (std: 5.1) and the mean HDRS was 9.8 (std: 3.9). At baseline, the mean for the MOCA was 27.2 (std: 1.9). All patients had a score of zero on the YMRS both at baseline and at completion of the stimulation week. Self-reported depression symptoms assessed by the BDI decreased from 25.2 (std: 5.4) before stimulation to 16.5 (std: 9.3) at the end of the stimulation week. Due to the small sample size and the fact that the data are blinded, no conclusion about efficacy can be drawn at this point. However, our early results demonstrate that the treatment is safe and well tolerated and that overall depression symptoms improved in the patients enrolled in this study. Leuchter et al. (2013). Title: Auditory steady state responses during wakefulness and nrem sleep

Authors: *C. LUSTENBERGER[1], Y. A. PATEL[2], J. M. PAGE[1], B. PRICE[1], S. ALAGAPAN[1], M. R. BOYLE[1], F. FROHLICH[1];
[1]UNC at Chapel Hill, Chapel Hill, NC; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Rhythmic sensory stimulations are able to drive brain oscillations by increasing phase-locking to the temporal structure of the stimulation and by increasing power of specific frequency bands [1]. Since distinct intrinsic oscillations such as alpha oscillations (8-12 Hz) and sleep spindles (11-16 Hz) are characteristic of different vigilance states [2], it remains to be investigated whether rhythmic stimuli elicit different brain responses during these states. Here, we compared the effects of auditory rhythmic stimuli on EEG brain activity during wake and sleep with a specific focus on the spindle frequency range, and delineated the topographical distribution of these modulations. We included 8 healthy, male participants in our study (18-29 years). During the wakefulness session (30 min), amplitude modulated (AM) white noise stimuli at different frequencies were applied for 1 s with inter-trial intervals of 2.5-3.5 s. The same auditory paradigm was repeated during a 60 minute nap. 128-channel high-density EEG was continuously recorded during the nap and wakefulness sessions. Event-related spectral power (ERSP) and inter-trial phase coherence (ITPC) analyses were performed for artifact-free wakefulness and NREM events in the spindle frequency range (11-16 Hz). We focussed our analysis on 14 Hz AM stimuli. ITPC at 14 Hz was more pronounced during wakefulness than sleep for a broad fronto-central cluster of electrodes (maximal ITPC difference +11%, $p<0.05$, paired t-test). However, ERSP increase in the slow spindle frequency range (11-13 Hz) relative to a pre-event baseline was significantly stronger for events applied during NREM sleep and nearly absent during wakefulness. The topography of this slow spindle activity increase was most distinct over fronto-central regions (maximal ERSP difference + 16%, $p<0.05$), which is characteristic for slow spindles. A similar picture emerges for the fast spindle frequencies (14-16 Hz). ERSP was again significantly increased during NREM sleep compared to wakefulness (maximal ERSP difference +25%, $p<0.05$) but with a distinct centro-parietal topography representative for fast sleep spindles. In conclusion, brain responses to temporally patterned auditory stimuli were different for wakefulness and NREM sleep and therefore specific to vigilance states. Strikingly, spindle-like AM stimuli increased spindle activity during NREM sleep but not during wakefulness. Thus, auditory stimulation during sleep might represent a powerful tool to boost sleep spindles and test their functional role in memory and cognition.

Title: Entrainment of thalamocortical networks by tACS is modulated by intra-area coupling

Authors: *C. HENRIQUEZ[1], G. LI[2], F. FROHLICH[2];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: Thalamocortical dysrhythmia has been proposed as a mechanism underlying neurological and psychiatric conditions. These conditions have been associated with persistent low-frequency activity that limits normal cognitive function, and may be a result of asymmetric synaptic coupling between the thalamus and cortical layers. We hypothesize modulation of the thalamocortical circuit using transcranial alternating current stimulation (tACS) depends on the degree of the asymmetry, since the current will mostly affect the closer cortical cells.
To test this hypothesis, we developed a biophysical thalamocortical model consisting of four, two-dimensional, layer networks consisting of a cortical region (CX) comprised of 225 pyramidal (PY) cells, 100 cortical interneurons (IN), and a thalamic region (Th) comprised of 100 reticular cells (RE) and 49 high threshold bursting thalamocortical (HTC) cells. Between CX and TH, HTC cells project with glutamatergic synapses to the both the PY and IN cells (HTC-CX) while the PY cells project back with glutamatergic synapses (PY-TH) to both the RE and HTC cells. A simulated LFP was computed by low-pass filtering the synaptic currents in the PY layer and used to compute the power spectral density (PSD). A dysrhythmic network was created by enhancing the HTC-CX and RE to HTC coupling and reducing the PY-TH coupling. In both normal and dysrhythmic alpha states, the TH and CX networks oscillated coherently at 10 Hz, but the oscillatory power was much stronger in the dysrhythmic condition. In the normal gamma state, the CX synchronizes the TH network at 32Hz, while under the dysrhythmic gamma state, the CX gamma oscillation failed to synchronize the TH network, which oscillated at 14Hz. As a

result, a strong 14 Hz peak appeared in the CX PSD along with the dominant 32 Hz peak. A sinusoidal current, 5Hz above the endogenous CX frequency, was applied to only the PY cells and the minimum current needed for entrainment was determined. Results showed that the dysrhythmic gamma state needed 15% lower current to entrain than the normal gamma state while the dysrhythmic alpha state needed 350% higher current to entrain than the normal alpha state. The findings suggest that in a dysrhythmic alpha state in which TH more strongly drives CX rhythm, it is more difficult to perturb the endogenous rhythm with tACS that targets the cortical cells. In contrast, for the dysrhythmic gamma state where the dominant CX rhythm is not synchronized with the TH rhythm, entrainment is easier. The development of models that are capable of generating a variety of dysrhythmic conditions may be valuable in designing more optimal stimulation therapies.

Title: Task dependent modulation of neural activity in the ferret lateral posterior pulvinar complex during preparatory attention

Authors: *C. YU[1], I. M. STITT[2], Y. LI[2], Z. ZHOU[2], K. K. SELLERS[2], F. FROHLICH[2];

Abstract: The pulvinar plays a key role in organizing cortico-cortical interactions during attention-demanding tasks in primates[1] .Little is known about the circuit dynamics within the pulvinar and its role in attentional behavior. Here, we performed multichannel electrophysiological recordings in the lateral posterior-pulvinar complex (LP/pulvinar) in the

ferret (*Mustela putorius furo*). We recorded single unit activity and local field potential during the performance of the touch screen version of 5-choice serial reaction time task (5-CSRTT). We found that freely moving, trained ferrets were able to consistently perform the task. Attention responsive neurons (n=130) clearly responded while the animal maintained attention during the delay period when no stimuli were present and exhibited a monotonically increasing firing rate during that period. Neurons non-responsive to attention (n=129) signaled in response to the stimulus, but not during the delay period. Spike-field coherence of the responsive neurons significantly increased during attention period until screen touch, predominantly in the theta frequency band (~5Hz). Furthermore, we found that theta power and theta-gamma phase amplitude coupling was substantially elevated throughout the delay period. Interestingly, the strength of the power in the theta frequency band was positively correlated with reaction time from stimulus onset to screen touch. Together, our results reveal task-dependent LP/Pulvinar theta oscillations in the freely moving ferret while performing an attention demanding task. Our findings further suggest that the theta oscillation may play an important role in coordinating cortical activity in the ferret. Title: Targeting auditory hallucinations with tdcs and tacs

Authors: *J. M. MELLIN, C. E. LUGO, M. L. ALEXANDER, S. ALAGAPAN, C. LUSTENBERGER, J. H. GILMORE, L. F. JARSKOG, F. FROHLICH;
Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Approximately 30% of patients with schizophrenia experience auditory hallucinations that are refractory to antipsychotic medications and cause a significant decrease in the quality of life [1]. Thus far, attempts for using transcranial current stimulation as a novel treatment have been limited to transcranial direct current stimulation (tDCS) [2]. A previous study conducted by Brunelin et al. [2] found a significant reduction in auditory hallucinations in people with schizophrenia after 5 days of twice daily tDCS that targeted both the left dorsolateral prefrontal cortex (dl-PFC) and the left temporo-parietal cortex. In contrast, a pilot study conducted in our laboratory found no difference in auditory hallucinations between once daily tDCS and sham as measured by the Auditory Hallucination Rating Scale (AHRS) [3]. Here, we evaluated the efficacy of transcranial alternating current stimulation (tACS) that we hypothesized would enhance synchronization between the frontal and temporo-parietal areas of the left hemisphere. In addition to behavioral assessments, EEG data were collected to determine if and how stimulation engaged the network-level stimulation targets. The study had a parallel group design with three arms (sham, tDCS, and tACS). Participants received twice daily, 20 minute sessions of active sham, 10 Hz 2mA peak-to-peak tACS, or 2 mA tDCS over the course of 5 consecutive days.Both high-density EEG and behavioral measures were measured to determine the efficacy of tDCS and tACS for the treatment of medication-refractory auditory hallucinations in patients with schizophrenia. The AHRS and EEG recordings were the primary outcomes for this study. The AHRS was administered at the baseline visit, the first and last day of stimulation, and at the one week and one month follow-up visits. EEG data was collected at the first and last day of stimulation, and at the one week and one month follow-up. Data from the Positive and Negative Syndrome Scale (PANSS), Brief Assessment of Cognition in Schizophrenia (BACS), Abnormal Involuntary Movements Scale (AIMS), Simpson Angus Scale (SAS), and Clinical Global Impression (CGI) were collected at the first and last day of stimulation, and at the one month follow-up. This study is currently enrolling participants, and the data remains blinded. Unblinded results will be presented at the meeting. 1. Shergill et al. (1998). Schizophrenia Research, 32(3). 2. Title: Fluctuations in neuromodulatory tone shape the dynamics of thalamocortical functional interaction

Authors: *I. M. STITT, Z. ZHOU, F. FROHLICH;
Dept. of Psychiatry, UNC, Chapel Hill, NC

Abstract: The brain continually transitions between states of varying arousal. These ongoing shifts in brain state are partially caused by changes in neuromodulatory drive to cortical and subcortical structures[1]. Converging evidence supports that neural activity in the locus coeruleus - the main source of noradrenergic input to the rest of the brain[2] - is correlated with fluctuations in pupil diameter[3]. Previous work linking fluctuations in pupil diameter and neural activity have primarily found that noradrenergic tone shapes the intrinsic properties of individual neurons[1]. However, state dependent shifts in behavior emerge from large-scale patterns of neural activity coordinated across many interconnected brain regions. Here, we hypothesize that spontaneous fluctuations in noradrenergic tone shape the dynamics of thalamo-cortical functional interaction. We recorded neural activity simultaneously from the lateral posterior/pulvinar nucleus in the thalamus and posterior parietal cortex of awake head-fixed ferrets. The noradrenergic state of the animal was continuously monitored by tracking of the pupil diameter under constant luminance. We found that local field potential (LFP) power and neuronal firing rate in both cortex and thalamus were significantly modulated with changes in pupil diameter ($p<0.01$). Thalamo-cortical LFP phase synchronization was observed at theta (4Hz) and alpha frequencies (14Hz) for low pupil dilation. However, as pupil diameter increased, alpha phase synchronization significantly decreased, while theta phase synchronization significantly increased ($p<0.01$). Further, LFP amplitude envelope correlation analysis revealed a strong antagonism between thalamic theta and cortical alpha rhythms. In contrast to the LFP, spike-spike and spike-LFP functional connectivity analyses predominantly revealed interactions in the alpha band. The strength of all spiking based functional connectivity analyses in the alpha band significantly decreased with pupil dilation ($p<0.01$). Collectively, these results show that neuromodulatory factors play a critical role in shaping the dynamics of thalamo-cortical functional interaction. Indeed, by extension, our findings give rise to the notion that complex patterns of brain dynamics may be readily inferred via the easily measurable external variable of pupil dilation.

Title: Rhythmic interactions between the higher-order visual thalamus and the posterior parietal cortex influence saccadic sampling

Authors: ***Z. C. ZHOU**, I. M. STITT, F. FROHLICH;
Psychiatry, Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Saccades, a form of visual sampling, serve to evaluate the dynamically changing external environment. Cortical neural activity is implicated in the voluntary control of gaze, whereas subcortical regions are important for the execution of saccades [1,2]. Neural activity and saccade-related behavior may be linked by common periodic rhythms [3,4]. However, little is known about how saccades are modulated by the interaction between subcortical and cortical regions, specifically in the context of rhythmic activity. To investigate this, we simultaneously recorded multi-unit and local field potential (LFP) activity from the lateral posterior/pulvinar nucleus (LP/pulv) and the posterior parietal cortex (PPC) in head-fixed ferrets. During these recordings, two experimenters engaged in verbal discourse in front of the animal in order to elicit visual sampling from the ferret in either lights-on or lights-off conditions. Coordinates of the pupil center were recorded using an eye-tracking system (ISCAN,Woburn,MA). We found peaks in the inter-saccade interval at around 250 ms (4 Hz, lights-on) and 160 ms (6.3 Hz, lights-off), and a strong correlation between saccade velocity and magnitude (lights-on: $r=0.87$, $t=134$, $p<0.0001$; lights-off: $r=0.88$, $t=151$, $p<0.0001$), similar to measurements recorded from humans and non-human primates. In cortex, we observed a transient increase in high frequency (20-100Hz) LFP power about 100ms in duration, and a decrease in low frequency (2-18Hz) LFP power about 1s in duration after the saccade. In LP/pulv, we found an enhancement of power in

the theta band throughout the duration of the saccade (4.4 Hz power, baseline vs saccade, t(26)=-5.399, p<0.0001). Importantly, thalamocortical phase synchronization in the theta band (4.4 Hz) increased prior to saccades and remained elevated for up to 1s, indicating the co-occurrence of dynamic LP/pulv and PPC functional interaction and saccadic sampling. As a whole, our study reveals that thalamo-cortical rhythms influence the integration of saccadic sampling and processing of visual input; importantly, these results may inform the study of the mechanisms underlying visual attention-deficit disorders.

Title: Enhancement of working memory performance by intracranial periodic pulse stimulation in humans

Authors: *S. ALAGAPAN[1], E. HADAR[2], H. SHIN[3], F. FROHLICH[4];
[1]Univ. of North Carolina At Chapel Hill Sch., Carrboro, NC; [2]Neurosurg., [3]Neurol., [4]Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Working memory (WM), an integral component of higher-order cognition, is impaired in many neurological and psychiatric disorders. The neural correlates of WM performance often include low-frequency cortical oscillations (4 - 12 Hz) which tend to be aberrant in disorders with impaired WM. Thus these oscillations might serve as targets for treating WM deficits [1]. The combination of electrocorticography (ECoG) and direct cortical stimulation (DCS) offers a platform to target specific areas and specific activity patterns in humans. In this study, we

present results from a participant with subdural electrodes who underwent periodic pulse stimulation of frontal and temporal cortices when performing a Sternberg verbal working memory task.
The participant, a 23 year old right handed female, was implanted with subdural and depth electrodes covering bilateral frontal, temporal, parietal cortices and hippocampi for epilepsy surgery planning. The participant performed a Sternberg verbal working memory task with randomized list lengths of 3, 4 and 5. Concurrently, electrical stimulation was applied to predetermined pairs of electrodes synchronized with the task. Stimulation consisted of 5 second long trains of 2 mA biphasic electric pulses 200 μS in duration at 10 Hz (1 pulse every 100 ms). Also, sham trials with no electrical stimulation were randomly interleaved with the patient blinded to the condition. We found that stimulation did not alter accuracy (Stim: 95.94 ± 2.17 % vs Sham: 98.48 ± 1.52 % Sham). However, stimulation resulted in a decrease in reaction times for trials in which list lengths were 4 (Stim: 988 ± 56 ms vs Sham: 1119 ± 29 ms; $p = 0.39$, two sample t-test) and 5 (Stim: 899 ± 49 ms vs Sham: 1140 ± 22 ms; $p = 0.01$). In contrast, the reaction times for lists of length 3 did not show any difference (Stim: 826 ± 58 ms vs Sham: 824 ± 9 ms; $p = 0.98$). Concurrently, the task-related signal power change in low frequency band (4 - 12 Hz) during stimulation measured by modulation index was higher compared to sham in the trials where list length was 4 (Stim: -0.003 ± 0.005 vs Sham: -0.015 ± 0.006; $p = 0.13$, two sample t-test) and 5 (Stim: 0.071 ± 0.005 vs Sham: 0.007 ± 0.006; $p < 0.001$) and there was no difference between the signal power change in trials where list length was 3 (Stim: - 0.027 ± 0.006 vs Sham: -0.026 ± 0.005; $p = 0.90$). The results suggest stimulation induced changes in oscillation power may be linked to the observed changes in reaction times. Thus, our data demonstrate the possible role oscillation power may play in cognition and the feasibility of periodic stimulation to modulate oscillation power and in turn cognitive performance.

Title: Oscillatory interaction dynamics in the frontoparietal attention network during sustained attention in the ferret

Authors: *K. K. SELLERS, C. YU, Z. C. ZHOU, I. M. STITT, Y. LI, S. RADTKE-SCHULLER, S. ALAGAPAN, F. FROHLICH;
Psychiatry, Univ. of North Carolina, Chapel Hill, Chapel Hill, NC

Abstract: Sustained attention requires the organization of activity across multiple cortical areas in the frontoparietal network [1]. Two brain regions critical for sustained attention are prefrontal cortex (PFC) and posterior parietal cortex (PPC). Previous work has demonstrated the coordination of these brain areas during attention at the level of local field potential (LFP) synchronization [2, 3]. However, the underlying mechanisms of these interaction dynamics in terms of organization of single unit activity (SUA) have remained poorly understood. To fill this gap, we asked how LFP and SUA organize local and long-range interactions in PFC and PPC. We hypothesized that local organization of SUA is mediated by high-frequency oscillatory activity and that long-range organization relies on low-frequency oscillations.
We simultaneously recorded SUA and LFP activity in PFC and PPC of three ferrets (*Mustela putorius furo*) during the five-choice serial reaction time task, a sustained attention task [4]. In a separate set of experiments, we established structural connectivity between these areas using anterograde tracer rAAV5-CamKII-GFP and retrograde tracer Alexa 488-CTB. We found modulation of SUA (87% of PFC units, 85% of PPC units) during the task. In PPC, there were local spectral peaks in the LFP at 5Hz and in the gamma band, with a modest power increase in power during the sustained attention period (PPC 5Hz theta, $t(41) = -6.62$, $p < 0.001$; PPC gamma, $t(41) = -10.30$, $p < 0.001$; PPC 80-120Hz high gamma, $t(41) = -6.73$, $p < 0.001$). Long-range functional connectivity between PFC and PPC was mediated by low-frequency oscillations at 5Hz. In agreement with our hypothesis, we found that SUA in PFC was organized by 5Hz theta oscillations in PPC (30.5% of units exhibited significant spike-LFP phase locking) and locally by both theta and high-gamma oscillations (25.5% and 57.5-72.9% of units, respectively). SUA in PPC was only guided locally by high-gamma oscillatory activity (58.0-70.0% of units). To our knowledge, this is the first multisite recording in PFC and PPC during a sustained attention task in the moving animal. Most strikingly, activity in the theta frequency band emerged as the fundamental rhythm that organized both local and long-range interactions in

these areas. These results support a crucial role of theta oscillations in organizing large-scale functional networks during behavior.

Title: Targeting alpha oscillations with amplitude-modulated transcranial alternating current stimulation (AM-tACS)

Authors: *E. NEGAHBANI[1], F. KASTEN[2], C. HERRMANN[3,4], F. FROHLICH[1];
[1]Dept. of Psychiatry, Univ. of North Carolina, Chapel Hill, NC; [2]Dept. of Psychology, [3]Exptl. Psychology Lab, Ctr. for excellence 'Hearing4all', European Med. Sch., [4]Res. Ctr. Neurosensory Sci., Carl von Ossietzky Univ., Oldenburg, Germany

Abstract: Endogenous brain oscillations can be entrained by externally applied weak electrical fields through transcranial alternating current electrical stimulation (tACS). Many studies have focused on comparison of neuronal activity between pre and post-stimulation periods, but the underlying mechanisms of tACS may be best understood by analysis of neural data during tACS. However, the pronounced stimulation artifact makes the study of the network dynamics during

tACS challenging. Here we use computer simulations to investigate a recently proposed solution to avoid such artifact issues. The nonlinear properties of the neuronal cell membrane make neurons responsive to envelope frequency of a modulated sensory input as reported in auditory and visual cortices [1]. Accordingly it is suggested that neurons might also be susceptible to modulating frequency of an amplitude-modulated tACS (AM-tACS) input [2]. AM-tACS enables a separation of the frequency of stimulation (FOS) from the frequency of interest (FOI) by selecting a modulating sinusoidal at the FOI and a high-frequency carrier [2]. We evaluated this approach with computer simulations of a cortical network and AM-tACS. The cortical model was set to exhibit an oscillation with an endogenous frequency of f_{end}~7.8 Hz. We first examined classical tACS with different amplitudes and frequencies resulting in entrainment delineated in the parameter space as an Arnold tongue centered around f_{end}. Next we applied AM-tACS with fixed modulating frequency of f_m=f_{end} and different stimulation amplitudes and carrier frequencies f_c. The result indicates filtering of high-frequency stimuli in agreement with the low-pass filtering by the neuronal cell membrane. We then applied AM-tACS with fixed fc=55 Hz and different f_m and stimulation amplitudes. The resulting Arnold tongue indicates clear entrainment around f_{end} induced by the low-frequency envelope of AM-tACS. Together, these results show that the envelope of AM-tACS can entrain neural oscillators at their endogenous frequency however the stimulation amplitudes need to be increased to compensate for the low-pass filtering of the neuronal cell membrane.

Title: Evaluating transcranial alternating current stimulation (tACS) for enhancing creativity

Authors: *B. PRICE, C. LUSTENBERGER, S. ALAGAPAN, F. FROHLICH;
Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Because creativity is an abstract idea indicative of higher order thought, it can be difficult to evaluate scientifically. However, as the workings of brain electrophysiology are studied, understanding the biology underlying creativity has become possible. We have previously shown that targeting bilateral frontal alpha activity using frequency-specific transcranial alternating current stimulation (tACS) resulted in enhanced creativity when compared with a 40 Hz sham condition [1]. EEG studies suggest that there are differences in the way that alpha oscillations mediate creativity in the left and right hemispheres, with a greater amount of alpha synchronization in the right hemisphere than the left hemisphere [2]. To further investigate the role of hemispheric alpha in creativity, we applied unilateral tACS to target the middle frontal gyrus.

A total of twenty healthy, male and female subjects over the age of eighteen were stimulated with tACS while taking the figural TTCT (Torrance Tests for Creative Thinking). Participants received 2 mA peak-to-peak alpha tACS (10 Hz) at either left frontal or right frontal locations, with a common electrode (Cz) over the apex. During the first round of stimulation, participants took one test form (A or B) of the TTCT. A thirty-minute resting period followed to minimize any aftereffects of stimulation before proceeding to the second stimulation session. During this second thirty minutes of tACS, participants were stimulated either right frontally or left frontally, whichever they did not receive before. Simultaneously, they took a second version of the TTCT. Administration of left or right tACS was determined according to a double-blind study design. In addition to Cz, two electrodes were fixed to locations F3 and F4 for the entirety of the study so that the participants were not aware of the location which received stimulation. Both the order in which the TTCT versions were administered, as well as the order in which each hemisphere was stimulated, were randomized within each participant. Additionally, saliva samples for BDNF genotyping were collected and the handedness of each participant was recorded.

The TTCTs will be evaluated by a blinded third party, assigning numerical values to a creativity index and allowing for statistical, quantitative analysis of creativity performance and the correlation between creativity performance and left- versus right-frontal stimulation at the alpha frequency. We will report the unblinded results of this study at the meeting.

Abstract: Alpha (8 - 13 Hz) asymmetry, characterized by increased alpha power in left frontal electrodes compared to right frontal electrodes in resting state electroencephalograms (EEG), is widely reported in patients with mood disorders [1]. This asymmetry could serve as a potential target for non-invasive brain stimulation that modulates oscillations such as transcranial alternating current stimulation (tACS). We are currently conducting a clinical trial investigating the efficacy of tACS as a therapeutic for MDD patients. Here, we present preliminary results on the baseline topographical distribution of resting state alpha asymmetry in participants with major depressive disorder (MDD) and contrast it with healthy controls (HC). A total of 15 MDD (12 - Female) and 12 HC (9 - Female) participants were included in this analysis. The average Hamilton Rating Scale for Depression (HAMD) score of the MDD participants was 14.9 ± 4.5 (mean ± sd.). Eyes-open (EO) and eyes-closed (EC) 128 channel EEG was collected at the screening visit. The EEG preprocessing steps included line noise removal, robust average referencing and independent component analysis (ICA) to remove non-neural artefacts. Alpha band power spectral density (psd) was then computed using multi taper spectral analysis. Alpha asymmetry scores were computed as the difference in the log transformed psd between the homologous right (R) and Left (L) electrode pairs (ln(R) - ln(L)). We found a trend-level increase in the alpha asymmetry in the frontal regions [near F5/F9] in the eyes open condition in

the MDD population when compared to HC (-0.18 ± 0.01 vs. 0.02 ± 0.02, (mean ± s.e.m); p = 0.07 , two sample t-test). These results are in agreement with previously reported findings about the alpha asymmetry in the prefrontal regions of MDD patients. In contrast, alpha asymmetry was not different in the EC condition (-0.04 ± 0.01 vs. 0.05 ± 0.02; p = 0.24). These findings suggest that a more differentiated view of alpha asymmetry in MDD may emerge from such a more detailed topographic analysis. The correlation between HAMD score and alpha asymmetry was not significant, likely due to the small size of the population (r = -0.3, p = 0.26). Taken together, our results support frontal alpha asymmetry as a plausible physiological target and might serve as a marker of effectiveness for non-invasive therapeutic brain stimulation strategies.

Title: State-dependent entrainment by stimulation and the emergence of an asymmetric arnold tongue in a biophysical thalamic network model

Authors: *G. LI[1], C. HENRIQUEZ[2], F. FROHLICH[1];
[1]Psychiatry Dept., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Dept. of Biomed. Engin., Duke Univ., Durham, NC

Abstract: The thalamocortical system plays a central role in cerebral rhythmic oscillations and abnormal thalamocortical rhythms have been implicated in neurological and psychiatric disorders. Targeting brain oscillations with both invasive stimulation such as deep brain stimulation (DBS) and non-invasive brain stimulation such as transcranial magnetic stimulation

(TMS) have emerged as new promising therapeutic techniques that aim to restore physiological brain dynamics. However, a systematic understanding of how these stimulation paradigms interact with endogenous neural activity and neural oscillatory patterns to deliver therapeutic effects is currently lacking. Due to the critical role of the thalamus in mediating thalamocortical oscillations, we have developed a biophysically realistic thalamic network model that can generate multiple distinct states of oscillations (delta, spindle, alpha, beta and gamma oscillations) dependent on cholinergic and noradrenergic neuromodulation and afferent excitation. The successful manifestation of multiple distinct thalamic oscillations in one unified computational construct enabled us to systematically study the impact of stimulation on thalamic network dynamics. By employing a stimulation protocol consisting of brief current pulses, we examined the stimulation effects in a wide range of stimulation frequency and amplitude, and under four major oscillatory states (delta, alpha, beta and gamma). We found that (1) modulation of thalamic network oscillations critically depends on the endogenous frequency and (2) stimulation generates an asymmetric Arnold Tongue that favors stimulation frequencies higher than the endogenous frequency. The stimulation effect is also state-dependent such that lower frequency oscillations (delta and alpha) endowed with dynamics driven by intrinsic ion channels are more robust to stimulation perturbation than higher frequency oscillations (beta and gamma) that are predominantly driven by synaptic inputs. The interaction of intrinsic cellular dynamics and stimulation induced emergent network behaviors such as bistability and a discontinuity in entrainment as a function of the stimulation frequency. Furthermore, the model revealed that stimulation of the thalamic reticular nucleus (TRN) induced differential effects than stimulation of the lateral geniculate nucleus (LGN). Therefore, this biophysical modeling study offers important insights on the application of brain stimulation to the thalamus as a perturbation technique to target pathologically altered network dynamics associated neurological and psychiatric disorders.

Title: Sleep spindles and cognitive social development in infants and toddlers

Authors: *J. PAGE[1], C. LUSTENBERGER[2], M. MURIAS[3], F. FROHLICH[2];
[1]Educ. and Psychology, [2]Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC;
[3]Duke Inst. for Brain Sci., Duke Univ., Durham, NC

Abstract: A characteristic of early childhood is rapid development of cognitive capabilities and their underlying network-level substrate. Sleep is put forth as a means to assess these changes by examining the presence of sleep spindles. Sleep spindles are thalamo-cortically generated brain rhythms at 10-16 Hz in non-rapid eye movement (NREM) sleep [1] and are related to intelligence and general learning traits in adults and school aged children [2]. Sleep spindle characteristics are widely studied young adults, in older children (5 – 15 years old), and show clear developmental changes [3]. Furthermore, they are altered in several disorders, including autism spectrum disorder [4], schizophrenia, and neurodegenerative disorders. They may, therefore, represent a useful baseline biomarker for neurodevelopment to distinguish typical development from atypical development. However, the topographical and spectral characteristics of sleep spindles has yet to be examined in typically developing infants/toddlers 12 -30 months of age and moreover how these features are associated with outcomes of early cognitive development in this population.

To do address this gap, we are conducting a study on characterizing the topography of sleep spindles in children 12 – 30 months of age. Here we report preliminary nap data of a 26 month-old male with high density electroencephalogram (hdEEG, 128 electrodes). Initial findings depict clear spindle activity with two distinct spindle peaks, one around 12.5 Hz and one around 16 Hz during NREM sleep. In the topographical analysis, we found that the 16 Hz peak is most pronounced at parietal and frontal locations whereas the 12.5 Hz peak is most distinct at central locations.

This finding is in contrast to the topographical distribution of sleep spindles in young adults where slow spindles occur frontally, and fast spindles are detected centro-parietally. Furthermore, the highest frequency peak in adults is around 14 Hz [1,5] compared to 16 Hz that is reported here. Further research will investigate whether this spindle frequency is representative of individuals of this specific age (12 - 30 months), or particular to this child.

The long-term goal of this research is to establish if sleep spindles present a biomarker of typical development, which could then be used at an early age to assess risk for neurodevelopmental disorders.

Title: Cortical oscillations in juvenile ferrets following maternal immune activation during pregnancy

Authors: ***Y. LI**[1], J. H. GILMORE[1], F. FROHLICH[1,2,3,4,5];
[1]Dept. of Psychiatry, [2]Neurobio. Curriculum, [3]Dept. of Cell Biol. and Physiol., [4]Dept. of Biomed. Engin., [5]Neurosci. Ctr., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Abnormalities in neuronal synchronization and oscillations have been implicated in schizophrenia and other psychiatric disorders. Although studies suggested that decreased amplitude and synchrony of cortical oscillations in adolescence underlie the pathology of schizophrenia[1], it is still unknown when in the course of development these alterations arise. Here, we adapted an existing prenatal maternal-immune activation paradigm[2], which models features of schizophrenia, and applied it in the ferret. We injected poly I:C (10mg/kg, i.p.) into pregnant ferrets at E30 (full gestation ~41 days) and confirmed the occurrence of an immune activation by detecting an increase of body temperature. Multi-electrode arrays were implanted in the primary visual cortex in the offspring; spontaneous and light-evoked unit activity and local

field potential (LFP) were recorded before and after eye-opening in the freely moving animal. The results were compared to data from age-matched controls.
Overall, the spontaneous oscillation amplitude was increased after eye-opening compared to before eye-opening, especially in the higher frequency range (>30Hz). These gamma oscillations were decreased in amplitude in the poly I:C group compared to the control in both age groups ($p<0.001$, student-t test). Furthermore, phase-amplitude coupling of the gamma oscillation amplitude to the phase of lower frequency oscillations (delta, theta and alpha) was significantly decreased in the poly I:C group in both age groups ($p < 0.01$). Whole-field light flashes induced a peak in the gamma band of the LFP and the amplitude of this visual response was decreased in the poly I:C group ($p < 0.001$ for both age groups). Finally, in control animals, cortical oscillations were entrained by visual stimuli with frequency up to 30 Hz after eye-opening. This effect was decreased in the poly I:C group for higher frequencies (> 10 Hz).
Our results suggest that the functional interaction between neuronal circuits by synchronization of electrical activity patterns is impaired from very early stage in childhood development after environmental insults that increase risk for schizophrenia. A parallel study is investigating whether the maternal-immune activated ferret offspring exhibit behavioral changes consistent with abnormalities observed in schizophrenia. The long-term goal is to leverage these findings into novel brain stimulation treatments that aim to correct the observed aberrant neuronal activity pattern to restore physiological development of cortical circuits.

Title: High-frequency electric field stimulation modulates neocortical network dynamics *In vitro*.

Authors: ***S. L. SCHMIDT**[1], E. NEGAHBANI[2], N. MISHAL[2], F. FROHLICH[2];
[1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: Low field magnetic stimulation (LFMS) is a form of brain stimulation that applies small magnitude transient magnetic fields and has been shown to rapidly improve mood in patients with bipolar disorder and major depressive disorder [1]. The mechanism of action of LFMS is unknown. Here we applied an electric field with the same waveform as the induced electric field resulting from LFMS (0.5 kHz pulse train, patterned at 0.5 Hz) to acute cortical slices and compared the resulting network dynamics to sham stimulation (i.e., no electric field stimulation). We asked if such high-frequency electric field stimulation can induce outlasting changes to the network dynamics *in vitro*. We recorded multiunit (MU) spiking activity with a 6x10 array of microelectrodes from coronal sections of mouse prefrontal cortex. The brain slices were perfused with *in vivo*-like artificial cerebral spinal fluid with 5 μM carbachol to provide neuromodulatory drive and increase neuronal excitability. We compared multiunit firing rate (FR) and oscillatory power before and after 20 minutes of electric field stimulation (20 mV/mm peak to peak, verum) or sham stimulation. The presence of carbachol caused the firing rate to gradually increase in absence electric field stimulation as reported in [2]. During verum stimulation, FR increased less than during sham stimulation (increase in FR: 29.0% verum stimulation vs. 39.1% sham, n = 631 and 832 MU, 13 and 17 slices respectively, p = 0.013 Wilcoxon ranked sum). These experiments suggest that LFMS-type waveforms can reduce neuronal excitability and that these changes outlast the stimulation. We will extend this study to examine the effect of stimulation in absence of exogenous neuromodulators and also combined with other forms of neuromodulatory activation. A limitation that our study shares with other *in vitro* examinations of EF stimulation is that the amplitude used here is substantially higher than used for human stimulation [3]. Further studies are needed to understand the underlying mechanisms and to link these findings to the observed clinical effects of LFMS.

Title: Nonsinusoidal oscillatory shape can drive spurious cross-frequency coupling

Authors: *S. R. COLE[1], B. VOYTEK[2];
[2]Cognitive Sci., [1]UCSD, La Jolla, CA

Abstract: Oscillatory activity is abundant in electrophysiology across species, brain regions, and spatial scales. Neural oscillations are thought to be critical for communication within and across brain structures, as supported by hundreds of publications that report cross-frequency coupling in electrophysiological signals.
While these analyses are based on the Fourier transform, a decomposition method that assumes a sinusoidal basis, numerous reports have shown neural oscillations that are nonsinusoidal. Therefore, we hypothesize that the temporal features of the shape of a nonsinusoidal oscillatory waveform, rather than sinusoidal spectral features, may underlie apparent cross-frequency coupling.
Here we simulate electrophysiological signals with different biophysically-plausible waveforms and show that the waveform shape biases measures of both phase-amplitude coupling (PAC) and n:m phase-phase coupling (PPC, see Figure). That a temporal domain feature arising from one rhythmic process can produce apparent PAC and PPC contrasts with the two distinct oscillatory components that are often assumed to underlie them.
We conclude that naive application of Fourier analysis to electrophysiology may lead to misleading interpretations stemming from the underappreciated fact that neural oscillations are nonsinusoidal. For this reason, we have developed alternative measures for analyzing time series data that are more parsimonious than frequency domain analyses that are biased by waveform shape. This temporal-domain approach is justified by reports showing that behavior, disease state, and neurotransmitter presence affect oscillatory shape. In conclusion, both spectral and temporal analyses may be necessary to extract, and interpret, information in electrophysiological signals.

Title: Sparsely synchronized brain rhythms in an inhomogeneous small-world complex neuronal network

Authors: ***W. LIM**[1], S.-Y. KIM[2];
[1]Daegu Natl. Univ. of Educ., Daegu, Korea, Republic of; [2]Inst. for Computat. Neurosci., Daegu, Korea, Republic of

Abstract: We consider an inhomogeneous small-world network (SWN) composed of inhibitory short-range (SR) and long-range (LR) interneurons, and study emergence of sparsely synchronized rhythms by varying the fraction of LR interneurons p_{long} from 0 to 1. Although SR and LR interneurons have the same average in- and out-degrees (representing the potentiality in communication activity), their betweenness centralities (characterizing the potentiality in controlling communication between other interneurons) are distinctly different. Hence, in view of betweenness, SWNs we consider are inhomogeneous, unlike the "canonical" Watts-Strogatz SWN with nearly same betweenness centralities. For small p_{long}, the average betweenness centrality of LR interneurons is much larger than that of SR interneurons. Hence, the load of

communication traffic is much concentrated on a few LR interneurons. However, with further increase in p_{long} the number of LR connections (coming from LR interneurons) increases, and then the average betweenness centrality of LR interneurons decreases. Hence, as a result of increase in p_{long}, the average path length becomes shorter, and the load of communication traffic is less concentrated on LR interneurons, which leads to better efficiency of communication between interneurons. Particularly, we investigate the effect of network topology (e.g., average path length and betweenness) on sparsely synchronized rhythms. When passing a small critical value $p^{(c)}_{long}$ ($\simeq$ 0.16), sparsely synchronized rhythms are found to emerge. This transition from desynchronization to sparse synchronization is well characterized in terms of a realistic thermodynamic order parameter. For $p_{long} > p^{(c)}_{long}$, sparse synchronization occurs in the whole population because the spatial correlation length between neuronal pairs covers the whole system, thanks to sufficient number of LR connections. The degree of sparse synchronization is also well measured in terms of a realistic "statistical-mechanical" spiking measure, and an optimal sparse synchronization is found to occur at a dynamical-efficiency optimal value $p^{(o)}_{long}$ ($\simeq$ 0.27) through trade-off between synchronization and axon wiring cost. For this optimal case, responses to external time-periodic stimulations (applied to sub-groups of LR and SR interneurons, respectively) are studied and discussed in relation to the betweenness, representing the effectiveness of information transfer in the whole network.

Title: Competence of neuronal network models with random couplings to support slow oscillations

Authors: ***C. A. FUNG**, T. FUKAI;
Lab. for Neural Circuit Theory, RIKEN BSI, 2-1 Hirosawa, Wako, Japan

Abstract: Slow oscillations (~1Hz) are observed in mammals' brains during sleeping or resting, which are also believed to be related to memory consolidation during non-rapid-eye-movement sleep. There are reports showing that removal or inactivation of the thalamus will not completely impair the occurrence of UP states, although the occurrence of UP states are found to be contributed by inputs from the thalamus (Crunelli and Hughes, 2010). This observation suggested that local networks may have the ability to support UP state for at least a transient

period, so that UP states may still occur without input from the thalamus. To understand the local dynamics enabling the transient sustainability of UP states, in this work, we have studied networks of spiking neurons with randomly-distributed couplings. By using mean-field analysis, condition of parameters to support sustainable UP states and transient UP states are obtained, which is further verified by series of simulations. We have also studied how network behaviors differ between networks with log-normal distributed couplings and sparse-Gaussian couplings. Statistical analysis of those network behaviors are also presented.

Title: Spontaneous intracellular membrane voltage fluctuations in cortical pyramidal cells are inconsistent with balanced excitation and inhibition

Authors: ***F. R. FERNANDEZ**, J. A. WHITE;
Biomed. Engin., Boston Univ., Boston, MA

Abstract: Analyses of cortical neuron intracellular membrane voltage fluctuations resulting from sensory evoked activity, as well as up-down state transitions observed in anaesthetized rodents, indicates that these events are generated through a joint increase in excitatory and inhibitory currents. Accordingly, an increase in excitation is quickly followed and matched with an increase in inhibition. This form of balanced and correlated excitation and inhibition results from feedforward- and feedback-inhibition present in cortical circuits. It remains unclear, however, if spontaneous voltage fluctuations under awake conditions are also the product of balanced and temporally correlated excitatory and inhibitory synaptic activity. Unlike sensory evoked depolarizations or up-states, spontaneous voltage fluctuations lack an external reference point from which to measure changes in currents and calculate synaptic conductances. Nevertheless, if balanced and temporally correlated synaptic activity underlie spontaneous fluctuations, we would expect that mutual cancelation of excitatory and inhibitory events is maximal near the net synaptic reversal potential. For this reason, the relationship between the standard deviation of

membrane voltage fluctuations and the mean holding voltage should be non-monotonic; fluctuations are smallest near the net synaptic reversal potential but grow larger at voltages above or below the net synaptic reversal value. To test this hypothesis, we carried out visually-guided intracellular patch-clamp recordings of layer II somatosensory neurons in awake, head-fixed mice using 2-photon microscopy. Using tdTomato expression in CaMK2-postive neurons, we targeted pyramidal cells and carried out recordings in both current- and voltage-clamp across a range of subthreshold voltage values. Contrary to predictions from models of balanced and correlated synaptic activity, the standard deviation and power of fluctuations increases monotonically with depolarization from -90 to -40 mV. Further analysis indicates that spontaneous voltage fluctuations are largely the product of excitatory synaptic currents that are amplified by a voltage-dependent increase in pyramidal cell membrane input resistance.

Title: Spike frequency adaptation and memory selectivity

Authors: *J. P. ROACH[1,2], L. M. SANDER[3], M. R. ZOCHOWSKI[3];
[2]Neurosci. Grad. Program, [3]Physics, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: In the brain, representations of the external world are encoded by patterns of neural activity. It is critical that representations be stable so that they are easily reproduced. On the other hand there are times when representations need to be rapidly moved between. In this work we point to the effects of the neurotransmitter acetylcholine (ACh) is a plausible mechanism for the contextual stabilization (and destabilization) of neuronal representations. Acting through the muscarinic system ACh regulates the magnitude of spike frequency adaptation (SFA) by deactivating slow potassium currents. We use two computational models to show that the

magnitude of SFA exhibited by neurons selects for representations that have been stored within synaptic weights at different strengths. For low levels of SFA (which correspond to high levels of ACh), networks will stabilize in a representation that most closely corresponds to the initial network state. Increasing levels of SFA, by decreasing modeled ACh, leads to only the patterns corresponding to the strongest memories being stable. We show in a modified Hopfield network that increased SFA destabilize representations in a manner similar to fast, or thermodynamic noise, but also allows for deterministic, periodic activation of representations through time. Additionally, we demonstrate that SFA modulation controls selectivity for spatially localized representations in a biophysical model of cholinergic modulation in cortical networks. This model produces localized bumps of firing. A region with enhanced recurrent excitation stabilizes the bump location as a spatial representation and selectivity for these regions is quickly diminishes as SFA levels increase. When multiple spatial representations of varying strengths are stored in a network moderate increases of SFA level lead to strength dependent destabilization of representations in a quantitatively similar manner to the Hopfield model. We argue that control of SFA level is a universal mechanism for network-wide memory selectivity and that SFA provides a biologically plausible mechanism for switching between stable representations in cortical networks.

Title: Glucose modulation of synchronized network oscillations in ventromedial hypothalamic nucleus of acute and organotypic newborn rat brain slices

Authors: B. RAWAL, V. RANCIC, A. SU, *K. BALLANYI;
Physiol., Univ. Alberta, Edmonton, AB, Canada

Abstract: Glucose-sensitive neurons comprise neural networks in the ventromedial hypothalamic nucleus (VMN). Here we studied in 300 μm thick coronal slices from 0-3 days old rats whether neonatal VMN neurons (i) are already glucose-sensitive, (ii) show early network oscillations (ENOs) like neurons in immature neonatal brain regions (iii) retain their properties under 'organotypic' culture conditions. Acute slices showed a rhythmic field potential (single event duration 12-15 s, rate 4-5 bursts/min). Whole-cell recording combined with cytosolic calcium imaging using the fluorescent dye Fluo-4 revealed the field potential is due to synchronized rhythmic action potential discharge of VMN neurons causing calcium rises. Bolus-loading with Fluo-4 showed that >80% of fluorescent cells are rhythmic. In slices generated and kept in 3 mM glucose, lowering glucose to 1 mM accelerated the rate of electrical and calcium oscillations and 10 mM glucose slowed both events by 15-20%. VMN cells in cultured slices did neither change their morphology nor their responses to neuromodulators like ATP or glutamate for up to six weeks. Synchronous oscillations like in acute slices emerged after one week of culturing and were stable (and glucose-sensitive) between weeks 2-6. Our data indicate that (i) glucose-sensitive neurons regulate ENO-like oscillations in which the majority of neonatal VMN cells are involved and (ii) cultured VMN slices are a potent model for studying long-term pharmacological or genetic modulation of neural network activity.

Title: Synchronous bursting properties of interneuron networks are affected by cholinergic modulation of intrinsic cellular properties

Authors: *S. RICH[1], V. BOOTH[2], M. ZOCHOWSKI[3];
[1]Mathematics, [2]Mathematics and Anesthesiol., [3]Physics and Biophysics, Univ. of Michigan, Ann Arbor, MI

Abstract: Acetylcholine (ACh) modulates cell excitability via the slow, M-type potassium current (M-current). There is evidence that some of the PV interneurons, present in the

hippocampus and cortex, contain a M-current and are reciprocally connected. The OLM interneurons of the hippocampus also contain a M-current, although the presence of reciprocal connections is less clear. A proportion of cortical pyramidal cells also contain a M-current. The dynamics of the M-current affect cellular properties, typified through the cell's IF (current-frequency) curve and PRC (phase response curve), which quantifies the change in phase of the subsequent firing of a neuron in response to stimuli at various phases within its periodic firing cycle. In the absence of ACh, the M-current is active and the neuron exhibits Type II properties, including a shallow IF curve with a minimum firing frequency and a PRC showing a phase delay in response to an excitatory pulse soon after firing. An active M-current also causes spike-frequency adaptation (SFA), leading to an increased firing rate if the cell has not fired in the recent past. However, ACh blocks the M-current, causing the neuron to exhibit Type I properties including a steep IF curve with repetitive firing at arbitrarily low frequencies and a PRC that always shows phase advance. Our research shows that the changes in cellular properties caused by ACh affect an interneuron network's tendency to exhibit synchronous bursts of activity, be the network comprised strictly of inhibitory interneurons or of excitatory and inhibitory cells in a coupled, excitatory-inhibitory (E-I) network. Simulated networks of randomly connected inhibitory Type I neurons exhibit bursting activity via one-cluster dynamics in which largely the same neurons participate in each burst; however, simulations containing Type II neurons with an active M-current either exhibit one-cluster dynamics or a distinct two-cluster dynamic in which subsequent bursts of network activity contain mutually exclusive neuronal populations. The observed clustering dynamic is dependent upon the duration of synaptic inhibition and the magnitude of the external drive to the network. This behavior is distinct from the dynamics of networks of neurons with Type II properties but lacking a M-current or SFA. Analysis of E-I networks reveals that cholinergic modulation of the M-current causes significant changes in the rhythmic dynamics of the network. When properties of the visual cortex motivate the neuronal makeup of the E-I network, the changes caused by ACh may elucidate the mechanisms underlying some of the observed behavioral effects of cholinergic modulation on this system.

Title: The role of Parvalbumin and Somatostatin interneurons in hippocampal gamma oscllations

Authors: *P. ANTONOUDIOU, A. L. UPTON, E. O. MANN;
Univ. of Oxford, Oxford, United Kingdom

Abstract: The generation and long-range-synchronisation of cortical network oscillations at gamma (γ)-frequency (30-100 Hz) appears to correlate with specific cognitive functions. In order to resolve how rhythmic and/or synchronous patterns of activity during γ-oscillations contribute to cortical circuit computations, it is necessary to understand the mechanisms underlying their generation. There is a consensus that these rhythms depend on the spiking of inhibitory interneurons, which synchronise the firing of excitatory pyramidal cells via fast synaptic inhibition. Inhibitory interneurons constitute a heterogeneous group of neurons that can be distinguished based on their expression of neuropeptides, calcium binding proteins, and the subcellular targets of their axonal projections. It has previously been shown that the parvalbumin-positive (PV+) interneurons, which target the perisomatic domain of pyramidal neurons, play a key role in generating and maintaining γ-oscillations in the brain. However, as far as we are aware, it has not been tested how direct activation of another major interneuron class, the somatostatin-positive (SST+) interneuron, affects the generation of rhythmic network activities. Therefore, we stereotaxically injected PV-CRE and SST-CRE mice in the ventral hippocampus with a CRE-dependent AAV5 vector that carried the light sensitive cation channel, Channelrhodopsin 2 (ChR2). This enabled us to examine how activation of PV+ or SST+ interneurons affects network activity in the CA3 of acute hippocampal slices. Light activation of either PV+INs or SST+INs at 40 Hz could entrain cholinergically-induced (5 μM carbachol) γ-oscillations in acute hippocampal brain slices. However, continuous activation of PV+INs suppressed ongoing γ-oscillations, whereas activation of SST+INs was able to induce γ-oscillations even in the absence of cholinergic drive. These results suggest that there may be more than one type of cortical microcircuit that generates γ-oscillations.

Title: Theta and delta rhythms underlie cross-regional interactions during semantic processing

Authors: *N. ADAMS[1], C. TEIGE[2], G. MOLLO[2], T. KARAPANAGIOTIDIS[2], P. L. CORNELISSEN[4], J. SMALLWOOD[2], M. A. WHITTINGTON[3], B. JEFFERIES[2]; [1]Biol., [2]Psychology, [3]HYMS, Univ. of York, York, United Kingdom; [4]Psychology, Northumbria Univ., Newcastle upon Tyne, United Kingdom

Abstract: Objectives: To investigate spatio-temporal aspects of cross-regional dynamics amongst brain areas involved in semantic processing.
Methods & Results: 17 participants performed a semantic task in which two words were presented in succession (these were either strongly or weakly related or unrelated). They decided if the two words were linked in meaning and were cued to make an overt response on occasional catch trials. Response times were also assessed for the same task outside the scanner. Data were beamformed following co-registration to the individuals' structural MR scan to give 7 nodes of interest in anterior, posterior and temporal cortices. All analyses were performed in MATLAB. Following stimulus delivery a clear trajectory of cross-covariant pairs was seen. However, strongly and weakly related word pairs generated differing trajectories resulting in co-activation of different node clusters immediately prior to when a response was expected. Highly synchronous activity was seen in the node triplet MFG-MTG-PCC prior to response in the strong association condition. In contrast a quadruplet of highly synchronous node pairs (ATL-AG-PCC-MTG) was seen prior to response in the weak association condition. Difference spectrograms for strong-vs-weak association trials revealed a theta-to-delta frequency inverse-chirp signal, with the response time corresponding to the lower bound of this event.
Conclusions: Although averaged individual regional responses to the two task conditions were indistinguishable, the resulting cross-regional interactions were both temporally and structurally different depending on the associative strength between semantically-related words.

Title: Striatal and cortical networks on microelectrode arrays - an *In vitro* model for Hepatic Encephalopathy

Authors: *S. THEISS[1], A. SCHNITZLER[1], O. A. SERGEEVA[2,1], W. FLEISCHER[1];
[1]Inst. of Clin. Neurosci., [2]Inst. of Neurophysiol., Univ. of Duesseldorf, Duesseldorf, Germany

Abstract: Hepatic encephalopathy (HE) is associated with pathologically raised ammonia and glutamine levels. HE patients present with severe but potentially reversible neurological symptoms, while functional imaging suggests basal ganglia involvement. Recent studies showed that oxidative stress in hyperammonemic animals was especially severe in somatosensory cortex. In order to establish a functional brain region specific *in vitro* model for HE, P0 rat coronal corticostriatal slices were processed to prepare parallel primary dissociated cultures of striatum or cortex, grown separately on microelectrode arrays (MEAs) with 60 Ti/TiN electrodes (30 µm diameter, 200 µm spacing; Multichannel Systems). Cultured striatal neurons widely expressed glutamate decarboxylase and vesicular GABA transporter, but only low levels of vesicular glutamate transporters VGLUT 1/2 (2—4% of cortical culture levels). Mature cortical and striatal cultures (>21 DIV) on MEAs showed spontaneous synchronous network bursts with distinct responses to elevated levels of ammonium or glutamine applied for 10 minutes. Ammonium (5 mM) increased burst rate of cortical neurons 1.3-fold, but inhibited bursting in striatal neurons 0.75-fold. In striatal cultures, glutamine (2 mM) increased spike rate 3.5-fold and burst rate 7.2-fold. Glutamine action was weaker in cortical cultures: spike and burst rates were increased 1.3-fold and 5-fold, respectively. In both striatal and cortical cultures, glutamine evoked a long-lasting stable network state with more and shorter bursts and more spikes outside of bursts that persisted over 20 minutes post washout. In Ca^{2+} imaging experiments, striatal cultures showed a glutamine-induced intracellular Ca^{2+} rise that was independent of neuronal activity (persisted in TTX), but could be blocked by competitive inhibition of system A amino acid transport (MeAiB), as well as by ionotropic glutamate receptor antagonists, suggesting a glutamate-mediated mechanism. Glutamate release from striatal cells could indeed be verified with an enzymatic assay kit. Thus, extracellular glutamine was taken up by neurons and triggered release of glutamate, which astrocytes then converted to glutamine and released back into extracellular space—a feedback-loop causing sustained long-lasting excitation of network activity after termination of drug application. Therefore, glutamine may play an important role in striatum-related symptoms of HE. In line with results from *in vivo* studies on HE models, this MEA-based *in vitro* approach revealed tissue-specific responses to ammonium and glutamine.

Title: Intrinsic network for mood in the human brain

Authors: *L. A. KIRKBY[1], F. LUONGO[1], M. NAHUM[2], T. VAN VLEET[2], M. LEE[1], H. DAWES[1], E. CHANG[1], V. SOHAL[1];

Abstract: Mood is an inherent part of what makes us human, however the neural circuits underlying mood regulation are poorly understood. Here, we used chronic, large-scale electrocorticography (ECoG) recordings from the human limbic system to identify sub-networks relevant to mood. Recordings were collected from patients with epilepsy undergoing surgical evaluation, over a period of several days. We assessed functional interactions between different brain regions by computing signal coherence across recording sites, from which we constructed a time series of coherence matrices in various frequency bands. We used independent components analysis to identify intrinsic connectivity networks (ICNs) within our datasets. Each dataset contained on the order of ten ICNs per frequency band, with some redundancy across bands. We postulated that sub-networks extracted in this way could be relevant to mood processing. Patients' psychological state was assessed using Posit Science's mood tracking application at several time points over the course of several days. Using a regression analysis, we found that activity patterns represented by a single ICN consistently correlated with mood state across patients. We identified the components that comprise this mood-correlated ICN to determine a neural representation for mood in the human brain. These findings have implications towards potential treatment for mood disorders, including anxiety and depression.
These data are part of the SUBNETS program, a collaborative project investigating circuit function and dysfunction in neuropsychiatric conditions.

Title: Attentional modulations of neuronal interactions during multisensory processing: An MEG study employing a visuotactile matching paradigm.

Authors: *F. GÖSCHL[1], U. FRIESE[1], J. DAUME[1], P. KÖNIG[2,1], A. K. ENGEL[1];
[1]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. of Cognitive Sci., Univ. of Osnabrück, Osnabrück, Germany

Abstract: Attentional selection of sensory signals and their integration across modalities require flexible interaction between remote brain areas. One candidate mechanism to establish local and long-range communication in the brain and thereby also address the challenge of binding stimulus features across modalities is transient synchronization of neural assemblies. In the present study, we used magnetoencephalography (MEG) to record brain activity from healthy human participants engaged in a pattern matching paradigm requiring the evaluation of concurrently presented visual and tactile stimuli. To investigate the interplay of bottom-up stimulus processing and top-down demands, we manipulated the crossmodal relation of the two stimuli as well as the focus of spatial attention. Spectral power in the theta- (2-7 Hz), alpha- (7-13 Hz), beta- (13-30 Hz) and gamma-bands (60-90 Hz) was analyzed on the sensor level and projected to the level of cortical sources using beamforming. We found neuronal activity in anticipation of crossmodal stimulation in the alpha- and beta-bands to be modulated by the direction of attention. Oscillatory power was reduced in cortical areas contralateral to the attended side, the maxima being located in higher visual areas, somatosensory association cortex, and supramarginal gyrus. For the processing of crossmodal information, attentional modulations were reflected in the beta- and gamma-bands and located in cortical areas largely overlapping with those observed in the baseline contrasts. In contrast, differences in spectral power related to visuotactile stimulus congruence were only apparent in beta frequencies and maximal in premotor cortices. Additional analysis of the phase dynamics of oscillatory signals suggested synchronization in low-frequency activity to be critically involved in the deployment of multisensory attention. Taken together, these results provide further evidence that oscillatory synchronization is functionally relevant for communication in distributed brain networks, and suggest that the integration of visuotactile information depends on both, bottom-up and top-down factors.

Title: Mesoscale, *In vivo*, functional voltage neuroimaging metrics for the assessment of normal and pathological brain function in mouse models of psychiatric disease

Authors: *A. W. CHAN, J. M. LEDUE, Y. WANG, T. H. MURPHY;
Brain Res. Ctr., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Increasingly, functional neuroimaging, principally using fMRI, is being applied to the investigation of psychiatric and neurodegenerative disease to reveal underlying long-distance network pathologies in brain function and the potential discovery of novel biomarkers of disease and disease progression. We propose that intermediate, mesoscale, neuroimaging approaches, using modalities that more directly reflect neuronal activity, in mouse models of psychiatric disease, presents an important parallel and complementary approach that can reveal much about disease pathology not possible in human imaging paradigms alone and may provide a platform for testing therapeutic interventions. Imperative to the interpretation of these approaches is the demonstration of robust functional neuroimaging metrics by which to assess abnormal, mesoscale, cortical activity. We used high-speed (150 Hz), wide-field (8.5x8.5 mm), voltage-sensitive dye (RH1692) imaging to examine spontaneous and sensory-evoked (somatosensory, visual, and auditory) networks of cortical activity in head-fixed awake and isoflurane-anesthetized C57Bl6 mice. Voltage sensitive dyes are advantageous for comparing mutant mouse lines that model human psychiatric disorders because they do not require breeding to introduce activity sensors that may alter disease characteristics. We demonstrate that infraslow (<0.1 Hz) and slow (0.5-6.0 Hz) correlated spontaneous activity can recapitulate analogs of human long-distance resting-state networks (Chan et al. 2015 Nature Comm). Intrahemispheric cortical connectivity revealed highest connectivity (R values >0.8) within medial medial cortical structures including cingulate, motor cortices, and parietal association cortex. Using resting state analysis we define standard deviation maps of regional activity in different frequency bands as an overall measure of activity while regional correlation reflects synchrony within networks. Interestingly, regional values of standard deviation reflecting baseline activity were highest in the same structures exhibiting greatest synchrony. In addition, our approach also allows for analyses of fast cortical dynamics. We assessed input-output strengths and variance of peripherally-evoked cortical sensory activity as well as the cortical receptive field sizes

associated with primary and secondary sensory cortical activation. Our intention is to use these approaches to evaluate leading models of psychiatric disorders related to autism spectrum disorder using the SHANK3 mutant mouse lines.

Title: Resting-state fMRI signals in the macaque are differentially altered by transient inactivation of specific basal forebrain subregions.

Authors: ***J. N. TURCHI**[1], C. CHANG[2], F. Q. YE[3], B. E. RUSS[4], D. K. YU[3], J. H. DUYN[2], D. A. LEOPOLD[4,3];

Abstract: The physiological origins of spontaneous fluctuations in functional MRI (fMRI) signals remain to be elucidated. One structure that may drive a component of spatially correlated spontaneous activity is the basal forebrain (BF), which provides significant input to widespread cortical areas. Here, we hypothesized that selective unilateral inactivation of BF subdivisions would affect spontaneous activity primarily in regions to which these subdivisions project, while spontaneous activity in the fields to which the other basal forebrain subregions project would remain unaltered. To investigate the contributions of different basal forebrain subdivisions, we measured changes in spontaneous fMRI fluctuations after reversibly inactivating specific BF regions. On separate dates, muscimol (18 mM-44mM, 1.8 - 2.5 µl/ site) was infused unilaterally into different portions of the BF in monkeys: Ch4al, Ch4am, and Ch2 (for a total of 22 infusions in 2 monkeys). For functional MRI, intravenous MION was administered and 3-5 resting-state scans, each lasting thirty minutes, were collected (EPI, 1.5 mm isotropic, TR = 2.5 s). Data from each scan were spatially co-registered to a single reference EPI scan, and fMRI time series were converted to units of percent signal change. We examined hemispheric differences in fMRI signal correlations after inactivating each of the above three BF subregions and found that across all targeted sites, correlated signal fluctuations and local signal amplitude were attenuated in

areas ipsilateral to the inactivation. The greatest attenuation in fMRI amplitude was localized to regions receiving projections from the inactivated BF subregion. Specifically, shared spontaneous fluctuations were attenuated in much of cortex ipsilateral to Ch4al injections (including visual, ventral posterior parietal, and insula), while the hippocampus and cingulate cortex were largely spared. This pattern showed high correspondence (hemisphere reversal) across the separate left- and right-hemisphere inactivation sessions. In contrast, inactivation of Ch4am mainly affected medial parietal and cingulate cortices, while the effects of Ch2 inactivation were observed primarily in hippocampus and cingulate. These results demonstrate the strong contribution of the basal forebrain in shaping spontaneous fMRI fluctuations, as well as their inter-area correlations.

Title: The ventral tegmental area is involved in the generation of high frequency oscillations in the nmda receptor antagonist model of schizophrenia

Authors: ***M. HUNT**[1], M. OLSZEWSKI[2], J. PIASECKA[2], M. WHITTINGTON[1], S. KASICKI[2];
[1]Univ. of York, York, United Kingdom; [2]Nencki Inst., Warsaw, Poland

Abstract: NMDA receptor antagonists are widely used to model some of the symptoms of schizophrenia. The pathophysiology of this disease remains unclear, however, certain brain regions including the nucleus accumbens (NAc) have been widely implicated in the disease. Systemic injection of NMDA receptors antagonists, such as MK801, are associated with the presence of high frequency oscillations (HFO, 130-180 Hz) which can be recorded in local field potentials from many brain regions, including the NAc. We have shown previously that reversible inhibition of the NAc by local infusion of tetrodotoxin (TTX) reduces the amplitude of MK801-enhanced HFO indicating that this oscillation involved the local NAc network.

Importantly, afferent regions powerfully modulate the activity of NAc neurons. However, it is not known to what extent HFO in the NAc may be driven by its afferent projections (ventral hippocampus, basolateral amygdala, prefrontal cortex and the ventral tegmental area). In this study, rats were implanted with electrodes in the NAc and guides targeted at these afferent sites. We found that unilateral infusion of TTX (1 ng in 1 μl) to the ventral tegmental area reduced the power of MK801 (0.15 mg/kg)-enhanced HFO on the ipsilateral but not contralateral side. Infusion of TTX (1 ng in 1 μl) to the prefrontal cortex or ventral hippocampus had negligible effect MK801-enhanced HFO, although TTX infusion to the amygdala produced a much weaker reduction in HFO power. These findings indicate that the ventral tegmental area is an important brain regions generating HFO in the NAc (and likely other regions) after systemic injection of NMDA receptor antagonists.

Title: State repertoire and self-organized criticality of mesoscopic cortical dynamics are not altered during anesthetic-induced unconsciousness

Authors: *A. G. HUDETZ[1], J. VIZUETE[2], S. PILLAY[3], G. A. MASHOUR[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Med. Col. of Wisconsin, Milwaukee, WI; [3]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Anesthesia may modify consciousness by altering information integration in cortical circuits. Consciousness has been linked to the repertoire of brain states and to self-organized criticality. Cortical neuronal populations form synchronized ensembles whose characteristics are state-dependent but this has not been rigorously tested in anesthesia. Spontaneous neuronal activity was recorded with 64-contact microelectrode arrays in visual cortex of chronically instrumented, unrestrained rats under stepwise decreasing levels of anesthesia with desflurane. In each condition, local field potentials (LFP) were recorded for 10 minutes, sampled at 1000 Hz and band-pass filtered at 4-60 Hz. The negative peaks of LFP exceeding mean minus 3 standard deviations (nLFPs) were detected at 10ms time bins and their spatial pattern was analyzed. The

nLFPs formed compact, spatially contiguous activity patterns (CAPs) with short lifetimes (~10ms). The frequency distribution of CAP sizes followed a power-law with slope -1.5 in deep anesthesia (8% and 6% desflurane) suggesting the presence of self-organized criticality. The distribution deviated slightly from power-law as the animals regained consciousness. Randomizing the LFP data destroyed the power-law. The average number of CAPs was elevated in both wakefulness (0% desflurane) and deep anesthesia (8% desflurane) associated with burst-suppression. The entropy of CAP sizes was highest in wakefulness but changed insignificantly at desflurane concentrations between 6% and 4% desflurane associated with the transition from unconsciousness to consciousness as implied by the return of the rats' righting reflex. The types of recurring CAPs categorized by K-means clustering were conserved at all anesthesia levels and wakefulness, although proportion of various types did change in a concentration-dependent manner. The results yield new knowledge about the dynamic landscape of ongoing population activity in rat visual cortex at graded levels of anesthesia. Neither the repertoire nor self-organized criticality of local population activity can account for anesthetic suppression of consciousness suggesting that the latter may depend more on large-scale or temporally longer-scale dynamics or changes outside of primary sensory cortex.

Title: Elicitation and rescue of schizophrenia-like gamma band abnormalities via optogenetic and pharmacological manipulation of cortical excitatory/inhibitory balance

Authors: *J. M. MCNALLY[1], S. THANKACHAN[1], J. T. MCKENNA[1], R. W. MCCARLEY[2], R. E. BROWN[2];
[1]VABHS, Harvard Med. Sch., West Roxbury, MA; [2]VABHS, Harvard Med. Sch., Brockton, MA

Abstract: Abnormalities in gamma band (30-80 Hz) oscillations (**GBO**) are an important feature of schizophrenia (**Sz**), which have been linked to all symptom classes. Current models suggest that impaired NMDA receptor activity, particularly in certain populations of cortical interneurons, alters the delicate balance in activity between the inhibitory and excitatory components of the cortical circuit (**E/I balance**), principally through a reduction of the activity of interneurons which express parvalbumin (**PV**), thereby causing GBO abnormalities. Numerous model systems, such as administration of sub-anesthetic doses of NMDA antagonists (e.g. ketamine), effectively model symptoms of Sz in humans and elicit Sz-like GBO and behavioral phenotypes reminiscent of Sz in animals. However, novel methods to restore E/I balance and Sz-related behavioral changes are needed. Further, it would be useful to have a non-pharmacological method to elicit Sz-like GBO abnormalities and correlate these abnormalities with behavior.

Here, utilizing both optogenetic and pharmacological techniques, we investigated whether: (i) Increased activity of cortically projecting basal forebrain (**BF**) GABAergic PV neurons, which target cortical PV interneurons and modulate cortical GBO (Kim et al., 2015, *PNAS* 112(11):3535), would mimic Sz-like increases in spontaneous GBO and locomotor activity; and (ii) Whether optogenetic inhibition of BF PV neurons or manipulation of the type 5 metabotropic glutamate receptor (**mGluR5**), which is expressed by cortical PV neurons, and has been shown to facilitate NMDA receptor function, would rescue ketamine-induced GBO abnormalities.

Tonic optogenetic excitation of BF PV neurons *in vivo* (n=6; 60 s constant 473 nm laser light at 5 mW) elevated spontaneous GBO and increased locomotor activity (n=4; 43%). Conversely, bilateral ArchT optogenetic inhibition of BF PV neurons in freely behaving mice (n=4; 2 min constant 532 nm laser light at 20 mW delivered at 2 min intervals) partially rescued the elevated spontaneous GBO activity elicited by acute ketamine (30 mg/kg). *In vitro*, using a slice model of GBO, CDPPB (10-20 μM; n=4) and CHPG (200 uM; n=8), positive modulators of mGluR5, while having no effect on the GBO alone, partially inhibited the acute potentiation of GBO by ketamine (100 μM).

Together, these findings suggest: 1) optogenetic manipulation of the activity of BF PV neurons is a non-pharmacological way to elicit Sz-like increases in spontaneous GBO and locomotor activity; 2) Inhibition of BF PV neurons or pharmacological facilitation of mGluR5 activity may be effective targets for modulating cortical E/I balance, and restoring normal GBO activity in Sz.

Abstract: Spontaneous brain activity patterns in the neocortex are believed to represent underlying brain circuits and their functions. Indeed, recent neuroimaging studies have demonstrated that the functional connectivity and graph theoretical structure of spontaneous activity correlate with anatomical connections and behavioral performances. However, previous studies used imaging modalities that record hemodynamic signals of relatively low spatiotemporal resolution. Little is known about the large-scale network structure of neuronal signals with relatively superior spatiotemporal resolution.
To address this issue, we used voltage-sensitive dye imaging(VSDI) in mice, covering most neocortical regions of a single hemisphere. The signal was then used to characterize both static and dynamics of neural activation patterns. The effects of neuromodulators such as cholinergic agonist carbachol and norepinephrine were also studied.
Characterization of the static large-scale network connectivity pattern and its dynamics was based on connectivity matrix created with spatial independent component analysis-derived functional ROIs and pixel-by-pixel comparison. Graph theoretical analysis was then performed to identify hub regions and modules along with calculation of other parameters such as the global efficiency, clustering coefficient. Subsequently, dynamic changes of neural activation pattern were characterized. This included k-means clustering and quantification of ”local oscillation“ time-points to represent the number of less synchronized time-points.
We first identified default mode network-like hyperactivating regions that cover midline and temporal regions of the neocortex. The midline part of the regions was highly connected to the cortical hub regions along the parietal association areas. Further analysis revealed that norepinephrine and carbachol drives the functional connectivity to shift in distinct directions - norepinephrine increasing the cortex-wide activation spatiotemporally, leading to increased efficiency and decreased modularity while carbachol had the opposite effect. The “local”

oscillation duration was also higher in norepinephrine applied group and lower in carbachol applied group although other features was more robust to neuromodulator application.
Our results provide pixel-wise and large-scale analysis of graph theoretical parameters at a relatively superior spatiotemporal resolution with VSDI. We also see the effect of neuromodulators on the large-scale neuronal activity in distinct manners, preserving key features as such the hyperactivation pattern.

Title: Physiological mechanisms underlying alpha frequency oscillations in the rat visual cortex.

Authors: ***K. HAWKINS**[1], A. SIMON[1], R. D. TRAUB[2], M. A. WHITTINGTON[1];
[1]Univ. of York, York, United Kingdom; [2]IBM, TJ Watson Res. Ctr., Yorktown Heights, NY

Abstract: Objectives: EEG alpha rhythms (8-12Hz) were the earliest brain rhythms discovered but remain the most mysterious in terms of mechanism. Functionally they play a fundamental role in cognitive processes such as selective attention and short-term memory. In the visual system, post-stimulus alpha oscillations are readily observed upon closing of the eyes or removal of visual stimulus. We therefore generated a post-stimulus model on activity in rat visual cortex *in vitro* to determine which physiological mechanisms are responsible for the generation of alpha rhythms.
Methods and Results: We isolated the V1 and V2 of the visual cortex from adult, male wistar rats in 450 μm thick slices. Extracellular field potential (LFP) recordings were taken from LIV of the V1 and gamma/beta2 activity was induced by application of 800nM Kainate (KA) to mimic sensory stimulation. This excitatory drive was then reduced by partial blockade of glutamate receptors. This manipulation alone reduced oscillation frequency to within the beta1 range and almost abolished LFP power. However, in the presence of cholinergic neuromodulation a near 4-fold increase in power was seen at alpha frequencies. This cholinergic effect could be mimicked entirely by blockade of I_h current: Control frequency 27.3 ± 0.6 Hz changed to 11. 2 ± 0.2Hz and

control power of 11.6 ± 1.7μV changed to 55.4 ± 8.2μV, n=51. The alpha rhythm dominated, as LFP, in layer IV of the V1. Intracellular studies showed 3 main types of LIV principal cell. Stellate cells and regular spiking, small pyramids spiked phase-locked to the control beta rhythm but not the alpha rhythm. Intrinsically bursting pyramidal cells spikes phase locked to both beta and alpha rhythms despite the presence of very little phasic synaptic inhibition. The dominance of this LIV bursting cell-associated alpha rhythm temporally uncoupled the majority of LIV principal cells from both LII/III and LV.
Conclusions: Alpha rhythms appear to dynamically uncouple the main thalamorecipient neurons in LIV V1 from other layers. We suggest this may represent the 'inhibition' of V1 by preventing ascending visual information from both passing on to higher order visual areas and also being influenced by top-down signal from these areas.

Title: Data mining to generate novel hypotheses for the genetic underpinnings and functional roles of cortical oscillations

Authors: *P. SEBASTIAN[1], T. DONOGHUE[2], T. NOTO[2], S. HAXBY[3], B. VOYTEK[2]; [2]Cognitive Sci., [3]Mathematics, [1]UCSD, San Diego, CA

Abstract: Neural oscillations are ubiquitous across species, across cortical and subcortical brain regions, and may play a critical role in neural computation, function, disease states, and behavior. While it is known that oscillations are heterogeneous across the human brain, with specific oscillatory sub-bands manifesting in preferred regions, the degree of this heterogeneity and their physiological origins remains underexplored. Here, we align multiple spatial data into a common reference frame in order to explore the genetic origins and functional associations of neural oscillations. We use publicly available data including magnetoencephalography (MEG) data from the Open MEG Archive (OMEGA) and the Human Connectome Project (HCP), transcriptome-wide gene expression estimates from human brains using the Allen Human Brain Atlas (AHBA), and functional mapping data from Neurosynth. This allows us to make

comparisons between different methodologies and disciplines, to validate current theories of neural oscillations, and to generate novel hypotheses about their physiological origins and functional roles. Resting state MEG data (5-10 mins) were pre-processed and source-projected to a group template brain. Power spectra were calculated across all cortical locations and automated methods were used to estimate the 1/f noise exponent, and to identify the center frequencies and bandwidths of any existing oscillations, at each location. Group oscillation maps were calculated by creating a normalized score, encompassing the probability of an oscillation weighted by its normalized power, which we compute for a priori oscillatory bands: theta, alpha, beta, and low gamma. For each oscillatory topography, we compute a spatial correlation with functional term maps from Neurosynth, and gene expression maps from the AHBA. Spatial correlations between oscillatory maps and functional terms corroborate known associations, for example, theta correlates highly with 'episodic memory', alpha correlates highly with 'vision', and beta with 'motor'. We also find that oscillatory maps correlate with expression of many specific genes, including ion channel subtypes. These results show that disparate databases can be integrated in ways that support previous findings and suggest future hypotheses for the origin and function of neural oscillations.

Title: Gap junction channels in the synchronization of neuronal oscillations in a model of neuronal activation

Authors: ***E. R. KINJO**[1], M. S. A. FERRAZ[1], B. A. SANTOS[1], D. S. KOSTECKI[1], L. M. SILVA[1], A. C. VALLE[2], A. H. KIHARA[1];
[1]UNIVERSIDADE FEDERAL DO ABC, SÃO BERNARDO DO CAMPO, Brazil;
[2]FACULDADE DE MEDICINA DA UNIVERSIDADE DE SÃO PAULO, São Paulo, Brazil

Abstract: The involvement of gap junction channels (GJC, composed of protein subunits called connexins-Cxs) in the synchronization of neuronal oscillations has been increasingly demonstrated, highlighting the importance of electrical synapses in shaping the neuronal

electrical activity. While most efforts have been dedicated to the understanding of chemical synapses, less is known regarding the plastic properties of electrical synapses. By using an *in vivo* model of neuronal activation induced by pilocarpine, our goal was to evaluate the effects of intrahippocampal administration of the GJC blocker carbenoxolone (CBX) in the hippocampal and cortical local field potentials (LFP). Male wistar rats were submitted to stereotaxic surgery for implantation of hippocampal cannula and cortical and hippocampal electrodes. After period of recovery, the animals were submitted to thirty minutes of recording of the basal activity. After that, animals were treated with methyl scopolamine (1 mg/kg; subcutaneous) followed by intraperitoneal pilocarpine (360 mg/kg) injection. Control animals received saline instead of pilocarpine. Thirty minutes after the establishment of status epilepticus, animals received intrahippocampal CBX (162 mM). The power spectrum density and spectrogram analysis revealed that the basal recordings from both cortical and hippocampal areas presented potentials that oscillated in the theta, beta and gamma frequencies, pattern that was not changed after methyl scopolamine administration. After pilocarpine injection, evident increase of the power of all the frequencies was observed, especially in the beta and gamma ranges, which were the same frequency ranges that presented large reduction of power after CBX administration, with smaller contribution than the observed during the basal period. After dissipation of the effects of CBX, ictal potentials were seen again, but the distribution of the frequencies was different from the detected before CBX administration, once the power of beta and gamma frequencies was significantly minor, suggesting that GJC has a fundamental participation in higher neuronal oscillations.

Title: Spatio-temporal modeling of a macroscopic brain tissue from multi-cells level to single proteins using gaming technology

Authors: *U. NEVO, E. OPHIR, A. LIBERMAN, D. KARIO, M. MUSSEL;
Biomed. Engin., Tel Aviv Univ., Tel Aviv, Israel

Abstract: We have created a generic platform for three dimensional, graphical, interactive simulations of macroscopic cerebral volume. Uniqueness of the software method is in: (a) its

capability to model the **spatial interactions of the neural network in 3D;** (b) modeling entities scaling from the level of cellular networks and down to single molecules and ionic fields (dynamics of concentrations of extracellular ions or of single proteins); (c) inclusion of chemical and biophysical interactions; (d) interactivity and user friendliness; The system features a graphical user interface to generate an experiment and displays an animated graphical representation of the experiment. The user may control the timeline of the experiment as well as intervene to affect the experiment itself (e.g. inject molecules). Two modes of operation are possible: (a) A “batch mode” is used to run multiple instances of the simulation with different parameters. The output is textual, including events and quantities from the experiment. It can easily be parsed, manipulated using "big data" tools, and graphed. (b) A real time (3D) animated view mimicking microscopy imaging of the cells, of membranal proteins that are visible as they diffuse and migrate on the surface and of action potentials. The "live" animation (not a movie, but a clip of simulation results!) allows to control the timeline of the experiment or the zoom and angle of the "microscope camera". The systems features oup to hundreds of neurons all operating in parallel, within a grid of 1 mm^3 tissue segment. Cells are 'decorated' by thousands of receptors and membrane proteins. Modeled biophysical and molecular mechanisms include: membrane excitability, release and diffusion of ions, apoptosis, release of neurotransmitters or other proteins, and more. Cellular actions are directed by state machine that defines signaling and response to environmental cues. Coding uses C++ and CUDA and the Unity3D game engine with its physics engine, scripting environment and GUI creator. We suggest the system for preliminary testing of hypotheses, optimization of experiments on neural systems (prior to "wet" experiments) and understanding of scenarios in which the exact spatial organization of the network is critical. Relevant pathological scenarios to be studied include the analysis of events such as **epileptic seizures, spreading depression or stroke** (with respect to the wave of secondary degeneration) or mechanisms of neurodegeneration. Our vision is that Cell Studio will become a ‘game-changer’ in neurobiology, and specifically in experimental biology, the same way simulations are used in engineering, physics and structural chemistry.

Title: Thalamic generation of propofol phase amplitude coupling

Authors: *A. SOPLATA[1], J. SHERFEY[1], E. N. BROWN[4,5,7], P. PURDON[4,6], N. KOPELL[2,3]; [1]Grad. Program in Neurosci., [2]Dept. of Mathematics and Statistics, [3]Cognitive Rhythms Collaborative, Boston Univ., Boston, MA; [4]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [6]Dept. of Anesthesia, Critical Care and Pain Med., [5]Harvard Med. Sch., Boston, MA; [7]Dept. of Anesthesia, Critical Care and Pain Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: Propofol, the most widely-used intravenous anesthetic, leads to both slow wave (0.1-1.5 Hz) and alpha (8-13 Hz) EEG oscillations at anesthetic doses. At these doses, propofol potentiates GABAa currents and antagonizes H-currents. At the deepest anesthetic level, there is phase-amplitude coupling (PAC) between the alpha and slow wave oscillations in which the alpha appears at the peak of the slow wave ("peak-max"). By contrast, at weaker doses corresponding to the time of loss or recovery of consciousness, the alpha appears in the trough of the slow oscillation ("trough-max") (Purdon et al., 2013). This change in PAC allows real-time determination of the depth of anesthesia (Purdon et al., 2013). To examine the mechanisms of this change in PAC, we simulated a thalamic system built from (Ching et al., 2010) and (Destexhe et al., 1996) consisting of thalamocortical and reticular nucleus cells with Hodgkin-Huxley dynamics and stochastic corticothalamic spiking input. We included propofol dose effects by increasing maximal conductance and decay time constant of GABAa-mediated inhibition by either 2X or 3X normal, and by decreasing maximal H-current conductance (gH). We then considered for each a pair of 2-D parameter spaces, varying gH and applied current corresponding to peak and trough phases of the cortical slow wave. The changes in the applied current allowed us to explore differences in voltage associated with changes along the slow wave and its effects on the thalamus' ability to oscillate at alpha frequency. Another difference between peak and trough states is that the former includes spiking cortical input. The value of gH was shown to be important in the creation of the alpha oscillations at either peak-max or trough-max. We found regions of alpha frequency oscillation and quiescence within this parameter space corresponding to peak-max when GABAa is 3X normal and trough-max when GABAa is 2X normal. These results suggest that the thalamus has the intrinsic mechanisms to produce the observed switch in phase-amplitude coupling.

Title: Arc/Arg3.1 and c-fos changes in response to *In vitro* models of wake and sleep-related cortical dynamics.

Authors: *I. J. HARTNELL[1], A. SIMON[1,2], S. CHAWLA[1], M. A. WHITTINGTON[1,2];
[1]Dept. of Biol., Univ. of York, York, United Kingdom; [2]HYMS, York, United Kingdom

Abstract: Objectives: Immediate early genes (IEGs) are rapidly transcribed after certain cellular cues. In studying the cortical environment during sleep and wakefulness two IEG are of particular interest: c-fos and Arc. C-fos signals an increase in neuronal activity whereas ARC has a complex association with synaptic plasticity involving both AMPA receptor internalisation and synaptic stabilisation depending on dynamics and magnitude of activation. Here we use markers for c-fos and Arc to differentiate regional and laminar cortical changes in network dynamics associated with non-REM sleep and cortical activation.
Methods & Results: Acute neocortical slices from adult rats containing primary sensory (S1 or Au1) and association (Par2) areas were maintained in vitro. Activation-associated (wake-state) rhythms (gamma (30-80 Hz) and beta (15-25 Hz)) were induced by bath application of kainate (400nM). Non-REM sleep-associated rhythms (delta (1-4 Hz)) were generated by bath application of 10μM SCH23390 and 4μM Carbachol. After 1hr of stable rhythms slices were fixed and immunohistochemistry performed for NeuN, GAD67, and c-fos and Arc.
Comparing delta to gamma/beta oscillations, c-fos levels were reduced by 19% in association cortex. This decrease was similar in all layers. In contrast, primary sensory areas showed only a 7% reduction in c-fos levels. Arc also showed a larger change (albeit in the opposite direction) in association cortex (55% increase in delta) than primary sensory cortex (36% increase). In addition, the laminar distribution of these ARC changes was different in each area: The majority of the ARC signal increase in primary sensory cortex was seen in supragranular layers, whereas in association cortex this was in layer 5 and the main apical dendrites ascending from layer 5 pyramidal cells.
Conclusions: A far greater change in IEG expression was seen in association cortex compared to primary sensory areas when comparing wake-related rhythms to non-REM sleep-related rhythms. The largest change observed (ARC) suggested an overt alteration in the environment supporting synaptic plasticity in output neurons from higher-order cortical regions during deep sleep.

Ctr., New York, NY; [8]Neurol., Kings County Hosp. Ctr., Brooklyn, NY

Abstract: Beta oscillations (15-30 Hz) are prevalent in the firing patterns of neocortical neurons and the microcircuits they are embedded in. Beta oscillations are hypothesized to enable effective communication between neurons, setting fluctuating windows of excitability when neurons are most likely to respond to or send information. Beta oscillations are expected to emerge from interactions across multiple spatial scales, arising from a diverse set of biophysical mechanisms. Key contributors to Beta oscillations are the Layer 5 (L5) pyramidal neurons, with their large dendrites which span multiple cortical layers. To explore the origins of neocortical Beta oscillations, we developed a 6-layer 1715 compartmental cell multiscale model of neocortex with multiple classes of excitatory (E) and inhibitory (I) neurons wired based on mouse neocortex circuit mapping experiments. We optimized models of L5 pyramidal cells using whole-cell somatic voltage recordings. Neurons contained membrane calcium, sodium, potassium, and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. In L5 pyramidal cells, increasing HCN channel density in apical dendrites with distance from soma promoted synaptic resonance in the Beta frequency range, with increasing resonant frequency

with distance from soma. The network model displayed coherent Beta oscillations produced through interactions between E and I neurons. We applied independent random variations in ion channel densities to cells in the network model to identify parameter sets that contributed to Beta oscillations. These variations produced simulations with distinct physiological (phys) and pathological (path) hyperexcitable states, each with different expressions of Beta oscillations, neuronal synchrony, and firing patterns. The simulation categories demonstrated degeneracy: there were many parameter combinations that produced each simulation type with weak intra-class similarity of parameter vectors (phys/phys r=0.06; path/path r=0.07; n=65 for each class) and weak inter-class dis-similarity (path/phys r=-0.05). Some of the model predictions were verified through analyzing Beta oscillations in laminar neocortex recordings of nonhuman primates. Our results suggest the neocortex contains a robust set of mechanisms that contribute to Beta oscillations at multiple spatial scales.

Title: Reliability of electrophysiological connectivity in the resting state.

Authors: *K. CASIMO, T. MADHYASTHA, J. G. OJEMANN, K. E. WEAVER;
Univ. of Washington, Seattle, WA

Abstract: A growing body of literature exists on variability in resting state functional connectivity. Studies of fluctuations in BOLD signal measured using fMRI have indicated that connectivity patterns are not static, but rather vary across time scales and between sessions. However, fMRI is limited to indirect measurement of brain activity driven by delayed-response blood flow. Resting state connectivity dynamics have received substantially less investigation using electrophysiology.
In this study, we used electrocorticography (ECoG) with video monitoring to identify multiple eight minute resting state sessions from epileptic individuals undergoing seizure monitoring. We

assessed connectivity using a range of interaction measures including linear regression, phase locking value, and phase slope index. To assess change between sessions, we calculated interclass correlations on mean connectivity values and used a mixed model regression approach. We sought to investigate reliability in connectivity across highly sampled brain regions at rest; thus, connectivity changes were assessed among all Brodmann area (BA) regions with sufficient data rather than known resting state networks. Electrode BA labels were identified using the MNI atlas.
We found connectivity changes spanned a wide range of cortical regions. We found regional variability in connectivity between spatially distant areas including prefrontal, superior parietal, and lateral and inferior temporal regions. We observed both increases and decreases in connectivity across canonical frequencies from delta (0-4Hz) through high gamma (70-200Hz) as well as changes in the 0.1-1Hz amplitude modulations of high gamma, which has been previously demonstrated to closely correspond to, and potentially give rise to, low-frequency BOLD signal. Variations were observed across the multiple connectivity measures.
The resting state connectivity trends we observe with electrophysiological techniques are consistent with the variability previously attributed to the resting state by studies using BOLD techniques. Here, we add the novel dimensions of direct measurement of neural activity using ECoG, a broad frequency range from 0-200Hz, and the use of multiple complementary connectivity measures. We estimated the natural variability in connectivity across a variety of electrophysiological metrics of the resting state, with the potential to illuminate critical cognitive functions over time, including memory and skill consolidation. This method will facilitate study of changes in resting state connectivity to interventions, such as learning of a skill, which are above and beyond natural variation.

Title: Histamine H1 receptor antagonist pyrilamine induces gamma oscillations in *In vivo* rat CA1 hippocampus

Authors: *C. A. VILLALOBOS[1], P. MALDONADO[2], J. VALDES[2];
[2]CENEM & BNI, [1]Univ. De Chile, Santiago, Chile

Abstract: Histamine is known to be involved in the regulation of many physiological process such as sleep/wake cycles, motivation, arousal and, recently in learning and memory. In freely moving animals, histamine H1 receptor (H1) antagonists has been shown to increase the abundance of sharp-wave ripples in the hippocampal CA1 region, widely associated with memory consolidation. Histamine acting intracellularly, in a similar fashion as serotonin and acetylcholine, has been shown to increase neuronal excitability by enhancing I_h and blocking the Ca^{2+}-sensitive K^+ channel responsible for the slow-afterhyperpolarization.
It has been thought that gamma oscillations (30-120 Hz), and their corresponding neuronal activity, underlie a variety of cognitive functions. *In vitro* studies have suggested that the generation of gamma oscillatory patterns is better explained by a pyramidal-interneuron network gamma (PING) model, however, the mechanisms by which this oscillation is generated *in vivo* is still not clear. In *in vitro* preparations, application of the cholinergic agonist charbacol induced gamma oscillations in CA3. High concentrations of kainate can also elicit gamma oscillation in the CA1 region. Given the involvement of histamine in hippocampus-dependent cognitive function, we investigated the effect of direct injection of the H1 antagonist pyrilamine on the oscillatory patterns of the CA1 region. Sprague-Dawley rats were implanted with an infusion cannula into CA3 together with an 8-tetrode hyperdrive aiming to record the oscillatory activity of the CA1 layer. The rat was habituated to sleep into a flowerpot while pyrilamine was slowly infused into the CA3 layer of the hippocampus. At the same time, LFP and single unit recordings from CA1 layer were obtained. Our study shows that acute perfusion of the H1 antagonist pyrilamine into the CA3 layer induced a high- and low-frequency gamma oscillation in the CA1 layer of the hippocampus. This result presents a novel effect of the H1 receptor antagonist pyrilamine in the oscillatory patterns of hippocampal CA1 region.

Title: Spiking regimes in model networks of hippocampal persistent firing neurons

Authors: *F. GIOVANNINI[1,2,3], B. KNAUER[4,6], M. YOSHIDA[5], L. BUHRY[1,3];
[1]Neurosys Team, Inria CR Nancy Grand-Est, Villers-lès-Nancy, France; [2]CNRS, Loria UMR 7503, Vandoeuvre-lès-Nancy, France; [3]Univ. de Lorraine, LORIA UMR 7503, Vandoeuvre-lès-Nancy, France; [4]Res. Sch., [5]Fac. of Psychology, Mercartor Res. Group - Structure of Memory, Ruhr Univ. Bochum, Bochum, Germany; [6]Dept. of Physiol., Monash Univ., Clayton, VIC, Australia

Abstract: Rapid persistent firing is thought to be the neural correlate of short-term memory maintenance (Fuster 1971), in which transient stimuli must be preserved during long delay periods outlasting them. Therefore, the brain structures commonly involved in working memory tasks, including the hippocampus, must possess the necessary substrates for the generation and maintenance of elevated persistent activity. Various synaptic mechanisms underlying mnemonic persistent firing have been suggested by neuroscientists. The common view is that networks with specific topologies, such as recurrent excitatory connections, depend on strong local excitation for the generation of long-lasting neuronal activity and rhythmic oscillations (Wang 2001). However, it has been shown that memory can also be encoded in brain regions which do not display such topologies, such as the CA1 area of the hippocampus (Amaral 1993). These regions display similar activation patterns, and must therefore rely on mechanisms which are independent of topology and connectivity, such as intrinsic cellular properties. Among these are the ionic currents mediated by calcium-activated non-specific (CAN) ion channels, which seem to be a valid candidate for rhythm generators in hippocampal networks.
Our work investigates the different patterns of activity displayed by model networks of hippocampal CAN-equipped persistent firing neurons. The neuron model is based on the Hodgkin-Huxley formalism for increased biological plausibility. We show that synchronized patterns elicited by a transient (250 ms) stimulus can be maintained solely by CAN currents, without the need for strong recurrent connections. In addition, such a CAN-network exhibits three main types of firing regimes depending on the value of the connection weights - a slow regime with firing rates $6\ \text{Hz} < f < 18\ \text{Hz}$, a bursting regime, and a fast gamma regime with firing rates $f > 40\ \text{Hz}$. These results are in accordance with in vitro recordings of hippocampal slice preparations (Knauer et al. 2013), and provide a possible explanation for the generation and maintenance of memory-related oscillatory activity in different frequency bands, within the hippocampus.

Title: Lactate cannot fully sustain gamma oscillations but sharp wave-ripple activity *In vitro*

Authors: *J. SCHNEIDER, J.-O. HOLLNAGEL, T. CESETTI, A. LEWEN, O. KANN;
Inst. of Physiol. and Pathophysiology, Heidelberg, Germany

Abstract: The sensitivity of higher brain functions to hypoxia and hypoglycemia implies that network activities, which underlie complex neuronal information processing, rely on the sufficient availability of energy substrates. While it is established that glucose can fuel neural network activity, it has been proposed by the astrocyte-neuron lactate shuttle hypothesis that lactate is the preferred energy substrate for neurons while glucose is primarily taken up by astrocytes. In this study we used local field potential recordings in organotypic hippocampal slice cultures and acute slice preparations from the rat to test if lactate can fuel gamma-oscillations and sharp wave-ripples. These network activities naturally occur in the hippocampus in vivo and are associated with memory formation and consolidation, respectively. Gamma-oscillations were induced in slice cultures that were supplied with 2 to 20 mM lactate and subsequently with 10 mM glucose containing ACSF. We found that the number of slice cultures that expressed gamma-oscillations and the oscillation power was reduced in the presence of lactate compared to glucose. In acute slices gamma-oscillations were abolished in the presence of 10 mM lactate. When slices were supplied with 20 mM lactate, gamma-oscillations were smaller compared to 10 mM glucose and interrupted by epileptiform activity. On the contrary, sharp wave-ripples evoked in acute slices had similar characteristics (amplitude, frequency) in the presence of both glucose (10 mM) and lactate (20 mM). Additionally, we estimated oxygen consumption rates in acute slices from oxygen recordings with Clark-type electrodes. We found that oxygen consumption rates were lower during sharp wave-ripple activity compared to gamma oscillations. Summarizing, we found that lactate can fully sustain sharp wave-ripples, but not gamma oscillations. Since oxygen consumption rates during sharp wave-ripples were lower than during gamma oscillations, this indicates that the sharp wave-ripple network activity state express a lower energy expenditure. Together, these findings suggest that the metabolic rate of a specific network activity state might determine if it can be exclusively fueled by lactate or not.

Title: Parvalbumin-positive interneurons regulate spatio-temporal network dynamics for population coding in mouse primary visual cortex

Authors: *M. AGETSUMA[1,2,3], J. HAMM[3], I. SATO[4], R. YUSTE[3];

Sci., Columbia Univ., New York, NY; [4]Dept. of Complexity Sci. and Engineering, Grad. Sch. of Frontier Sciences,, The Univ. of Tokyo, Tokyo, Japan

Abstract: For efficient information processing in the brain, neural circuit dynamics must be spatially and temporally regulated with great precision. Although parvalbumin-positive (PV) interneurons are known to control network synchrony, how their activity contributes to spatio-temporal activity patterns remains unclear. We investigated this using *in vivo* two-photon Ca^{2+} imaging from populations of neurons in mouse visual cortex with simultaneous optogenetic inactivation of PV cells. As expected, network synchrony in visual cortex was locally sustained by PV interneurons. But interestingly, the reliability of multineuronal activity during visual stimulation was specifically disrupted by PV-cell suppression. Machine-learning based decoding confirmed the importance of PV cells in population coding, and further correlation analyses suggested the link between distance-dependent regulation of network synchrony by PV cells and the underlying computation. Our study indicates that interneurons can control the spatio-temporal dynamics of cortical information, and therefore are critical for building a population code.

Title: Chemokine effects on cerebellar oscillations *In vitro*.

Authors: *A. SIMON[1,3], A. ROT[2], M. A. WHITTINGTON[1,3];
[1]Dept. of Biol., [2]Ctr. for Immunol. and Infection, Univ. of York, York, United Kingdom; [3]Hull York Med. Sch., York, United Kingdom

Abstract: Objectives: Besides their well-established role in the immune system chemokines have been suggested to play a role in the central nervous system (CNS). Recent studies clearly demonstrate that these small cell signalling molecules and their receptors are constitutively expressed by glial cells and neurons, where they are involved in intercellular communication. They also have a role in neuroinflammation, neurodegenerative diseases and depression. We have investigated the effects of two different chemokines (recombinant murine KC/CXCL1(KC) and recombinant murine rantes/CCL5(rantes)) on cerebellar gamma oscillations in Chemokine (C-C motif) Receptor 5 (CCR5)- and Atypical Chemokine Receptor1 (ACKR1)- deficient mice and on wild type (WT) animals.
Methods and Results: Using 450 μm coronal cerebellar slices from adult male mice, oscillations were induced either through G-protein coupled metabotropic glutamate receptors (mGluR) by bath application of 10 μM (S)-3,5-Dihydroxyphenylglycine (DHPG) or through nicotinic acetylcholine receptors (nAchR) by adding 10 μM nicotine (NIC). Both methods induced a robust and persistent high gamma frequency oscillation (60-80Hz) with an element of very fast oscillation (VFO, >100 Hz). Local field potentials (LFPs) were recorded from crus1 and crus2 areas associated with expectancy and non-motor shifts in attention. In WT animals 100ng/ml KC decreased the power of both DHPG- and NIC induced oscillations by 30% and 80%, respectively. 10 ng/ml rantes did not change the DHPG oscillation but decreased the NIC induced oscillation by 50%, leaving the frequency components unaffected. In tissue from the ACKR1 mutant mouse DHPG and NIC failed to evoke cerebellar oscillations of a similar power to control; evoked gamma oscillations were ~80% smaller and occurred in the absence of VFO. In these experiments KC also failed to modulate gamma/VFO rhythms in either case. However, rantes selectively doubled the power of the NIC-evoked oscillation in the ACKR1 mutant; introducing high frequency gamma and VFO. Since the ACKR1 and CCR5 receptors can also hetero-oligomerize and rantes is a ligand for both receptors, we investigated the effects of rantes on CCR5 deficient animals too.

Conclusions: Our results show that chemokines might be able to significantly alter oscillatory dynamics in a manner where selectivity is dependent on the presence of the ACKR1 protein.

Title: Functional connectivity structure of cortical calcium dynamics in anesthetized and awake mice

Authors: ***P. WRIGHT**, A. Q. BAUER, G. A. BAXTER, M. D. REISMAN, A. BICE, J. P. CULVER;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Hemodynamic-based markers of cortical activity (e.g. fMRI, optical intrinsic signal imaging), driven by electrical and metabolic activity through neurovascular coupling, are an indirect and slow report of brain function and are limited in their utility to deduce underlying brain network dynamics. Here we extend functional connectivity (FC) analysis, a method for mapping functional relationships using spontaneous brain activity, from hemodynamic to Ca^{2+}-dynamic imaging. Transgenic mice (n=7) expressing a fluorescent calcium indicator (GCAMP6) driven by the *Thy1* promoter in cortical glutamatergic neurons were imaged transcranially in both ketamine-anesthetized and awake states. Sequential LED illumination (λ=470, 530, 590, 625nm) enabled concurrent imaging of both GCAMP6 fluorescence emission (corrected for hemoglobin absorption) and hemodynamic activity. Somatosensory responses were evoked using a 0.5mA electrical hindpaw block paradigm. FC patterns were generated for low (0.009-0.08Hz) and high (0.4-4Hz) frequency bands. Following paw stimulation, GCAMP6 provided a response

time course sensitive to individual high frequency (2Hz) pulse presentations and preceded the stereotypical hemodynamic response function by ~0.65s (data not shown). Homotopic HBO2 and GCAMP6 FC maps have similar topographies at low frequencies (Fig 1A). At higher frequencies, GCAMP6 is sensitive to delta band (0-4Hz) activity associated with slow-wave sleep which provides a striking effect on the correlation structure of the FC maps from anesthetized mice that is diminished upon wakefulness (Fig 1A, & Fig 1B for a pairwise matrix of correlation values across networks). In summary, functional neuroimaging of Ca^{2+} dynamics in mice provides evidence that spatiotemporal coherence in cortical activity is not exclusive to hemodynamics. Concurrent Ca^{2+} and hemodynamic-based imaging will enable the dissociation of changes in ionic networks, hemodynamic networks, and neurovascular coupling and provide a framework for subsequent studies of neurological disease, such as stroke.

Title: Acute alcohol attenuates regional bilateral connectivity in the rat brain

Authors: *N. M. ZAHR[1], D. KWON[3], E. T. PETERSON[3], E. V. SULLIVAN[2], A. PFEFFERBAUM[3];
[1]Dept. of Psychiatry and Behavioral Sci., [2]Psychiatry and Behavioral Sci., Stanford Univ. Sch. of Med., Stanford, CA; [3]Neurosci., SRI Intl., Menlo Park, CA

Abstract: Acute, binge, and chronic alcohol exposure have distinct effects on the brain. Although the effects of acute ethanol (EtOH) exposure on various magnetic resonance imaging (MRI) metrics have been evaluated in humans, systematic evaluations of the effects of acute, binge, and chronic EtOH administration on the brain have not been conducted in animal models. This resting-state functional MRI (rsfMRI) study was conducted in 12 wild-type Wistar rats (425.8±25.5g) at 4 time points: baseline (scan 1); following acute intragastric administration of 4g/kg EtOH (resulting in blood alcohol levels (BALs) of ~300mg/dL) or saline (scans 2 and 3) with random assignment; and following 2g/kg EtOH (scan 4, with BALs ~150mg/dL). Animals, anesthetized with dexmedetomidine (0.1mg/kg/h s.c.), were scanned on a 7T Bruker imaging system. rsfMRI analysis utilized our in-house rat brain atlas, including 68 labels comprised of 24 bilateral and 20 midline regions of interest (ROI), constructed using the Paxinos/Watson atlas and wire frame images (http://www.nitrc.org/projects/jip). fMRI image processing included motion correction, registering and warping structural to fMRI space, registering to template space, warping fMRI to template space, and cropping. Subsequent processing was conducted in atlas space. Pre-processing used AFNI with high and low pass filtering and smoothing with a Gaussian kernel. Processed fMRI data was mapped into atlas space by registering mean fMRI images to our rat atlas. For connectivity analysis, correlation map computation involved mean fMRI signal calculation for each ROI and computing correlations between mean fMRI signals in each ROI. Correlation maps showed significant bilateral regional connectivity at baseline, which was attenuated more by 4g/kg EtOH than by 2g/kg EtOH. The regions showing the greatest signal loss - visual and auditory cortex, temporal association cortex, and inferior colliculs - are among the regions with the highest cerebral blood flow and deoxyglucose uptake. These results suggest that acute EtOH administration initially disrupts activity in brain regions that typically consume the greatest energy.

Title: Salicylate induces type 2 theta oscillation in the hippocampus

Authors: *R. N. LEAO[1], R. FRANZON[1], S. MIKULOVIC[2];
[1]Brain Inst., UFRN, Natal, Brazil; [2]Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: Salicylate in high doses is cause of tinnitus in humans and it is often used to produce tinnitus-like perception in animal models of the condition. Here we assess whether salicylate induces anxiety-like electrophysiological and behavioural signs. Using multielectrode probes, we recorded local field potential (LFP) in the dorsal and ventral hippocampus in an open field 60-min after salicylate (300mg/kg) injection. We found that animals treated with salicylate moved dramatically less than saline treated animals. Consequently, dorsal hippocampus theta (8-9Hz, associated with movement) in these animals was significantly lower. However, salicylate-treated animals showed a strong 4-7Hz oscillation in the ventral hippocampus (with smaller peaks in dorsal hippocampus electrodes). These oscillations were abolished by atropine application, suggesting that this rhythm is a theta type 2 oscillation (atropine sensitive). Granger causality analysis demonstrated that the dorsal hippocampus Granger-caused 8-9Hz theta in the ventral hippocampus while the ventral hippocampus Granger-caused type-2 theta in the dorsal hippocampus in salicylate-treated animals. Theta type 2 is elusive to be elicited in rodents and have been associated to anxiety-like behaviours. Here we show that salicylate application can consistently generate type 2 theta in the ventral hippocampus. Future studies will show whether ventral hippocampus type 2 theta is caused by salicylate itself or by tinnitus perception.

Title: Stimulus specificity and task condition dependence of field potential oscillations in the solitary nucleus

Authors: *A. DENMAN-BRICE, P. M. DI LORENZO;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Synchronous neural activity has been found between several cortical and subcortical regions of the rodent taste system. The role of oscillatory activity in the nucleus of the solitary tract, however, has not been investigated. The solitary nucleus, which is located in the brainstem and receives descending projections from numerous cortical and subcortical structures, integrates information across many sensory modalities, including olfactory and viscerosensory, and contains neurons that convey information about stimulus identity through temporally precise codes. We analyzed recordings from rats with chronically implanted 8-channel microwire electrodes in the solitary nucleus. Spiking activity of single units and field potential signals were recorded as the rats freely licked taste solutions from a computer controlled lickspout. In some recording sessions, taste stimuli were presented in random order, and in other sessions a subset of the same stimuli were used in a go / no go task, which required subjects to attend to specific stimuli in order to obtain rewards and avoid punishment. Analysis of field potential signals revealed the presence of a robust oscillation in the theta range, which was phase locked to licking activity but sometimes occurred in the absence of licking behavior and sometimes absent during licking behavior. Power of this oscillation following stimulus presentation was reliably modulated by stimulus identity, but the pattern of stimulus modulation differed across subjects and between the random stimulus presentation paradigm and the go / no go paradigm. Analysis of single units revealed that the firing of a subset of neurons previously identified as lick-related was better correlated with phase of the local field oscillation than with licking. Additionally, some neurons in the NTS synchronized with the local oscillation more strongly following presentation of some stimuli and others. Another subset of neurons was identified which consistently fired during different phases of the local field oscillation depending on which stimulus was presented. These results suggest that field potential oscillations in the solitary nucleus may reflect processing of sensory information and/or the influence of top-down control.

Title: Transcranial direct current stimulation facilitates associative learning and alters functional connectivity in the non-human primate brain

Authors: M. R. KRAUSE[1], T. P. ZANOS[2], B. CSORBA[1], M. PHILLIPS[3], P. K. PILLY[3], *C. C. PACK[1];
[1]Neurol & Neurosurg, McGill Univ., Montreal, QC, Canada; [2]Feinstein Med. Inst., Manhasset, NY; [3]Hughes Res. Labs., Malibu, CA

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive technique for modulating brain activity. Given its safety and low cost, interest in tDCS has grown rapidly in recent years, and there is now some evidence that tDCS has therapeutic value for a range of neurological and psychiatric disorders, including stroke, depression, addiction, and schizophrenia. Other work claims that tDCS affects healthy subjects' perceptual and cognitive performance, as well as their creativity. At the same time, very little is known about how tDCS influences activity in the human brain, and there is some debate about whether it has any effect at all. Here, we examine the influence of tDCS on multi-site neural activity in awake, behaving non-human primates, which provide the best available animal model of the human brain. Monkeys performed an oculomotor foraging task, which required them to learn the association between a natural visual image and a specific location within that image. Animals received liquid rewards in return for executing saccades to this location, and they were required to learn different locations for different images. This task allowed us to separate potential effect of tDCS on learning from those on visual processing, motor performance, and overall attention and arousal. During performance of this task, we recorded simultaneously from multiple sites within prefrontal cortex (PFC) and inferotemporal cortex (ITC), using chronically implanted multi-electrode arrays. In alternating blocks of trials we applied "sham" stimulation, which simulated tDCS while delivering no current to the brain.
We found that, compared to sham stimulation, anodal tDCS applied to prefrontal cortex (PFC) accelerated the learning of new associations, and that this increased plasticity was accompanied by altered functional connectivity between PFC and ITC. Specifically, tDCS increased oscillatory coherence between the prefrontal and visual cortices in the theta band (6 - 10 Hz) of the local field potentials. This increased coherence was specific to the period within each trial when the association was being learned or encoded; tDCS had no effect on coherence during the initial period following the presentation of each image. Moreover, there was no consistent effect of tDCS on single-neuron firing rates or stimulus selectivity; effects on the local field potentials at individual sites were broadband and similar for different time periods within the trial. These results show that tDCS is capable of modulating learning and its neural correlates in the primate brain.

Title: Different isoflurane levels have distinct effects on cross-hemisphere functional connectivity during unconsciousness

Authors: *A. SZYMANSKA[1,2], M. ALCALA ALVAREZ[2], A. AFSHEEN BAZRAFKAN[3], M. FARAHABADI[3], Y. AKBARI[4], Z. NENADIC[2];
[1]BME, UCI, Irvine, CA; [2]Dept. of Biomed. Engin., [4]Dept. of Neurol., [3]Univ. of California Irvine, Irvine, CA

Abstract: Background: It is relatively well understood that brain states vary in awake and anesthetized subjects. The effects of anesthesia include, but are not limited to, the suppression of nonsynchronous responses, as well as general depression of neurological signals. However, few studies have investigated the effects of varying levels of anesthesia on spontaneous (baseline) neurological activity, as well as synchrony across the two brain hemispheres. In order to determine the effects of varying levels of anesthesia on cross-hemisphere spontaneous neurological activity, we have collected cross-hemisphere electroencephalogram (EEG) and multi-unit activity (MUA) on anesthetized rats. Methods: Rats were anesthetized using isoflurane (2.0%) and implanted with two EEG screw electrodes in the left hemisphere. A 2 mm burr hole was then drilled through the skull, and a 7-channel microelectrode was lowered into layer 2-3 of the cortex of the right hemisphere. Spontaneous EEG activity on the left hemisphere was then recorded simultaneously with spontaneous MUA activity from the right hemisphere. The isoflurane level was then increased to 2.5%, and recording was repeated after the neurological activity had stabilized (about 5 min). This was then repeated at 3.0% isoflurane. Results: As expected from previous studies, the overall EEG neurological activity decreased under anesthesia. This was also true for MUA. The activity continued to decrease as anesthesia levels were increased. Interestingly, the correlation between the right hemisphere EEG and left hemisphere spiking frequency increased as anesthesia levels increased. Furthermore, the maximum correlation shifted from the Theta band to the Alpha band with increasing anesthesia. We also calculated the spike-triggered average (STA) at each anesthesia level, by averaging over 150ms of EEG centered on individual recorded APs. Although less overall activity was present as anesthesia levels increased, the STA magnitude significantly increased. Conclusion: Cross-hemisphere interactions were affected by the level of anesthesia administered. As anesthesia levels were increased the correlation between the EEG and MUA increased, and STAs

significantly increased in magnitude. This may imply that higher anesthesia levels selectively inhibit background or asynchronous activity, causing the low level of activity present to be higher in magnitude and more correlated across the two hemispheres.

Title: Frequency bands are an organizational force of intrinsic brain networks

Authors: S. MOWLAEI[1], A. SINGH[2], *A. S. GHUMAN[1];
[1]Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA; [2]Machine Learning, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Studies have increasingly demonstrated the importance of oscillatory dynamics in neural coding and interregional communication. While it has become clear that frequency-specific activity is a critical feature of brain activity, whether brain networks organize by "frequency band" or whether the spectrum does not enforce functional brain network organization. Specifically, here we ask if there is a functional parcellation of the frequency spectrum or not in resting-state magnetoencephalography (MEG) data based on large-scale brain

network connectivity patterns. To answer this question, we used network analyses and unsupervised and supervised pattern recognition algorithms in conjunction with whole brain MEG resting-state connectivity measures. Specifically, we recorded 5 minutes of eyes open, fixated resting-state MEG data from 18 healthy subjects. After artifact removal, in each subject, for each frequency from .5-50 Hz with 0.5 Hz steps, we calculated the source-localized, all-to-all connectivity matrix based on phase locking values between each pair of points on the cortex (5124x5124 connectivity matrix). Using matrix and network similarity measures, we then assessed the spatial similarity of these full connectivity matrices between each pair of frequencies. Unsupervised and supervised analyses were used to assess whether there was consistent groupings of frequencies across subjects. The results of this analysis show that there are between 5 and 6 data-driven frequency bands that organize intrinsic brain networks. These bands roughly correspond to classic frequency bands: .5-2.5 Hz (~delta), 3-9 Hz (~theta), 9.5-13 Hz (~alpha), 13.5-21 Hz (~low beta), 21.5-32.5 Hz (~high beta), and 33+ Hz (~gamma). The bands also show very high consistency across subjects allowing one to classify each frequency to the correct band at the single subject level with 90+% accuracy. The results also show that there is a substantial spatial overlap between the spatial topography of the theta and low beta bands (with 5 bands, these two frequency ranges are grouped together, with 6 they separate). Furthermore, the results show that the low and high beta bands are substantially distinct and therefore should not be grouped together. In addition, we used network analyses to determine the characteristic brain networks that correspond to each frequency band. Taken together, these results suggest that synchronized activity grouped by frequency bands is a strong and consistent organizing force of large-scale, intrinsic brain networks.

Title: Modelling pyloric dilator neurons in the pyloric network

Authors: ***F. DOS SANTOS BRANDAO**, P. ANDRAS;
Keele Univ., Newcastle, United Kingdom

Abstract: Recent studies of the neurons in the Tritonia pedal ganglia and the spherical neurons in the electrosensory lobe of the electric fish have suggested that the same neuron can play different functional roles in the neural circuits to which it belongs. We study the pyloric rhythm

network of the crustacean stomatogastric ganglion (STG).
Most commonly the STG network models use single model neuron for the same kind of neurons, assuming the same parameters and implying their synchronous firing. However, simultaneous recordings of pyloric dilator neurons (PD) show differences between the timings of spikes. We built a pyloric network with nine neurons (AB - anterior burster, LP - lateral pyloric, two PD and five PY - pyloric neurons) using two-compartment (soma-dendrite) models for each neuron. The parameters of the model neurons are from published papers. We analysed the behaviour of the two model PD neurons. We varied the conductance parameters (g_K - delayed rectifier potassium and g_{CaT} - transient calcium) of one of the PD within functional ranges, while the other had fixed parameters.
Our results show that the PD neuron with higher g_{CaT} and g_K leads the spiking in the PD phase of the pyloric rhythm and have greater or equal number of spikes compared to the follower PD neuron. The leading role is determined primarily by the calcium conductance. The temporal delay between the corresponding spikes of the two PD neurons gets shorter if the potassium conductance of the follower is larger - see figure 1.
Figure 1 - Time distances of the first spike as a function of the g_K and g_{CaT} conductances of the neuron with variable conductances. A) From literature, B) lower conductances and C) higher conductances.
The simulation results show that some combinations of potassium and calcium conductances lead to abnormal spiking behaviour in the model neurons. Based on the activity and spiking patterns we defined two abnormal behaviours that were excluded from further analysis.
Our work aims to establish a robust and accessible computational and experimental framework for the analysis of functional variability of neurons.

Title: Paired recordings of pyramidal cells in the subiculum reveal local excitatory microcircuits

Authors: *M. P. FISKE, G. MACCAFERRI;
Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL

Abstract: Information exchange between neurons is accomplished using sequences of action potentials that result from the integration of local microcircuits. Unraveling the connectivity of these microcircuits and how they contribute to network activity is vital for understanding how information is relayed through the brain. Interestingly, despite its role as the main output region of the hippocampus, the microcircuity of the subiculum remains understudied. Additionally, recent evidence suggests that the subiculum is involved in generating both interictal and ictal activity in epileptic patients, providing impetus to study how these microcircuits contribute to disease. Most work involving the subiculum has focused on the excitable properties of the constituent pyramidal cells, which can be classified as either regular spiking or bursting. However, little is known about the regional synaptic connectivity. We sought to physiologically and anatomically characterize the excitatory connections of the subiculum at the individual neuron level. Using paired whole cell recordings, we have shown significant levels of connectivity between the principal cells of the subiculum. Connections were observed between bursting to bursting, regular to regular, bursting to regular, and regular to bursting neurons. These synaptic connections are excitatory and mediated by AMPA receptors at resting potential. The EPSP kinetics were similar between connection patterns, but the connection probability was highest when bursting cells were the post-synaptic target. Additionally, anatomical reconstruction of recorded cells allowed us to map the location of putative synapses. Ultimately, this work will provide insight into the population dynamics of the subiculum, which is vital for understanding the physiology of the subiculum and its role in epilepsy.

Title: Temporal lobe epileptogenesis affects motor cortical spine dynamics *In vivo*

Authors: *C. SCHUBERT, A.-K. GELLNER, J. REIS, B. FRITSCH;
Dept. of Neurol., Albert Ludwigs Univ. Freiburg, Freiburg, Germany

Abstract: Changed dynamics of dendritic spines, as a reflection of microstructural plasticity within the hippocampus [HC], have been reported during temporal lobe [TL] epileptogenesis. However, little is known about structural remote effects on the synaptic level. Here we investigated the effects of kindling epileptogenesis in the HC on spine dynamics in the primary motor cortex [M1] longitudinally by 2-photon microscopy [2PM]. As earlier studies indicate a role of brain derived neurotrophic factor [BDNF] in the development of TLE and in synaptic plasticity we further aimed to reveal its involvement in the observed remote effects.
Combined Thy1-GFP positive and BDNF heterozygous knock out [KO] mice with a 50% reduction in neuronal BDNF and their wildtype [WT] littermates were surgically equipped with a kindling electrode in the right olfactory bulb and a chronic cranial window over the left M1. After 2 weeks of recovery the afterdischarge threshold was determined and animals were stimulated daily until the 10^{th} generalized seizure [GS]. Motor performance tests (Rotarod, Adhesive Removal Test [ART]) were performed at baseline and after the 10^{th} GS. Dendrites in layer II/III in M1 were imaged by 2PM before (baseline), during kindling (after 1^{st} stimulation, 1^{st} GS, 10^{th} GS) and 2 weeks without seizures after the 10^{th} GS.
The previously described delay in amygdala kindling epileptogenesis was also present in olfactory bulb kindling in BDNF KO mice. 2PM data of the M1 of kindled mice show a reduction of spine density during kindling epileptogenesis compared to their sham controls regardless of the genotype with a tendency towards normalization 2 weeks after the last GS. During the kindling process spine survival of pre-existing spines was significantly lower in both kindled groups compared to their sham. Only in WT the turnover ratio was significantly increased during the kindling process. Motor performance evaluated as removal time in the ART was impaired in the BDNF deficient kindled group.
We present temporal lobe epileptogenesis associated remote effects on M1 dendritic spine dynamics by longitudinal in vivo imaging. Overall temporal lobe epileptogenesis appears to result in reduced connectivity within the motor network, representing a potential mechanism underlying cognitive deficits in epilepsy patients. BDNF appears to be involved but not mainly responsible for these alterations.

Title: Telemetric analysis of the dentate gyrus using the lithium/pilocarpine model of acquired epilepsy provides evidence for the progressive nature of epileptogenesis

Authors: *Z. Z. SMITH[1], F. E. DUDEK[2], D. S. BARTH[1];
[1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Dept. of Neurosurg., Univ. of Utah Sch. of Med., Salt lake City, UT

Abstract: Epilepsy is a chronic disorder characterized by recurrent unprovoked seizure activity. The most common type being Temporal Lobe Epilepsy (TLE) resulting from an acute brain insult such as a Traumatic Brain Injury (TBI), infection, ischemia, or status epilepticus (SE). Pharmacological treatments produce a variety of adverse side-effects and do not adequately control seizures in over half of patients with TLE. While acquired epilepsy is commonly thought of as a progressive disorder, surprisingly little is known about the progression of the disease. Importantly, the apparent seizure free "latent period" prior to the development of spontaneous seizures may represent a therapeutic window of opportunity to halt epileptogenesis before it becomes intractable. The lack of understanding of disease progression means that there are no measures of disease risk or drug efficacy other than self-reported behavioral seizures. In order to tackle these issues, we aimed to chart the entire time course of epileptogenesis in an animal model using hippocampal and cortical 24/7 video EEG combined with a variety of pattern recognition techniques supported by complete visual analysis. We found that when using a modified lithium/pilocarpine model of epilepsy that aimed to enhance animal survivability while standardizing an acute brain insult, we could produce a variable epileptogenic response that accurately recapitulates disease progression in humans. We show that no measure of insult severity accurately predicts epileptic outcome. Moreover we show that non-convulsive seizures in our animals are visually indistinguishable from and highly prevalent prior to the development of convulsive seizures. Further analysis of hippocampal spectral electrographic signatures reveals only subtle differences between the two classes of seizures. Isolating seizure events, extensively monitoring behavior, and quantifying field potential activity around seizures allows for an accurate measure of ictal associated brain activity that provides much needed depth to the analysis of a seizure. Understanding the temporal progression of epileptogenesis and establishing targeted end points may help elucidate the underlying mechanisms of seizure disorders and aid in the development of anti-epileptic strategies.

Title: An acute seizure impairs the long-term retention of a new hippocampal-dependent memory

Authors: *A. HOLLEY[1], M. S. BINDER[2], J. N. LUGO[1];
[1]Psychology and Neurosci., [2]Psychology & Neurosci., Baylor Univ., Waco, TX

Abstract: Introduction. Recent reports have indicated that a single short seizure can impair the retention of learning in delay fear conditioning. However, it is not clear how long-lasting the memory impairment can occur. The current study seeks to assess memory impairment at 24 hr and 1 wk following an acute seizure in C57BL/6 mice.
Methods. We placed 6 wk old male C57BL/6 mice into an inhalation chamber and infused flurothyl into the chamber until a generalized (tonic-clonic) seizure occurred. Control animals were run concurrently in a second inhalation chamber, but not exposed to flurothyl. An hour later mice were trained in trace fear conditioning. The mice were then tested 24 h and 1 wk later for cued recall. To assess changes to locomotor activity following a seizure another cohort of mice was tested in a 10 min open field test 24 h and 1 wk after seizure induction.
Results. A two-way ANOVA indicated a main effect of time for the 24-hour cued recall test ($p < .0001$), however no significant difference between the control and seizure groups ($p = .1763$). The 1 week follow up test showed a significant main effect of group ($p < .01$) and an effect of time ($p < .0001$) and indicating that there was a significant difference in memory retention at this time point. Results from the open field indicated a significant suppression of locomotor activity at 24 h, but not 1 wk. There were no differences between groups in horizontal movement, time spent in the center versus surround, stereotypy, rearing, or clockwise and counterclockwise revolutions.
Discussion. There was significant impairment of a marked difference in cued recall 1 wk after a seizure, but not at 24 h. Together this data suggests that there may be a period after a seizure in which new learning can be retained, but that hippocampal-dependent memory may be impaired as time passes following the seizure.

Title: Spectrographic analysis of the acute behavioral impact of early-life seizures on ultrasonic vocalizations in 129SvEvTac and C57BL/6 mice

Authors: *C. REYNOLDS, S. O. NOLAN, J. HUEBSCHMAN, J. N. LUGO, Jr;
Dept. of Psychology & Neurosci., Baylor Univ., Waco, TX

Abstract: Seizure activity during early development is known to cause long-term deficits in social behavior, learning, and memory. However, little is known regarding the acute behavioral impact of early-life seizures. Ultrasonic vocalization (USV) recordings have recently been developed as a tool for investigating early communicative deficits in mice. Previous investigation from our lab found that seizures on postnatal day (PD) 10 cause male-specific suppression of 50-kHz USVs on PD12 in 129 SvEvTac mice pups. The present study aims to extend these findings by examining putative differences in spectrographic characteristics of USVs following kainic acid-induced seizures in mouse strains with known resistance (129SvEvTac) and sensitivity (C57BL/6) to the drug. On PD10, pups were administered intraperitoneal injections of 0.5% kainic acid (2.5mg/kg), or an equivalent dose of 0.9% physiologic saline. On PD12, pups were removed from the home cage while isolation-induced recordings were captured by a broad-spectrum ultrasonic microphone and Avisoft Automated Recording Software. All recordings were converted to spectrograms by Fast Fourier Transformation (FFT) and analyzed using SASLab Pro (Avisoft Bioacoustics, Germany). These studies enhance existing evidence for neonatal vocalization behavior as an indicator of select communicative impairment in neonatal mice. In addition, this investigation provides the first known spectrographic characterization of USVs following early-life seizures.

Title: Hippocampal glutamate neurotransmission control using optogenetics and its effects on epileptogenesis

Authors: F. POMERLEAU[1], R. ALCALA[2], P. HUETTL[1], Y. AI[1], J. JAKOBSSON[4], G. A. GERHARDT[1], *J. T. SLEVIN[3];
[1]Dept of Anat. & Neurobio., [3]Dept Neurology, L-445, [2]Univ. Kentucky, Lexington, KY; [4]Mol. Neurogenetics, Lund Univ., Lund, Sweden

Abstract: Studies that establish direct causality between neuronal activity and behavior remain scarce. Optogenetics holds the promise of possibly bridging this gap. This technique, which introduces light sensitive proteins (opsins) into neurons to regulate transmembrane ion conductance, has evolved into a salient tool for targeted control of neural systems. Using optogenetics, we have shown the feasibility of directly measuring glutamate release *in vivo* while controlling neurotransmission in the hippocampus of anesthetized animals. We hypothesized that optical modulation of hippocampal neurotransmitter dynamics would affect the complex process of epileptogenesis during amygdalar kindling. We infused (1 µl/each) AAV5-Syn-ChR2-EYFP (blue light (488 nm) induces depolarization) or AAV5-Syn-NpHR-EYFP (yellow light (594 nm) induces hyperpolarization) into the right dentate gyrus (DG) of the hippocampus. Histological analysis using yellow fluorescence revealed that, 5 weeks post-infusion, EYFP was present throughout the right hippocampus; there was some evidence of bilateral distribution. We studied 3 groups of animals: 1) ChR2-animals implanted with an optical fiber (200 µm o.d.) directly into the DG, 2) NpHR-animals implanted with electrodes in the amygdala and optical fiber in the DG and 3) sham-animals with the similar implants. Using blue light activation (488 nm, ~50 mW, 20 secs, twice a day), we kindled the ChR2 animals to Racine stage 5 seizures after ~20 stimuli. In the other groups, using yellow light activation (594 nm, ~40 mW) beginning 5 seconds prior to electrical stimulation of the amygdala (100-800 µA; 1 sec) and continuing throughout the evoked seizures, NpHR animals required more stimulations to achieve stage 4/5 seizures (20.5 ± 5.4 [SD]) than sham animals (8.2 ± 3.1 [SD]). These preliminary data suggest optogenetic manipulation of hippocampus can both induce epileptogenesis for discrete analysis of molecular and network changes and delay the epileptogenesis of amygdalar kindling.

Title: *In vivo* interneuron circuit dysfunction in chronically epileptic mice

Authors: *T. SHUMAN[1], D. AHARONI[1], J. TAXIDIS[1], M. JAVAHERIAN[1], C. KABA[1], D. J. CAI[1], K. CHENG[1], S. E. FLORES[1], J. HODSON[1], N. RAO[1], A. FARIBORZI[1], J. LOU[1], J. GOLSHANI[1]; [1]Univ. of California Los Angeles, Los Angeles, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Epilepsy causes dramatic cell death and reorganization of interneuron circuits in both humans and rodent models but the consequences of these changes on hippocampal processing remain unknown. We used silicon probes to record single units and local field potentials throughout dorsal CA1 and dentate gyrus in head-fixed epileptic and control mice running through a virtual linear track. We found dramatic alterations of hippocampal synchronization in chronically epileptic mice, at least two months after pilocarpine-induced status epilepticus. Epileptic mice had reduced theta and gamma power and coherence, altered cross-frequency coupling, and altered phase preferences to ongoing theta oscillations. In particular, dentate hilar neurons had a similar magnitude of theta phase modulation of their firing rate, but the preferred phase of these cells as a group was more dispersed and shifted to a later phase of theta. Together, these findings indicate a significant desynchronization within and between the CA1 and dentate gyrus regions of the hippocampus that may lead to cognitive dysfunction in chronically epileptic mice. To further examine contextual information processing in these animals we recorded CA1 place cells in epileptic and control mice using custom-made head-mounted miniature microscopes to image calcium transients in large populations of CA1 neurons as animals ran across a real-world linear track over several days. We found that place fields in chronically epileptic mice were larger and contained less spatial information than in control mice. Finally,

we transplanted embryonic interneuron precursors from the medial ganglionic eminence (MGE) into the hippocampus and are testing whether these transplants, which rescue seizures and cognitive deficits in epileptic mice, can also rescue the electrophysiological and contextual processing deficits observed in epileptic mice. We predict that transplantations will restore specific deficits in hippocampal synchronization and place cell dynamics reflecting rescue of hippocampal processing.

Abstract: Temporal lobe epilepsy (TLE) is a form of acquired epilepsy displaying recurrent seizures arising from one or both lobes of the brain. Extreme changes in neuronal excitability perturb energetic demand (initial decrease in focal O_2) and produce a vascular response (increased cerebral blood flow, CBF, and volume). The spatiotemporal dynamics of neurovascular and neurometabolic coupling during the evolution of an ictal event are poorly understood. The measurement of changes in interstitial [O_2] is attractive as it reflects both neurometabolic and vascular function. *In vivo* electrochemistry combining fast electrochemical

techniques (amperometry) with multisite microelectrodes allows us to directly measure interstitial [O_2] in the brain with high spatiotemporal resolution. The ability to record changes in brain electrical activity simultaneously and using a single electrode is particularly attractive, allowing correlations to be established between electrical activity and changes in neurometabolic and neurovascular coupling with unmatched spatial and temporal resolutions. Here we investigate changes in O_2 in the hippocampus of **awake-behaving** pilocarpine-treated rats to induce TLE. We show that seizure activity is accompanied by drastic changes in O_2. Seizure onset is accompanied by increased O_2 consumption followed by increase in interstitial [O_2] resulting from typical increase in CBF at the epileptic focus. Furthermore, the use of a microelectrode to measure changes in local field potential related currents in awake behaving rats allowed us to confirm seizure activity through the evolution of frequency power during seizure progression with a good correlation with scoring seizure intensity as well decrease with pharmacological control of seizure activity.In summery, we present a novel approach to the study of neurometabolic events associated with epileptic seizure activity with potential to be translated into the clinical setting, for example in the localization of epileptic foci in preparation for resection surgery.

Title: Brain oxygen changes precede electrophysiological and behavioral signals during seizures, a new approach for epilepsy research

Authors: *J. CHANG, D. WOODWARD;
Neurophysiol., Neurosci Res. Inst. North Carolina, Winston Salem, NC

Abstract: Electrophysiological methods, including EEG, (local field potentials) LFP and single unit recordings, have been mainstream approaches for epilepsy research in decades. Recent

development of imaging technology is a significant addition to the repertoire of research tools. However, restrictions by most instrumentation for imaging studies do not allows real time monitor of epileptic seizures during freely moving conditions. Recent studies demonstrated that real time brain oxygen measurement can be a proxy for fMRI in freely moving rats (Lowry 2010). We have developed 8 carbon fiber electrode arrays to record both O_2 transients and LFP signals in freely moving rats subject to kindling and chemical induced seizures. Brain tissue O_2 content was measured by fast scan cyclic voltammetry (FSCV) using a 6 carbon fiber electrode array. LFP were recorded using two adjacent carbon fiber electrodes at the same location. Simultaneous behavioral responses were recorded by a video camera. This experimental setting allows measurement of metabolic, electrophysiological and behavioral signals simultaneously in freely moving rats in different models of epilepsy. In an amygdala kindling model, subthreshold kindling at 25 uA induced a clear increase in oxygen concentration, lasting 3-10 s in dorsal hippocampus and nucleus accumbens without detecting behavioral and LFP responses. Continuous kindling at high current induced stage 5 seizures accompanied by both the increase of O_2 content and electrophysiological seizures. In chemical induced seizures, pentylenetetrazole was injected (50mg/kg, i.p.) and convulsive seizures developed within 2 min. An initial increase in oxygen concentration appeared well before the LFP and behavioral seizures became evident during this 2 min window. At this point the earliest event leading to seizure is found to be a local increase in oxygen concentration in limbic regions. This appears before detection of both electrical and behavioral signs of seizure. Preliminary data show an increase in local oxygen with spontaneous seizures induced by status epilepticus in temporal lobe epilepsy model. These experiments demonstrate that use of distributed sensors of real time transient changes in tissue oxygen is a promising new tool for study of events predicting seizures that will complement traditional electrical and behavioral measures.

Abstract: Epilepsy is a spectrum of neurological disorders, characterized by recurrent seizures. The available anti-epileptic drugs (AEDs) control seizures in about two thirds of epilepsy patients but leave a third poorly treated, creating demand for new therapeutic strategies. Phenotypic behavior-based screens are powerful and effective tools for CNS drug discovery and could potentially lead to identification of novel AEDs. We have developed a unique platform for *in vivo* high throughput and behavior-based screens in zebrafish. The platform is a high content imaging system that combines robotic stimulus presentation in 96-well format with high-quality digital video capture and image processing algorithms, allowing us to profile the behavioral responses of zebrafish to small molecules. Using this platform we modeled epileptic-like activity in zebrafish larvae using the potassium chloride co-transporter KCC2 inhibitor VU0463271. Because KCC2 loss-of-function has been associated with epilepsy in humans, we screened for suppressors of the VU0463271-induced epileptic-like behaviors. We identified two compounds, TT0023831 and TT0042607 that reverse the VU0463271-induced effect in zebrafish. In addition, TT0042607 reverses epileptic-like behaviors induced by the GABA antagonist pentylenetetrazole (PTZ) and both compounds reduce excitability in rat cultured hippocampal neurons, as evidenced by reduced firing rates and delayed spike initiation. These compounds are compelling starting points for ongoing drug discovery efforts including lead optimization and validation in mammalian epilepsy models.

Title: The role of tau in modulating hyper-excitability in an emerging model of tumor associated epilepsy

Authors: *A. HATCHER[1], K. YU[2], J. LALONDE[3], B. DENEEN[2], J. NOEBELS[3];
[1]Dept of Neurosci., [2]Ctr. of Stem Cell & Regenerative Med., [3]Neurol., Baylor Col. of Med., Houston, TX

Abstract: Hyper-excitability of neuronal networks underlies the pathophysiology of epilepsy, and is known to be a component of other neurological disorders including cancers of the brain. Previous work has shown that genetic removal of neuronal microtubule organizer and stabilizer *tau* can significantly reduce epileptiform activity and lethality across a number of models of hyper-excitability, including Alzheimer's Disease models, the Kcna1 early lethal mouse model of epilepsy, and the Scn1a mouse model of Dravet syndrome. We recently confirmed a progressive seizure phenotype in a novel transgenic mouse model of brain tumor associated epilepsy. The effect of *tau* loss on hyper-excitability and lethality in this glioblastoma model is unknown. To answer this question, we generated glial derived brain tumors on a *tau* knockout background using a CRISPR *in utero* electroporation strategy. Using chronic video electroencephalography (EEG), we recorded cortical inter-ictal spike and seizure activity in these tumor mice at various timepoints in disease progression, monitored survival, and assessed tumor burden via immunohistochemically methods. In preliminary results, *tau* KO tumor mice exhibited reduced inter-ictal spike activity and slightly longer survival margins compared to *tau* WT tumor-bearing littermates. These data suggest that *tau* loss may provide a modest protective effect in this model of cortical hyper-excitability, and further investigation is under way to confirm these initial findings.

Title: Oriental medicine Woohwangchungsimwon attenuates kainic acid-induced seizures and neuronal cell death in the hippocampus

Authors: *J. CHOI[1], M. JANG[2], I.-H. CHO[2];
[1]Col. of Korean Medicine, Kyung Hee Univ., Seoul, Korea, Republic of; [2]Dept. of Convergence Med. Sci., Col. of Korean Medicine, Kyung Hee university, Seoul 02447, Korea, Republic of

Abstract: Woohwangchungsimwon (WCW) is an oriental medicine that has been extensively prescribed in Asia to patients with apoplexy, high blood pressure, acute/chronic convulsion, etc. However, the potential therapeutic value of WCW in treating the pathologic brain has not yet been fully investigated. In the present study, we evaluated whether WCW has beneficial effects on kainic acid (KA)-induced excitotoxicity. An intraperitoneal injection of KA (40 mg/kg) and an intracerebroventricular (i.c.v.) injection of KA (0.2 μg) produced typical seizure behavior and neuronal cell death in the CA1 and CA3 pyramidal layers of the hippocampus, respectively. However, the systemic administration of WCW significantly attenuated the seizure behavior and neuronal cell death. WCW was found to exert the best protective effect when it was administrated 2 hours before a KA-injection. Moreover, this WCW-induced neuroprotection was accompanied by a reduction in microglia activation and tumor necrosis factor-alpha, interleukin (IL)-1beta, IL-6, heme-oxygenase-1, inducible nitric-oxide synthase, and cyclooxyganase-2 in the hippocampus. These results suggest that WCW has therapeutic potential to suppress KA-induced pathogenesis in the brain by inhibiting inflammation.Rejuvenation Res. 2016 Mar 16. [Epub ahead of print]

Abstract: Epilepsy is common disorder that affects over 50 million people worldwide. It is characterized by occurrence of two or more unprovoked seizures. Despite extensive research and discovery of several treatment options, seizures remain refractory in 30% of patients. This long-standing poor response to the available treatment options indicate that the current research models are not sufficient and new models need to be discovered in order to better understand this disease. Mammals have been traditionally used to study epilepsy. Aves remain a promising yet largely under explored model of epilepsy. In this study we compared the response of two species of birds, Australian Parrots (APs) and Sparrows (SPs), to a pro-epileptic drug, Pentylenetetrazole (PTZ). First, APs and SPs were injected with saline intraperitoneally to get accustomed to handling and injecting. After 30 minutes the birds were injected with 25mg/kg, 50mg/kg and 75mg/kg PTZ or saline. The behavior of birds was video recorded and analyzed by two observers. Myoclonic jerks (MJ) and tonic clonic seizures (TCS) were observed in both species however unique behavioral changes in response to PTZ, including tonic posturing, intermittent rapid alternating neck movement, biting behavior and head bobbing, were only seen APs. The frequency of MJ in APs was greater at the dose of 75 mg/kg (3.84 ± 1 MJ/min) compared to both 50 mg/kg (0.42 ± 0.1 MJ/min) (p value < 0.005) and 25 mg/kg (0.49±0.1 MJ/min) (p value < 0.006). In SPs the frequency of MJ was not significantly different at the dose of 75 mg/kg (1.21 ± 0.49 MJ/min) compared to 50 mg/kg (0.17 ± 0.1 MJ/min) (p value < 0.134) or 25 mg/kg (0 ± 0 MJ/min) (p value < 0.085). The frequency of MJ was greater in APs as compared to SPs at 25 mg/kg (p value <0.016) and 75 mg/kg (p value < 0.034). APs also had significantly reduced latency of onset of MJ compared to SPs at 25 mg/kg (p value < 0.001) and 50 mg/kg (p value < 0.004). Interestingly SPs had a reduced latency to TCS as compared to APs at the dose of 75 mg/kg (p value < 0.037). These findings indicate that APs have a significantly greater frequency and lower threshold of onset of MJ and induction of unique behavioral changes in response to PTZ treatment as compared to SPs. Interestingly SPs have reduced latency of TCS as compared to APs, indicating SPs are more predisposed to directly developing a TCS. Further studies need to be conducted to identify the reason for these variations in responses of APs and SPs to PTZ. As it is known that PTZ is an inhibitor of GABA, future studies should be conducted to identify if difference in regional and total expression of GABAergic and Glutamatergic neurons and GABA receptors occurs in APs and SPs.

Title: Role of sharp-wave fast ripples in deficits of episodic-like memory in temporal lobe epilepsy

Authors: *M. VALERO[1], R. G. AVERKIN[2], D. LOPEZ-PIGOZZI[1], J. R. BROTONS-MAS[1], E. CID[1], L. M. DE LA PRIDA[1];
[1]Inst. Cajal - CSIC, Madrid, Spain; [2]Dept. of Physiology, Anat. and Neurosci., MTA-SZTE Res. Group for Cortical Microcircuits, University of Szeged, Hungary

Abstract: Hippocampal sharp wave (SPW)-ripple (100-200 Hz) complexes emerge during immobility and slow-wave-sleep to regulate single-cell activity in memory consolidation. In temporal lobe epilepsy (TLE) SPW-ripples are faster (200-600 Hz) so called fast-ripples (SWP-FR). Despite their clinical value as epileptogenic biomarkers, the cognitive implications of SPW-FR remain unknown. To address this issue, we evaluated SPW events recorded with multi-site silicon probes during offline processing in rats experiencing an object-recognition episodic-like memory task. SPW-FRs recorded during immobility and slow-wave sleep in TLE animals were characterized by a stronger contribution above the normal ripple band (>250 Hz, FR-index) in association with increased spectral entropy. Interestingly, the FR-index correlated specifically with the rat's ability to discriminate the temporal component of episodic-like memory. Moreover, consolidation of a spatial memory was impaired in TLE rats when tested at 100 min versus 50 min interval in a simplified version of the task. We looked for the mechanisms of this disruption at the single-cell level with juxtacellular recording and labeling of CA1 hippocampal cells in freely moving rats. Single-cells recorded from epileptic rats were more desynchronized and positively modulated during SPW-FR than control cells during ripples. Applying methods of clustering analysis to SPW-ripple events we observed a high firing selectivity for certain ripple-waveforms in control cells, whereas epileptic cells fired more and indistinctly over all groups. We propose that SPW-FR act to disorganize hippocampal activity during memory consolidation processes.

Title: Inactivation of fgfr1 and fgfr2 in postnatal astrocytes

Authors: *L. RUBIN, K. SMITH, C. BARNETTE, D. ROGERS;
Biol., Univ. of Louisiana At Lafayette, Lafayette, LA

Abstract: Fibroblast growth factors (Fgfs) are a family of 22 cytokines that bind to 4 receptors, many of which play a critical role in cortical development. Fgf ligands, including Fgf2, and the Fgfr1 and Fgfr2 receptors are expressed by astrocytes and astrocytic stem cell lineages of the developing and adult CNS. Previous studies have shown that Fgfrs can have compensatory effects on proliferation and development. We have inactivated Fgfr1 and Fgfr2 in postnatal astrocytes by tamoxifen inducible Cre mediated recombination using the hGFAP-CreERT2 (GCE) transgene. We targeted postnatal astrocytes by administering injections of tamoxifen from P14-17, 60 mg/kg i.p. We tested locomotor behavior of the mice for 30 minutes in an open field. Male double KO mice showed hypoactivity compared to male control littermates with total time immobile having a p-value of .0380. Other trends were less distance travelled (p=.0542), lower mean speed (.0567), and more total mobile episodes (0521) possibly indicating that the animals began more movements but were slower and spent more time resting. We observed no differences in anxiety behaviors on the elevated plus maze test, and no differences in memory were observed in the 1-day morris water maze. It was previously shown that Fgfr1 and Fgfr2 double KO starting at E13.5 lead to multiple cerebellar abnormalities. The locomotor behavior findings lead us to hypothesize that there may be a postnatal cerebellar defect in Fgfr1/Fgfr2 double KO mice. We compared control and Fgfr1/Fgfr2 double KO mice on a hindlimb clasping test. We found double KO mice had significantly higher scores on this test (p=.05), indicating an impairment in motor coordination. Future work will examine cerebellar morphology. We will compare the effects of Fgfr1 single and Fgfr1/Fgfr2 double mutants upon PV neuron maturation, and postnatal hippocampal proliferation.

Title: *Drosophila* astrocytes span functional neural domains

Authors: *E. HERNANDEZ[1], S. E. MACNAMEE[2], L. R. KAPLAN[1], J. A. CHARLTON[1], D. S. FARHADI[1], K. N. LANCE[2], L. P. TOLBERT[2], L. A. OLAND[2];

Abstract: Ignorance of the contribution of glial cells limits our understanding of how neuronal circuits function. Astrocytic processes invest synaptic neuropil at high density and astrocytes both respond to and modulate neuronal activity, even in invertebrates. *Drosophila,* with its extraordinary genetic toolkit, can be exploited to probe the contribution of astrocytes to neuronal circuit function. In the current study, we ask whether astrocytic arbors map specifically onto functional neuropilar domains (e.g., sensory, motor) or more broadly span across domains in *Drosophila*. We also ask how individual astrocytes interface with neighboring astrocytes.
We are analyzing astrocytes in detail, both individually and as parts of the complex neuron-glia network, in the segmented ventral nerve cord (VNC) of the third-instar larva. Of the 12 astrocytes present in each of the repeating segments, 4 can be reliably identified by the position of their cell bodies. Our recent characterization of the electrophysiological and morphological features of the VNC astrocytes demonstrated strong similarities to vertebrate astrocytes: low membrane resistance and high capacitance, passive membrane properties, expression of the EAAT1 glutamate transporter, and limited dye-coupling (MacNamee et al., J Comp Neurol 2016). Here we use Flp-out (Ito et al., 1997) and MultiColor FlpOut (Viswanathan et al., 2015) genetic constructs targeted to astrocytes via the *alrm*-GAL4 driver (Doherty et al., 2009) to generate high-resolution, detailed images of these astrocytes. Our examination of the processes of individual astrocytes as well as the interfaces between adjacent astrocytes has revealed that (1) the arbors of individual astrocytes span multiple functional neural domains and (2) astrocytic branches have convoluted spatial domains, in which the finest distal branches of adjacent astrocytes interweave with a variable, but small, amount of interdigitation.
These findings suggest the following functional consequences: Because the arbors of astrocytes span functional domains and the astrocytes also can be dye-coupled, astrocytes may have the role of integrating neuronal activity across disparate neural circuits. Alternatively, there may be functional sub-compartments in astrocytes that are differentially active in response to local synaptic activity; this possibility remains to be explored. The limited overlap between astrocytes indicates that electrical coupling among astrocytes is likely to occur at the distal-most tips. And finally, any given synapse is likely to fall exclusively within the domain of a single astrocyte.

Title: Mechanism of phasic D-Aspartate false-gliotransmitter release in the rodent barrel cortex

Authors: ***S. ANTONIO**[1], D. URSU[2], R. PARRI[1];
[1]Aston Univ., Birmingham, United Kingdom; [2]Eli Lilly and Co., Windlesham, United Kingdom

Abstract: Astrocytes modulate synaptic transmission, control blood flow, and extracellular ion and transmitter concentrations, and thus are of great importance in the normal and pathological brain. Astrocytes show bidirectional communication with neurons, releasing gliotransmitters (GTs) such as glutamate, ATP, and GABA that modulate synaptic and neuronal network activity. Various mechanisms of GT release have been proposed, such as via calcium dependent vesicular release, Excitatory amino acid (EAA) transporters, large pore channels, ion channels such as TREK1 and Bestrophin-1 (Best-1), and hemichannels. In this study we investigated the mechanism underlying NMDA receptor mediated slow inward current (SIC) generation in an enhanced EAA release model. Following pre-exposure to 100 μM D-Aspartate, Patch clamp recordings were conducted in layer 2/3 pyramidal neurons in rodent thalamocortical slices from animals at P10-P28. TTX-insensitive slow-inward currents (SICs)(defined as having an amplitude >20pA and rise time >20ms) were observed and pharmacological methods were used to characterise the mechanisms of release. SICs were not abolished by inhibition of VGLUT1, hemichannels, TREK1 channels, temperature or volume regulated channels, or anion channels such as Best-1. SICs still occurred in the presence of Ca^{2+} ATP-ase inhibitor cyclopiazonic acid. Similarly, there was no significant difference in SIC rate between wild-type and inositol 1,4,5-triphosphate (IP_3) type-2 receptor knock-out mice, indicating that spontaneous SIC emergence can be independent of IP_3 mediated intracellular store calcium release. Together, these results suggest that this enhanced astrocyte EAA release model is resistant to pharmacological blockade of individual efflux pathways.

Title: Highly distinct CREB-dependent transcriptional programs in astrocytes and neurons

Authors: L. PARDO[1], L. VALOR[2], A. ERASO[1], A. BARCO[3], R. MASGRAU[1], *E. GALEA[4,5,1];
[1]Inst. de Neurociencias and Departament of Bioquímica, Bellaterra, Spain; [2]Hosp. Universitario Puerta del Mar, Cadiz, Spain; [3]Inst. de Neurociencias, Alicante, Spain; [4]Univ. Autònoma de Barcelona, Bellaterra, Barcelona, Spain; [5]ICREA, Barcelona, Spain

Abstract: The cAMP response element binding protein (CREB) is a primary hub of activity-driven genetic programs in neurons controlling plasticity, neurogenesis and survival. By contrast, the gene networks coordinated by CREB in astrocytes are not yet characterized despite the fact that astrocytic CREB is also activity-driven and neuroprotective like its neuronal counterpart. To fill this gap, we characterized in six stages the transcriptional programs regulated by CREB in astrocytes as compared to neurons. First, CREB-dependent transcription was activated in primary cortical rat astrocyte cultures with noradrenaline (NE), the adenylate cyclase activator, forskolin (FSK) or a virally transduced constitutively active CREB (VP16-CREB). Second, transcriptomic changes were characterized with Agilent DNA microarrays. Third, the differentially expressed genes ($p<0.05$) were filtered through the first quartile of the translational ribosome affinity purification (TRAP) repository of adult astrocyte genes to remove embryonic signatures. Fourth, the resulting list was subjected to functional enrichment analysis with Gene Ontology (GO) using ClueGO v1.4 and ReviGo softwares. Fifth, candidates for direct CREB target genes were identified with the CREB-target gene database of the Salk Institute. Sixth, the functional and molecular CREB signatures in astrocytes were compared to the neuronal ones identified in cultured neurons stimulated with FSK or over-expressing VP16-CREB (ArrayExpress database; accession number E-MEXP-3167). We found that VP16-CREB, FSK

and NE significantly changed the gene expression profile in astrocytes. The FSK and NE groups were very similar (Pearson's correlation = 0.72), while the VP16-CREB group was markedly different from the other two (Pearson's correlation = 0.18 vs FSK; 0.21 vs NE), indicating that the chronic activation of CREB dependent transcription comprises the programs regulated by FSK and NE and activates additional programs. The ranking according to statistical significance of GO groups regulated by CREB, and of CREB candidate target genes, revealed little overlap between astrocytes and neurons. "Nuclear functions" including "Transcription" was the top hit in both cells—represented by different genes—confirming the central position of CREB in transcriptional networks. Ranked second were, as expected, "Plasticity" or "Neurotransmission" in neurons and, unexpectedly, "Mitochondrial functions" in astrocytes. The databases generated in this study will provide a tool to explore novel means whereby CREB impinges on key brain functions by coordinating gene networks and sub-organellar functions in astrocytes.

Title: Co-exposure to arsenic and fluoride increases Glutamate uptake in Bergmann glial cells: evidence of oxidative stress involvement

Authors: A. L. GARCÍA LÓPEZ, O. G. MÉNDES FLORES, L. DEL RAZO, *E. LOPEZ-BAYGHEN, A. ORTEGA;
Toxicology, CINVESTAV-IPN, México, Mexico

Abstract: Inorganic arsenic (iAs) and fluoride (F^-) are known neurotoxicants that are able to cause structural and functional damages in the Central Nervous System (CNS). The concomitant exposure to iAs and F^- doses commonly occur. In the cerebellum, Bergmann glial cells (BGC) enwrap the excitatory synapses established between parallel fibers of granular cells and Purkinje cells and participate in pH regulation, K^+ homeostasis, lactate supply and the Glu/glutamine shuttle. BGC express glutamate transporters of the GLAST/EAAT1 subtype that allow them to remove the excitatory signal of the synaptic cleft and by these means prevent an excitotoxic insult. To gain insight into the molecular events that can be induced upon coexposure to iAs and

F^- in these cells at the level of glutamate transporter function. we used the well established model system of cultured chick cerebellum BGC. We detected a significant increase in Glu uptake activity after 3μM iAs and 500μM F^- co-exposure. Kinetic studies revealed that the increase is related to an augmented transporter affinity. Pretreatment of the exposed cells with the antioxidant Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) prevented the metalloid effect (in Glu uptake) demonstrating that reactive oxygen spices might be implicated in the molecular mechanisms involved in the described phenomena. These preliminary studies suggest that exposure to these pollutants could have the transporter EAAT1/GLAST in glial cells a molecular target of toxicity and that this effect is closely related with oxidative stress.

Title: Wakefulness-dependent modulation of D-serine

Authors: *M. TOLMAN[1], P. G. HAYDON[2];
[1]Neurosci., Tufts Univ., Boston, MA; [2]Neurosci., Tufts Med. Ctr., Boston, MA

Abstract: Cholinergic signaling controls brain states, modulates circuit function, and is a primary therapeutic strategy for a number of diseases including Alzheimer's disease. Recent work from our lab has demonstrated in mouse hippocampal slices that wakefulness-dependent acetylcholine release acts on alpha 7 nicotinic acetylcholine receptors (α7nAChRs) expressed by astrocytes to control the availability of the obligatory NMDA receptor (NMDAR) co-agonist, D-serine. However, wakefulness dependent changes in hippocampal D-serine levels have not been measured *in vivo.* To address this, I am using *in vivo* microdialysis and high pressure liquid chromatography (HPLC) to directly measure D-serine levels as a function of wakefulness. During periods of sustained wakefulness, we find that D-serine levels remain high in the hippocampus, but decrease when the mouse transitions to sleep. This change is observed independently of changes in L-serine and are in agreement with our previous *in situ* data. Using

cell type specific deletion and activation of the α7nAChRs, we are determining the role of cholinergic activation of astrocytes and neurons in mediating wakefulness-dependent elevations in D-serine.

Title: Processing of afferent information at the level of NTS: the role of astroglial 5-HT_{2A} receptors

Authors: *S. MASTITSKAYA[1], P. S. HOSFORD[1], E. TUROVSKY[2], A. V. GOURINE[1], A. G. RAMAGE[1];
[1]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom; [2]Inst. of Cell Biophysics, Russian Acad. of Sci., Pushchino, Russian Federation

Abstract: Introduction. 5-HT (serotonin) is one of the principal transmitters implicated in central cardiovascular regulation. 5-HT_{2A} receptor activation at the level of the nucleus tractus solitarius (NTS) produces hypotension and facilitates bradycardias evoked by vagal afferents and activation of arterial baroreceptors (Ramage & Villalón, 2008, *TiPS*. 29:472-81). Recently, it has been suggested that astrocytes play an important role in cardiovascular integration at the level of the NTS (Lin et al., 2013, *J Neurosci*. 33:18608-17)**.** In this study we investigated the effects of 5-HT on NTS astrocytes and tested the hypothesis that 5-HT receptors contribute to astroglial activation in response to incoming afferent information.
Methods. Primary brainstem astroglial cultures were loaded with a Ca^{2+} indicator Fura-2, and changes in intracellular [Ca^{2+}] evoked by 5-HT were recorded using fluorescent microscopy. 5-HT agonists and antagonists were used to characterize the identity of 5-HT receptors. $[Ca^{2+}]_i$ responses in NTS astrocytes *in vivo* were visualized using a genetically encoded Ca^{2+} indicator

GCaMP6. NTS astrocytes of young male rats (~100g) were targeted to express GCaMP6 using microinjections of an adenoassociated viral vector under control of an enhanced GFAP promoter. 4 weeks later, rats were anaesthetized with α-chloralose, neuromuscular blocked and artificially ventilated. The dorsal surface of the brainstem was exposed and astroglial $[Ca^{2+}]_i$ responses evoked by electrical stimulation of the vagus nerve (5 Hz, 0.8 mA, 1 ms pulse duration) were recorded using MiCam02 high-resolution camera.
Results. Brainstem astrocytes in culture responded to 5-HT with vigorous elevations in intracellular $[Ca^{2+}]$ (EC_{50} 10 μM). 5-HT-induced $[Ca^{2+}]_i$ responses were blocked by phospholipase-C inhibitor U73122 (5 μM) and by 5-HT_{2A} antagonist ketanserin (0.01 - 1 μM). Neither 5-HT_{2C} agonist WAY161503 (0.01 - 5 μM) nor 5-HT_{2B} agonist BW723C86 (0.001 - 1 μM) had any effect on $[Ca^{2+}]_i$ in brainstem astrocytes. *In vivo*, electrical stimulation of the vagus nerve induced rapid $[Ca^{2+}]_i$ responses in the NTS astrocytes as determined by changes in GCaMP6 fluorescence ($\Delta F/F_{max}$=2.0±0.06; n=5). Intravenous administration of ketanserin (300 μg kg^{-1}) significantly ($p<0.01$) decreased the peak magnitude of $[Ca^{2+}]_i$ responses ($\Delta F/F_{max}$=1.0±0.02; n=5), indicating that 5-HT acting at 5-HT_{2A} receptors mediates (at least in part) the effects of vagal afferent evoked changes in NTS astrocytes.
Conclusions. These data suggest that 5-HT-induced modulation of cardiovascular reflexes at the level of NTS may involve its actions on local astrocytes expressing 5-HT_{2A} receptors.

Title: Synapse pruning by astrocytes regulates hippocampal circuit development

Authors: *L. CLARKE[1], W.-S. CHUNG[2], B. BARRES[1];
[1]Neurobio., Stanford Univ., Stanford, CA; [2]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: During normal brain development excessive synapses are formed between neurons, and in order to refine the information processing capacity of the brain unnecessary synapses are eliminated or pruned. We have discovered that this pruning process is carried out by a class of glial cells called astrocytes. These cells express the phagocytic receptors MEGF10 and MERTK which recognize 'eat me signals' on the unwanted synapses, and by the process of phagocytosis they engulf the unwanted connections. Importantly, when astrocyte-mediated phagocytosis is impaired developmental synapse remodeling in the visual system remains incomplete, indicating that astrocytes actively promote synapse elimination. Despite this important role for visual system development, it is not known whether astrocyte-mediated synapse elimination is important for other fundamental aspects of brain function, such learning a memory, which requires both the formation of new synapses and the elimination of pre-existing synapses. To investigate the role of astrocyte-mediated synapse elimination in learning and memory, whole-cell patch-clamp recordings were performed to compare the number of functional synapses in the hippocampus of mice deficient in MEGF10 and MERTK with normal mice. Interestingly, mice deficient in MEGF10 and MERTK received three times more the number of functional excitatory synapses when compared to normal mice. In contrast, impaired astrocyte-mediated synapse elimination did not change the number of inhibitory synapses, suggesting that different refinement pathways exist for different types of synapses. After establishing a role for astrocytes in the development of hippocampal neural circuits, ongoing experiments are being performed to assess the role of astrocyte-mediated synapse elimination in *in vitro* models of learning and memory and *in vivo* hippocampal dependent behavioral tasks in adulthood. These experiments will address the question of whether astrocytes can respond to the changes in neural activity thought to underlie learning and memory and prune neural circuits to allow for long-term changes in neural connectivity.

Title: Tubastatin A and other HDAC6 inhibitors regulate FGF21 transcript expression in glia cells

Authors: *Y. LENG[1], J. WANG[1], P. LEEDS[1], Z. WANG[1], M. PENZO[2], D.-M. CHUANG[1]; [1]Mol. Neurobiol Section, [2]Unit on the Neurobio. of Affective Memory, Natl. Inst. Mental Health/NIH, Bethesda, MD

Abstract: Histone deacetylases (HDACs) are promising therapeutic targets for CNS diseases by epigenetic regulation of gene expression. Among them, HDAC6 is exclusively located in the cell cytoplasm and involved in various neuropathological conditions. Recently, our lab reported that Tubastatin A (TubA), a potent and highly selective HDAC6 inhibitor, alleviates stroke-induced brain infarction and functional deficits possibly through α-tubulin acetylation and up-regulation of fibroblast growth factor 21 (FGF21) (Wang et al, *Scientif Rep*, Jan, 2016). FGF21, a newly determined regulator of glucose and lipid metabolism, is neuroprotective and a novel target of mood stabilizers lithium and valproate (VPA) in brain neurons (Leng et al., *Mol Psychiatry*, 2015). Moreover, VPA and other pan HDAC inhibitors upregulate FGF21 gene expression by inhibiting HDAC 2 and 3 in C6 glioma and primary glial cells (Leng et al, *Intl J Neuropsychopharm*, 2016). As an extension of previous work, this study investigated the effects of TubA and other HDAC6 inhibitors on the expression of FGF21 in C6 glioma (C6) cells. Incubation of C6 cells with TubA at concentrations of 1 to 5 μM induced a dose-dependent increase in FGF21 mRNA levels with a maximum increase of 3-fold at 5 μM. Acetylated histone H3 and acetylated α-tubulin protein levels were also markedly increased by TubA treatment. Other HDAC6-specific inhibitors, Nexturastat A and Tabacin, increased FGF21 mRNA expression dose-dependently, reaching a significant increase at 2μM, and maximum increases of 6- and 8-eight-fold, respectively, at 5 μM. Two other non-specific HDAC6 inhibitors ACY1215 and CAY10603 were found to increase FGF21 mRNA levels up to 20- or 80-fold, respectively. To investigate whether HDAC6 silencing also regulates FGF21 transcription levels, we utilized the lentiviral small hairpin RNA (shRNA)-mediated knockdown technology. In C6 cells, we tested five clones and found that HDAC6 #414 produced the most efficient knockdown (ca. 63%) of HDAC6 mRNA. FGF21 transcript level was significantly increased by 1.7-fold with lentiviral mediated HDAC6 knockdown using three pairs of different primers from Integrated DNA Technologies Inc. Similar results were confirmed using three other pairs of primers from ThermoFisher Scientific, in which FGF21 mRNA level was increased 1.5-, 1.6-, or 1.7-fold. Taken together, our novel results show that inhibition of HDAC6 by five different HDAC6 inhibitors, or lentiviral mediated shRNA knockdown, up-regulates FGF21 transcript levels in C6 glioma cells. Further studies of the neurobiological significance of HDAC6 inhibition on FGF21gene regulation in brain disease models are warranted.

Title: Estrogen-responsiveness of prepubertal vs. adult female hypothalamic astrocytes

Authors: *M. A. MOHR, P. MICEVYCH;
Dept of Neurobiology, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Puberty is a complex developmental stage that results in reproductive maturation. In females, reproductive circuits are considered mature when estrogen positive feedback is able to elicit a luteinizing hormone (LH) surge. The LH surge triggers ovulation and the luteinization of the ruptured ovarian follicle - critical events for reproduction. We have previously shown that peripheral estradiol (E2) increases neuroprogesterone (neuroP) synthesis in the hypothalamus in postpubertal astrocytes. This newly synthesized neuroP stimulates kisspeptin release to initiate the LH surge. Interestingly, E2-facilitated neuroP synthesis by hypothalamic astrocytes only occurs in post-pubertal females and has not been observed in prepubertal females in vivo, prepubertal hypothalamic astrocytes in vitro or males at any age - including male astrocytes in vitro. How puberty affects hypothalamic astrocytes to begin to allow E2-facilitated neuroP release has not been elucidated. The focus of the current study is to determine if the cellular machinery responsible for neuroP release is upregulated in adult female mice compared to prepubertal females. Of particular interest are translator protein (TSPO) and StAR (steroidogenic acute regulatory protein), which mediate the rate-limiting step in steroidogenesis, and 3beta-hydroxysteroid dehydrogenase (3β-HSD), an enzyme that catalyzes the biosynthesis of progesterone. Hypothalamic astrocyte cultures were generated from female mice at two different developmental ages: prepubertal (postnatal day (P) 23) and adult (~P60). The ability to release neuroP in response to E2 was monitored via progesterone ELISA. Western immunoblotting and quantitative real-time PCR was performed to determine differences in TSPO, StAR, and 3β-HSD protein and RNA, respectively. Determining if there are developmental increases in the expression of the cellular machinery involved in neuroP synthesis will provide a mechanism for the development of E2-facilitated neuroP synthesis in hypothalamic astrocytes.

Title: Impact of the GFAP gene variant rs2070935 on the structure and function of the human brain

Authors: *Y. TAKAHASHI, M. SAKAI, Z. YU, H. TOMITA;
Dept. of Disaster Psychiatry, Tohoku Univ., Sendai-Shi, Japan

Abstract: Grial fibrillary acidic protein (GFAP) is one of the main intermediate filament proteins in astrocytes. GFAP has key roles in maintainance of mechanical strength of astrocyte, astrocyte-neuron communication during synaptic plasticity, and reactive gliosis. GFAP is widely used as a marker for astrocytes. GFAP is induced upon brain damage or during central nervous system degeneration. Accumulating evidence suggests involvement of GFAP dysregulation in the pathogeneses of various psychiatric or neurological disorders. Expression changes in GFAP have been reported in the brain from patients with schizophrenia, bipolar disorder, major depressive disorder, Alzheimer disease, and Parkinson disease. Also, GFAP mutations cause a rare, progressive and often fatal neurodegenerative disorder, Alexander disease, which is characterized by cytoplasmic inclusion of GFAP in astrocytes. Recently, C allele of a single nucleotide polymorphism (SNP), rs2070935 (A/C), located in GFAP promoter region, has been shown to be related with upregulation of GFAP and severe symptom of alexander disease, which suggests that the polymorphism may affect brain function as well as susceptibility to psychiatric or neurological disorders. However, the associations between the functional SNP and brain structure and function remain unelucidated. To investigate effect of the genetic variations in GFAP on the structure and function of the human brain, we evaluated association between the SNP and MRI findings, including gray and white matter volumes, mean cerebral blood flow during rest using arterial spin labeling, and diffusion tensor imaging(DTI)-based white matter integrity among 1212 healthy Japanese people. The C allele of the SNP was significantly associated with decreased volume of gray and white matter in inferior frontal lobes, decreased cerebral blood flow in broad area in cerebrum, and increased mean diffusivity in subcortical region of left temporal and posterior lobes. These variations in volumes, diffusivities, activities of the brain modulated by the genetic variation in GFAP might be relevant to susceptibility to neuropsychiatric and neurodegenerative disorders.

Title: Astrocyte mediated neuronal synchronisation properties revealed False Gliotransmitter release

Authors: *R. PARRI[1], G. SAUNDERS[1], N. CODADU[2], T. M. PIRTTIMAKI[3], R. E. SIMS[1]; [1]Aston Univ., Birmingham, United Kingdom; [2]Newcastle Univ., Newcastle, United Kingdom; [3]Univ. of eastern Finland, Kuopio, Finland

Abstract: Astrocytes spontaneously release glutamate as a gliotransmitter (GT) resulting in the generation of extrasynaptic NMDA-R mediated slow inward currents (SICs) in neighbouring neurons, which can increase local neuronal excitability. However, there is a deficit in our knowledge of the factors that control spontaneous astrocyte GT release, and the extent of its influence. We found that increasing the supply of the physiological transmitter glutamate increased the frequency (control : 0.066±0.01 /min; Pre-Glut: 1.26±0.2 SICs/min; $p<0.0001$; n=50, 25 cells respectively) and signalling charge of SICs in VB thalamus over an extended period. This phenomenon was replicated by exogenous pre-exposure to the amino acid D-Aspartate (0.74±0.23 SICs/min, n=10 compared to 0.062±0.01 SICs/min,n=15, in control). SIC frequency increase for glutamate and D-Aspartate was abrogated by co-treatment with TBOA indicating a role for EAAT uptake. Using D-Aspartate as a "False" GT we determined the extent of local neuron excitation by GT release in VB thalamus, CA1 hippocampus and somatosensory cortex. By analysing synchronised neuronal NMDA mediated excitation we found that the properties of the excitation was conserved in different brain areas. In the three areas, astrocyte derived GT release synchronised groups of neurons over distances of over 200µm. Individual neurons participated in more than one synchronised population, indicating that individual neurons can be excited by more than one astrocyte, and that individual astrocytes may determine a neuron's synchronised network. The results confirm that astrocytes can act as excitatory nodes that can influence neurons over a significant range in a number of brain regions. Our findings further suggest that chronic elevation of ambient glutamate levels can lead to increased gliotransmitter glutamate release, which may be relevant in some pathological states.

Title: Astrocytic regulation of synaptic transmission in central medial amygdala

Authors: *M. MARTIN-FERNANDEZ[1], G. MARSICANO[2], A. ARAQUE[1];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Bordeaux, NeuroCentre Magendie, Bordeaux, France

Abstract: The central medial amygdala (CeM) plays an important role in the responses to fear stimuli, as it is the major output of the amygdala, projecting to fear effector structures. Astrocytes release gliotransmitters that modulate synaptic transmission; however, how astrocytes modulate synapses that produce a different outcome has not been elucidated. The different amygdala subnuclei were identified in acute slices (350 μM thick) from C57BL/6 and $IP3R2^{-/-}$. by transillumination and the CeM nuclei identification was confirmed by the electrical properties of CeM neurons, which were classified as Low Threshold Bursting (54.3%,), Regular Spiking (28.5%), Late Firing (14.3%), and stuttering neurons (2.9%). Using whole cell electrophysiological recordings and calcium imaging techniques, we investigated the astrocytic responsiveness to the endogenous release of endocannabinoids (eCBs) evoked by neuronal depolarization (ND) of CeM neurons. We monitored the intracellular calcium levels of astrocytes, identified with SR101, using the fluorescent dye Fluo4-AM, and induced eCBs release by ND of the recorded CeM neurons. The ND elevated calcium levels in CeM astrocytes, increasing the calcium event probability. This increase in astrocytic calcium event probability was abolished in the presence of the CB1R antagonist AM251, indicating a CB1R-dependent mechanism. The astrocytic response to eCBs was absent in the $IP_3R2^{-/-}$ mice, in which G protein-mediated calcium elevations are selectively impaired in astrocytes, indicating that astrocytic CB1R activation leads to calcium mobilization from internal stores. We then investigated the consequences of the astrocyte calcium signal on the glutamatergic excitatory and GABAergic inhibitory synaptic transmission in CeM neurons. We recorded excitatory or inhibitory postsynaptic currents (EPSCs or IPSCs) evoked by electrical stimulation with an extracellular electrode located in the Basolateral (BLA) or CentroLateral (CeL) sunbuclei, respectively. EPSCs and IPSCs were isolated in the presence of either, AMPAR and NMDAR antagonists, or $GABA_AR$ and $GABA_BR$ blockers, respectively. We depolarized one neuron to induce eCBs release and recorded CeL-CeM IPSCs or BLA-CeM EPSCs in the other paired recorded neuron in order to identify the astrocytic modulation of CeM synaptic transmission. The probability of release of the recorded EPSCs was decreased, with no change in synaptic potency. The

probability of release of IPSCs recorded was increased, with no change in synaptic potency. These data reveal the involvement of astrocytes in synaptic transmission in the CeM

Title: Rapid astrocytic control of neural activity by optogenetic Gq-coupled receptor activation *In vivo*

Authors: *Y. IWAI, K. OZAWA, K. YAHAGI, S. SATO, H. HIRASE;
RIKEN Brain Sci. Inst., Wako-Shi, Japan

Abstract: Astrocytes express a wide variety of Gq-type G protein-coupled receptors (GPCRs) and respond to their agonists with intracellular Ca^{2+} elevations. Recent studies show that Gq-GPCR activation by neuromodulators strongly increases astrocytic Ca^{2+} and represents a major mechanism for astrocytic Ca^{2+} dynamics *in vivo* (Bekar et al., 2008; Takata et al., 2011; Ding et al, 2013; Paukert et al, 2014). However, the functional significance of astrocytic Gq-GPCR signaling in neural activity modulation remains controversial (Agulhon et al, 2010), because pharmacological manipulations of GPCRs affect neuronal GPCRs as well. In order to specifically and dynamically activate astrocytic Gq-GPCR signaling *in vivo*, we have generated transgenic mice in which EYFP-fused OptoA1AR, an optically activatable Gq-GPCR (Airan et al., 2009), is expressed under the control of a BAC-GLT1 promoter. Among the transgenic lines

established, several lines showed selective astrocytic expression, with differences observed in their expression strength and positive astrocytic proportion ranging from ~50% to 90%. In these lines, cortical GFAP expression appeared generally low, suggesting that the expression of OptoA1AR-EYFP does not cause glial inflammation. We next confirmed that astrocytic Ca^{2+} elevation was triggered by brief illumination of blue light in anesthetized conditions. *In vivo* rhod-2 Ca^{2+} imaging of the ~50% positive line revealed that a short blue light pulse (~1 s) induced Ca^{2+} elevations within a few seconds in OptoA1AR-EYFP-positive astrocytes but not in negative astrocytes. The magnitude and frequency of spontaneous astrocytic Ca^{2+} surges were similar in both astrocytic populations, and the magnitude of optically-evoked Ca^{2+} surges was comparable to that of spontaneous Ca^{2+} activities. This optical activation was repeatable with an interval of 1 min, although the response magnitude was decreased from the second stimulus onwards. A non-stimulus period of 3 minutes restored the original response magnitude. Remarkably, stronger optical stimulation could induce astrocytic Ca^{2+} wave propagation, in which Ca^{2+} elevations were observed in OptoA1AR-EYFP-negative astrocytes with a delay of several seconds after the activation of the neighboring OptoA1AR-EYFP-positive astrocytes. Furthermore, some of the surrounding neurons were found to be rapidly activated following the astrocytic optical stimulation. We are currently exploring downstream molecular mechanisms and behavioral impacts induced by the astrocytic GPCR activation.

Title: A candidate screen to identify novel regulators of astrocyte development and astrocyte-synapse interaction

Authors: *K. T. BALDWIN, J. A. STOGSDILL, C. EROGLU;
Dept. of Cell Biol., Duke Univ., Durham, NC

Abstract: Dysfunctional synaptic connectivity is thought to be the underlying cause of many neurological disorders, including autism, schizophrenia, and various forms of intellectual disability. Astrocytes are morphologically complex cells that structurally and functionally interact with synapses to regulate synapse formation and maturation. Disruption of astrocyte-synapse interactions is a major pathological mechanism seen in many neurological disorders, yet whether astrocyte dysfunction contributes to synaptic pathologies in neurological disorders is largely unknown. Interestingly, a number of disease-linked genes encode cell surface proteins that are highly expressed and significantly enriched in astrocytes. However, the function of these genes in astrocytes, and how disruption of their astrocytic function can contribute to neurological disorders, is not known. We hypothesized that many of these astrocyte-enriched disease-linked genes play critical roles in astrocytes to regulate astrocyte development and astrocyte-synapse interactions, and that disruption of their functions in astrocytes critically contributes to synaptic pathologies associated with neurological disorders. To test this hypothesis, we employed an astrocyte and cortical neuron co-culture system to screen carefully selected candidate genes for their role in astrocyte development and astrocyte-synapse interaction *in vitro*. Using this setup, we found that depletion of select candidate genes significantly impairs the ability of astrocytes to establish a complex morphology. Ongoing studies are focused on determining the *in vivo* astrocytic function of these candidate genes using a concurrent labeling and genetic modification strategy. Collectively, these experiments will provide novel insights into the role of astrocyte dysfunction in neurological disorders, and reveal specific molecular mechanisms that facilitate disease pathogenesis.

Title: Anandamide decreases [^{3}H] D-aspartate uptake activity in cultured Bergmann glia cells

Authors: M. DE JESÚS SÁNCHEZ[1], E. SUÁREZ POZOS[2], L. C. R. HERNÁNDEZ KELLY[2], *C. J. JUÁREZ-PORTILLA[3], A. ORTEGA[2];

Abstract: Glutamate is the major excitatory transmitter in the vertebrate brain. It acts through specific membrane receptors present in neurons and glial cells. Bergmann glia completely surrounds glutamatergic synapses and it is thought to be involved in their regulation. The endocannabinoid system integrate a regulatory system present in central and peripheral systems, thus it may be involved in the glutamatergic signaling in the brain, particularly in the cerebellum. In order to gain insight the molecular mechanisms of cannabinoid regulation on glutamate signaling we characterized the effect of the activation of cannabinoid receptors in the glutamate uptake process in the well-known model of chick cerebellum primary cultures of Bergmann glial cells stimulated with the endocannabinoid system agonist anandamide. Our first approach was to establish the expression of endocannabinoid receptors CB1 and CB2 in Bergmann glia. Immunochemistry assays as well as western blots demonstrated the expression of both receptors. When the cultured cells were exposed to anandamide, a time and dose-dependent decrease in [^{3}H]D-Aspartate uptake activity was detected. A detailed kinetic analysis demonstrated that the effect of anandamide is related to a decrease in the plasma membrane glutamate transporters. These results strength the notion of glial cells as targets of endocannabinoids and support the idea of a critical involvement of glia cells in the function and dysfunction of the brain.

Title: Dietary impact on astrocytes in the arcuate nucleus of the hypothalamus

Authors: *J. GAMMONS[1,2], A. SMITH[1], K. O'CONNELL[2,3];
[2]Physiol., [3]Neurosci. Inst., [1]Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Obesity leads to chronic metabolic disruption and continues to be a rising epidemic. Centrally projecting neurons from the arcuate nucleus of the hypothalamus orchestrate feeding behavior, and previous work for our lab demonstrates their altered biophysical properties in response to the consumption of high levels of dietary fats, prior to gaining weight. However, it remains unclear to what extent food intake is under the control of glial cells, which are well

known to contribute to inflammatory processes associated with obesity. Astrocytes function to maintain homeostatic conditions for neuronal activity and regulate neurotransmission. To investigate the impact of high-fat diet (HFD) consumption on astrocytic excitability, mice were fed HFD ad libitum for 2 days or 3 weeks. Recordings from acute brain slices using whole-cell patch clamp were used to compare the effects of HFD to chow-fed and fasting animals. Our data suggest that the electrophysiological properties of astrocytes located in the arcuate are feeding-state dependent and are distinctively altered by short-term, as well as chronic, exposure to high fat diet. Using immunohistochemistry, we discovered that expression of astrocytic K_{ir} 4.1 was significantly decreased in the brains of mice fed HFD. To this end, we characterized the effect of diet on Ba^{2+}-sensitive currents in arcuate astrocytes. Additionally, we assessed the integrity of the astrocytic network by measuring gap junction coupling and intracellular Ca^{2+} signaling using a genetically encoded Ca^{2+} indicator. These findings suggest prodromal astrocytic dysfunction may contribute to obesogenic factors that precede weight gain.

Title: Autophagy in astrocytoma monolayer and hydrogel cell culture systems.

Authors: ***M. P. JOGALEKAR**[1], L. G. COOPER[2], E. E. SERRANO[2];
[1]Mol. Biol., [2]Biol., New Mexico State Univ., Las Cruces, NM

Abstract: Astrocytoma is a primary malignant brain tumor that invades the surrounding tissue. The cancer is aggressive and the estimated survival rate of patients following diagnosis is 12-15 months. Cell lines derived from human donors diagnosed with astrocytoma are an essential tool for *in vitro* studies of disease progression and treatment. Traditional methods for cell culture maintain cells in monolayer (2D) environments, with growth on a rigid substrate and immersed in liquid media. However, a growing body of evidence suggests that cancer cells maintained in hydrogel environments (three-dimensional; 3D) are biologically more similar to *in vivo* tumor tissue (Kenny et al, 2008; doi: 10.1016/j.molonc.2007.02.004). We undertook the current study

to assess whether a 3D cell culture platform can afford utility in developing interventions against astrocytoma. To this end, the Grade IV astrocytoma cell line ATCC CCF-STTG1 (a glioblastoma) was maintained in conventional monolayer culture on tissue culture polystyrene, and in 3D culture using the extracellular matrix hydrogel, Geltrex^{TM}. When cells were imaged with phase contrast and laser confocal imaging methods, we observed that cells grown on polystyrene appeared flat-layered in sheets, adhered to the chamber surface, and grew parallel to the substrate. In contrast, 3D matrix-organized cells formed compact multilayer aggregates interspersed with regions of cell clusters . Ultrastructural analysis with transmission electron microscopy (TEM) showed a prevalence of autophagic structures in both 2D and 3D cultures, an observation consistent with prior TEM studies from our laboratory with the triple negative breast cancer line HCC70. Analysis of an open source GEO DataSet (GSM886923) uncovered expression of 219 of 222 genes implicated in autophagic pathways by the Human Autophagy Database (HADb). Microarray measurements of gene expression ranged from 3.2 to 14.7 arbitrary units of fluorescence (AU; 8.1 ± 2.4; mean ± S.D.) and included detection of BECN1 (9.3 AU), PIK3 (8.7 AU), and BCL2 (5.1 AU). Our results demonstrate that the organization of astrocytoma cells in culture can be influenced by the surrounding microenvironment. Moreover, ultrastructural and molecular characteristics of autophagy are features of this astrocytoma cell line. Future studies will analyze the molecular pathways for autophagy using fluorescent probes and expression analysis methods with the goal of identifying potential molecular targets for control of astrocytoma cell proliferation.

Title: Astrocyte regulation of neuron circadian behavior

Authors: ***O. BARCA-MAYO**, M. PONS-ESPINAL, L. BERDONDINI, D. DE PIETRI TONELLI;
Neurosci. and Brain Technologies, IIT, Genova, Italy

Abstract: Circadian rhythms govern a large variety of physiological and metabolic functions. Although growing evidence suggests a major involvement of astrocytes in the regulation of

circadian rhythms in invertebrates, its role in mammals is currently unknown. Using rodent as main model, we characterize the role of astrocytes as modulators of neuronal rhythms by performing co-culture of synchronous astrocytes with asynchronous neurons onto physically separated layers, but sharing the same culture media. We found that astrocytes induce synchronization of circadian oscillators genes in neurons. Moreover, *Bmal1* knockdown in astrocytes partially suppresses circadian entrainment in cortical neurons, suggesting that astrocytes are competent circadian oscillators able and required to synchronize cortical neurons in vitro. Additionally we generated an inducible conditional mouse model where Bmal1 can be deleted in astrocytes and found impaired oscillation of canonical clock genes in cortex and hippocampus of the mutant as compared to control mice. Mutant mice displayed altered circadian locomotor activity, severe cognitive impairments and peripheral metabolic abnormalities. Those results suggest that astrocyte circadian rhythms interface and modulate the neural circuitry thereby controlling neuronal rhythmic behavior at cellular, tissue and organism level.

Abstract: Recently, bioactive lipids, such as lysophosphatidic acid (LPA), were described to be involved in the control of neuronal signaling. We have recently reported on plasticity related gene 1 (PRG-1), a phospholipid interacting molecule, acting as a regulator of LPA signaling at

excitatory synapses. In order to understand the molecular function of LPA, we focused our work on the role of autotaxin (ATX), the main LPA-synthetizing molecule, at glutamatergic synapses. We show that ATX is expressed in the astrocytic compartment of the excitatory tripartite synapse and that its secretion is regulated by glutamate acting on AMPA and NMDA astrocytic receptors. To gain further insight into the effect of the LPA/ATX axis, we performed electrophysiological recordings where ATX activity was either inhibited by pharmacological blockers or genetically deleted in astrocytes. While pharmacological inhibition disrupted ATX function in the neuronal network, genetic deletion allowed us to selectively delete ATX in astrocytes and to inhibit the LPA-synthesis at the synaptic cleft. In fact, inhibition of LPA synthesis was able to normalize excitation/inhibition balance under pathophysiological conditions associated with hyperexcitability. Our data underline the role of synaptic lipid signaling in the regulation of excitatory transmission in the brain.

Title: Fananas cells: the forgotten type of cerebellar astroglia?

Authors: A. GOERTZEN[1], *R. W. VEH[2];
[1]Klinik für Neurologie, Katholisches Klinikum Oberhausen, Oberhausen, Germany;
[2]Universitaetsklinikum Charite, Berlin, Germany

Abstract: For long times astrocytes were regarded as non excitable cells, passively filling the spaces between neuronal cell bodies, dendrites, axons, and synapses. During the last decades, however, it has been recognized that astrocytes are involved in a variety of biological functions such as regulating cerebral blood flow, supporting neuronal metabolism, controlling the extracellular potassium concentration, and clearing neurotransmitters between synapses. In addition to principal forms like protoplasmic and fibrous types, in line with so many biological functions, astrocytes display a conspicuous regional heterogeneity including choroid plexus epithelial cells, marginal glia, tanycytes, radial astrocytes, retinal Müller glia, vellate glia, and cerebellar Bergmann glial cells.
The cerebellum is thought to host several types of astrocytes: protoplasmic, fibrous, vellate and Bergmann cells. At present it is not known, whether these glial cells together are sufficient to

cope with the increasing complexity of cerebellar functions. The older literature presents an additional potentially astrocytic glial type: the Fananas cell, which, if existing in reality, has completely disappeared from scientific awareness. These cells were identified by a special staining procedure (gold sublimate technique) at the beginning of the 20th century. Their structure is similar but not identical to that of Bergmann cells, making the differentiation just by morphological methods impossible. Based on our long standing interest in morphology and function of the cerebellum we set out to use a battery of about 50 antibodies against potassium channels and related proteins to find molecular support for the existence of Fananas cells in the mammalian brain. Indeed we could identify the Kv2.2 potassium channel protein as molecular marker for Fananas cells. This finding may be helpful to characterize potential biological functions of this forgotten glial cell type.

Title: Detailed morphometric analysis of a glial process in the adult rat hippocampus

Authors: ***C. CALI**[1], K. KARE[2], D. J. BOGES[2], H. LEHVASLAIHO[2], P. J. MAGISTRETTI[2,3]; [2]BESE, [1]KAUST, Thuwal, Saudi Arabia; [3]Brain and Mind Inst., EPFL, Lausanne, Switzerland

Abstract: Early observers including Cajal and Golgi, noted the complex morphology of astrocytes, and showed that they are strategically located at the interface between neurons and vasculature in the brain. Astrocytes have been shown to be involved in a numerous tasks in the CNS that include metabolic support of neuronal function and regulation of chemical compounds in the extracellular space, in order to sustain synaptic transmission. This is also reflected in their complex morphology and intimate relationship with all elements of the neuropil. A detailed knowledge of the morphology of these cells at the resolution that is below that of light microscopy can shed light on astrocytic functions. In particular, perisynaptic processes, that cannot be currently investigated *in vivo* or *in situ*, can be reconstructed in detail using electron microscopy imaging and three-dimensional reconstruction *in silico*. Here, we describe in detail a 220 cubic micron volume of adult rat hippocampus, where we reconstructed all the cellular

components, with particular emphasis on the astrocytic processes. This gave us information on astrocytic coverage, extent of individual synapses, the widespread presence of ER and mitochondria in lamelliform processes, and their proximity to spines, boutons, and PSDs. This information provides the structural basis for understanding higher-level phenomena that involve astrocyte-neuron crosstalk, like ANLS or calcium-induced-calcium-release.

Title: Exploring the maturation of human iPSC-derived astrocytes in 3D cerebral cortical cultures

Authors: ***S. A. SLOAN**[1], S. DARMANIS[2], N. HUBER[3], F. BIREY[3], C. CANEDA[1], S. R. QUAKE[2], B. A. BARRES[1], S. P. PASCA[3];

Abstract: Astrocytes play critical roles in nervous system function and contribute to the pathophysiology of multiple neuropsychiatric disorders. Therefore, there is a significant need to develop physiologically relevant cellular models for investigating human astrocytes in both health and disease. Here we present an approach for reliably generating human astrocytes from induced pluripotent stem cells (iPSC) in a three-dimensional (3D) cytoarchitecture using human cerebral cortical spheroids (hCS). By tailoring existing immunopanning techniques designed to harvest astrocytes from primary human samples, we were able to acutely purify astrocytes and neurons from hCS and perform high-depth RNA-sequencing and single cell RNA-sequencing of iPSC-derived astrocytes to directly compare with primary human astrocytes. By leveraging long-term cultures of hCS (over 500 days), we were able to transcriptionally and functionally capture astrocytes at several *in vitro* developmental stages. We found that iPSC-derived astrocytes in hCS closely resemble primary human fetal astrocytes and that over time they transition from a predominantly fetal to a mature human astrocyte signature. Importantly, these changes are accompanied by age-dependent changes in the functional properties of astrocytes. Together, these data suggest that astrocytes generated within a hCS system resemble primary human

astrocytes with high fidelity, and that the intrinsic and/or extrinsic signals required for astrocyte maturation are present in long-term cultures of hCS.

Title: Astrocytic glucose metabolic flow correlates with high expression of LDH and implicates in radical proliferation ability of GBM.

Authors: ***J. KIM**[1,2], J. HAN[1], Y. JANG[1,2], S. KIM[1,2], M. LEE[1,2], I. RYU[1,2], M. RYU[1], G. KWEON[1,2,3], J. HEO[1,2,4];

Abstract: Among the primary brain tumors, glioblastoma multiforme (GBM) has a radical proliferation ability that complicates the therapeutic modulation of cancer progression. The majority of GBM patients have a low survival rate (<1 year) due to radical tumor growth and late cancer diagnosis. Previous reports have shown that astrocytes have a specific metabolic organization that includes the production of lactate, the storage of glycogen, and use of lactate to support neurons which possess higher capacity of metabolism compared to neurons. We hypothesized that these characteristics of astrocytes could contribute to enhanced proliferation of GBM compared to neuroblastoma (NB). Here, we show that U87MG cells (a model of GBM) proliferate more rapidly than SH-SY5Y cells (a model of NB). A higher extracellular acidification rate and maximal mitochondrial oxygen consumption rate were observed in U87MG cells compared to SH-SY5Y cells. The expression levels of lactate dehydrogenase (LDH)-A and LDH-B were higher in U87MG cells and primary cultured astrocytes than in SH-SY5Y cells and neurons. Furthermore, the mRNA levels of *succinate dehydrogenase* and *peroxisome proliferator-activated receptor-γ* were high in U87MG cells, suggesting that these

cells have high capacity for mitochondrial metabolism and uptake of fatty acids related to synthesis of the cell membrane, respectively. Taken together, we demonstrate that GBM cells are characterized by activation of the LDH-expression-related glycolytic pathway and mitochondrial metabolic capacity, suggesting two innate properties of astrocytes that could provide a driving force for the growth ability of GBM. Based on these findings, we propose that therapeutic approaches aimed at treating GBM could target LDH for modulating the metabolic properties of GBM cells.

Title: Molecular specification of functionally heterogeneous dorsoventral and subcortical astrocyte sub-populations in adult central nervous system (CNS)

Authors: ***Y. YANG**[1], L. MOREL[1], M. CHIANG[1], H. HIGASHIMORI[1], R. BRADLEY[2], L. IYER[1], S.-C. ZHANG[2];
[1]Neurosci., Tufts Univ. Sch. of Med., Boston, MA; [2]Waisman Ctr., Univ. of Wisconsin, Madison, WI

Abstract: *In vivo* molecular markers that characterize heterogeneous astroglial populations in adult CNS remain essentially unknown. In the current study, we profiled ribosome-associated mRNA, presumably actively translating mRNA in astrocytes, from adult (P70) cortical (cortex and hippocampus) and subcortical (caudate putamen, nucleus accumbens, thalamus, and hypothalamus) regions using translational ribosome affinity purification (TRAP) and RNA-Seq techniques. Our results found that the similarity of ribosome-associated mRNA profile in astrocytes closely follows the dorsoventral axis, especially posteriorly from cortex to hypothalamus. We further identified specific mRNA transcripts that showed significantly differential expression patterns in region-specific astrocytes. These genes include modulators of synaptogenesis (*sparc*, *thsb4*), enzymes (*agt*), and transcription factors (*emx2*, *hopx*, and *lhx2*). Their differential expression patterns were confirmed by qRT-PCR and immunostaining in adult mouse CNS. Moreover, the differential expression pattern of identified genes was also validated

in human dorsal or ventral forebrain astrocytes derived from induced pluripotent stem (ips) cells. By establishing region mis-matched neuron and astrocyte co-cultures, we further showed that subcortical astrocytes induce significantly fewer numbers and less mature glutamatergic synapses when compared to cortical astrocytes, consistent with the expression pattern of synaptogenic molecules (*sparc*, *thsb4*) in astrocytes from these regions. By examining astrocyte labeling on EAAT2-tdT^{+} ALDH1L1-eGFP^{+} reporter mice, we next identified tdT^{-}eGFP^{+}, tdT^{low}eGFP^{+}, and tdT^{high}eGFP^{+} cortical astrocyte sub-populations. Interestingly, tdT^{-}eGFP^{+} astrocytes are selectively distributed in cortical layer I-II and exhibit significantly different membrane and potassium channel properties. These sub-populations were subsequently isolated through fluorescence active cell sorting (FACS) and their mRNA profile was compared following RNA sequencing. The tdT^{-}eGFP^{+} astrocytes also showed unique molecular signatures when compared to tdT^{low}eGFP^{+} or tdT^{high}eGFP^{+} cortical astrocytes. In summary, our study characterized molecular signatures of dorsoventral and cortical subpopulation astrocytes, providing new molecular markers to better understand their heterogeneous functions in adult CNS.

Title: Astrocytes control microglia reactivity through TSPO

Authors: *O. CHECHNEVA[1], F. MAYRHOFER[2], W. DENG[3,2];
[1]Biochem. and Mol. Med., Univ. of California, Davis, Sacramento, CA; [2]Shriners Hosp. for Children, Sacramento, CA; [3]Biochem. and Mol. Med., Univ. of California Davis, Sacramento, CA

Abstract: Microglia and astrocytes provide immune surveillance in the central nervous system (CNS) and their intercellular communication is essential for maintaining CNS homeostasis. The mechanisms and molecules involved in astrocyte-microglia cross talk are not well known. Mitochondrial translocator protein (TSPO) is expressed in microglia and astrocytes and its expression is increased during injury to the CNS and used as diagnostic biomarker of neuroinflammation. TSPO is highly expressed in steroidogenic cells and has been implicated in mitochondrial cholesterol import and steroids biosynthesis. Recent findings using conditional

knockout animal models questioned a pivotal role of TSPO in steroidogenesis. The physiological role of TSPO in cellular function is still unclear. We found that knockout of TSPO in postnatal astrocytes *in vivo* using a Cre-LoxP system causes microglia activation and an increased expression of microglia specific calcium-binding protein Iba1 in the brain and spinal cord. Activation of microglia is accompanied by an increased level of pro-inflammatory cytokine IL-1beta mRNA expression. We also observed an increase in TSPO expression in the CNS of knockout animals in association with microglia and blood-brain barrier endothelial cells. Thus, our data showed that loss of TSPO in astrocytes results in activation of microglia and suggests an important role of TSPO specifically in astrocyte-microglia communication and implies the suppression of microglia reactivity by astrocytes for efficient CNS immune regulation.

Title: Non cell autonomous regulation of proliferation in the injury microenvironment by Sonic hedgehog signaling.

Authors: *R. ALLAHYARI, K. CLARK, B. TING, A. D. R. GARCIA;
Biol., Drexel Univ., Philadelphia, PA

Abstract: Following brain injury, astrocytes undergo a series of biochemical and morphological changes collectively known as reactive astrogliosis. Reactive astrocytes increase expression of glial fibrillary acidic protein (GFAP), undergo proliferation, and participate in complex glial scar formation, segregating the injured from healthy tissue. Understanding the molecular regulators of reactive astrogliosis is key to developing novel therapeutic strategies for treating neurological injury or disease. In this study, we examined the role of Sonic hedgehog (Shh) signaling in reactive astrogliosis. Discrete subpopulations of astrocytes in the adult mammalian forebrain express the transcription factor, Gli1, indicating active Shh signaling. Shh has been shown to play an important role in the neural response to injury. However, the precise role of Shh signaling in regulating reactive astrogliosis is not well understood. We performed forebrain stab injuries in transgenic mice possessing a conditional knock out (CKO) of the obligatory Shh receptor, Smoothened (Smo), specifically in astrocytes (GFAP Smo CKO). Our results show

that injury-induced proliferation is dramatically reduced in GFAP Smo CKO mice. However, the vast majority of proliferating cells at the lesion site do not express Gli1. Moreover, single cell analysis of Gli1-expressing astrocytes at the lesion shows that the majority of Gli1 cells do not undergo proliferation at 3 and 7 days post injury. Consistent with this, glial scar formation is unimpaired in GFAP Smo CKO animals. These data suggest that injury-induced proliferation of Gli1-negative cells is regulated through interactions with Gli1-expressing astrocytes.

Title: Astrocytes regulate glucagon-like peptide-1 receptor-mediated effects on energy balance

Authors: *D. REINER[1], E. G. MIETLICKI-BAASE[1], L. E. MCGRATH[1], D. J. ZIMMER[1], K. K. BENCE[1], G. L. SOUSA[1], V. R. KONANUR[2], J. KRAWCZYK[1], D. H. BURK[3], S. E. KANOSKI[2], G. E. HERMANN[3], R. C. ROGERS[3], M. R. HAYES[1];

Abstract: The anorectic effects of glucagon-like peptide-1 receptor (GLP-1R) agonists are partly due to direct GLP-1R signaling in the central nervous system (CNS). A small body of literature suggests that GLP-1Rs are expressed on CNS astrocytes. As astrocytes play a critical role in modulating extracellular glutamate, and the hypophagic effects of GLP-1R activation are

partially mediated via glutamatergic signaling, GLP-1R agonists may act directly on astrocytes in feeding-relevant nuclei to regulate energy balance. We hypothesized that GLP-1R ligands act on astrocytes within the nucleus tractus solitarius (NTS), a hindbrain nucleus critical for energy balance control, to affect feeding and body weight in rats. Given the lack of a commercially available GLP-1R-specific antibody, we availed of a novel use of a fluorescently-tagged version of the GLP-1R agonist, exendin-4 (Ex4). Central or peripheral administration of fluorophore-labeled Ex4 localizes within astrocytes and neurons in the NTS, providing evidence of GLP-1R expression in both cell types. Live cell calcium imaging of hindbrain slices showed prolonged Ex4 activation in ~40% of both NTS-astrocytes and neurons. Application of GLP-1R agonists increases cAMP in immortalized astrocytes. These data indicate that astrocytes respond to GLP-1R activation through recruitment of appropriate intracellular signaling cascades. To determine whether endogenous GLP-1 could potentially activate NTS astrocytes, we performed immunohistochemical analyses and show that endogenous NTS-derived GLP-1 axons form close synaptic apposition with NTS astrocytes. Further, inhibition of NTS astrocytes with the astrocyte inhibitor fluorocitrate significantly attenuates the 24h anorectic and body weight-suppressive effects of intra-NTS Ex4, suggesting that NTS astrocytes mediate the energy balance effects of GLP-1R signaling. Preliminary data suggests a down-regulation in gene expression for the astrocytic glutamate transporter 1 (GLT-1) and the glutamate aspartate transporter (GLAST) within the NTS after acute central administration of Ex4, providing a potential cellular mechanism for increased glutamatergic signaling after GLP-1R activation. Collectively, these data demonstrate a role for NTS astrocytic GLP-1R signaling in energy balance control.

Title: The effect of whisker plucking on the astrocyte-blood vessel interaction in the barrel cortex of neonate and juvenile mice

Authors: *A. MIGIROV, P. SINGH, I. REYES, A. CHAWLA, X. CHEN, L. SHI, A. RODRIGUEZ-CONTRERAS;
Neural Develop., City Col. Ctr. For Discovery and Innovation, New York, NY

Abstract: Astrocytes interact with arteries and microcapillaries through end feet connections that are thought to be involved in neurovascular coupling and the maintenance of the blood brain barrier. Recent studies indicate that manipulations of sensory input affect the development of the vascular network (Lacoste et al., 2014; Whitheus et al., 2014). We hypothesize that depriving sensory input will result in a decreased interaction between astrocytes and blood vessels. To test this hypothesis, we examined the mouse barrel cortex, a model system for studying sensory-dependent plasticity during postnatal development. We used a unilateral whisker-plucking paradigm to reduce activity in the barrel cortex of juvenile mice expressing Cre recombinase driven by the GFAP promoter. The left set of whiskers were plucked daily from postnatal day 15 (P15) until P21, and the right set of whiskers were left intact and used as the control (n=3 mice). At P21, the mice were perfused with fixative solution and their brains were processed with multiple fluorescence labeling using IB4 histochemistry to label blood vessels and anti-GFAP or anti-ALdh1L1 immunohistochemistry to label astrocytes (2-4 slices per mouse). We used confocal imaging and 3D segmentation analysis to visualize and measure vessel and astrocyte labeling volume, and astrocyte-vessel interactions in cortical layer 4 of the barrel cortex. Our preliminary results show that IB4 volume in controls (mean ± sem, in μm^3) was 12526 ± 324 in double-labeled ALdh1L1/IB4 slices and 8532 ± 942 in double-labeled GFAP/IB4 slices. IB4 volume in the whisker pluck condition (mean ± sem, in μm^3) was 12157 ± 344 in double-labeled ALdh1L1/IB4 slices and 8115 ± 990 in double-labeled GFAP/IB4 slices. This is an approximate 3-5% decrease in blood vessel volume in whisker pluck compared to control. However, we did not find apparent changes in astrocyte marker volume. Our next step is to determine if whisker plucking affects astrocyte-vessel interactions during the critical period of vascular development. In current experiments, we are using the same unilateral whisker plucking paradigm, with the difference of whisker-plucking taking place within P0 - P5, the critical period for sensory development and vascular growth in the mouse barrel cortex.

Title: Recombinant adeno-associated virus serotype 6 (AAV6) preferentially transduces astrocytes in the rat brain cortex

Authors: *A. L. SCHOBER[1], D. A. GAGARKIN[1], Y. CHEN[2], L. JACOBSON[1], A. A. MONGIN[1];
[1]Dept. of Neurosci. and Exptl. Therapeut., Albany Med. Col., Albany, NY; [2]ViGene Biosci., Rockville, MD

Abstract: Recombinant AAV vectors are an increasingly popular tool for gene delivery to the CNS, because of their non-pathological nature, low immunogenicity, and ability to stably transduce dividing and non-dividing cells. One of the limitations of AAV vectors is that the majority of them have preferential tropism for neuronal cells. Glial cells, specifically astrocytes, appear to be infected at low rates. Although a number of studies utilized AAV vectors with astrocyte-specific promoters or certain AAV serotypes and pseudotypes with purported selectivity for astrocytes (such as AAVrh43 and AAV2/5), glial infection rates were not consistently high. In the present work, we tested seven common commercially available recombinant AAV serotypes - AAV1, 2, and 5 through 9, all of which expressed GFP under the CMV promoter, for their ability to transduce rodent astrocytes. In primary rat astrocyte cultures, we found that only AAV6 consistently had the highest infection rates. Among the remaining serotypes, AAV2 showed substantial infection rates in some, but not all, of the tested viral batches. As a control, all AAV constructs were re-evaluated in retinal pigmented epithelial cells, which have a high affinity for various AAV serotypes. Based on in the *in vitro* efficacy, we tested cell specificity of AAV6 and AAV2 *in vivo*, which were both injected in the barrel cortex at approximately equal dosages. Three weeks later, brains were sectioned and immunostained for viral GFP and the neuronal marker NeuN or the astrocytic marker GFAP. We found that AAV6 consistently and preferentially transduced astrocytes (95% of cells in the virus-infected areas), but not neurons (13% infection rate). On the contrary, AAV2 infected preferentially neurons (64%), but not astrocytes (20%). Overall, our results suggest that AAV6 can be used as a tool for manipulating gene expression (either delivery or knockdown) in rodent astrocytes *in vivo*. Commercially available AAV6 constructs, packaged on a large scale using standardized techniques, will likely make this approach reproducible across many laboratories.

Title: New tools for studying microglia in the mouse and human CNS

Authors: ***M. L. BENNETT**[1], F. C. BENNETT[2], B. A. BARRES[2];
[1]Neurobio., Stanford Univ. Sch. of Med., Stanford, CA; [2]Stanford Univ., Palo Alto, CA

Abstract: The specific function of microglia, the tissue resident macrophages of the brain and spinal cord, has been difficult to ascertain because of a lack of tools to distinguish microglia from other immune cells, thereby limiting specific immunostaining, purification, and manipulation. Because of their unique developmental origins and predicted functions, the distinction of microglia from other myeloid cells is critically important for understanding brain development and disease; better tools would greatly facilitate studies of microglia function in the developing, adult, and injured CNS. Here, we identify transmembrane protein 119 (Tmem119), a cell-surface protein of unknown function, as a highly expressed microglia-specific marker in both mouse and human. We developed monoclonal antibodies to its intracellular and extracellular domains that enable the immunostaining of microglia in histological sections in healthy and diseased brains, as well as isolation of pure nonactivated microglia by FACS. Using our antibodies, we provide, to our knowledge, the first RNAseq profiles of highly pure mouse microglia during development and after an immune challenge. We used these to demonstrate that

mouse microglia mature by the second postnatal week and to predict novel microglial functions. Together, we anticipate these resources will be valuable for the future study and understanding of microglia in health and disease.

Title: Regulation of microglial biology by the chemokine receptor CX3CR1 and brain microenvironment: a RNASeq-based transcriptome analysis using low RNA inputs

Authors: ***S. GYONEVA**[1], R. HOSUR[2], B. COTLEUR[1], K. MIAO[1], N. ALLAIRE[2], C. ROBERTS[2], R. M. RANSOHOFF[1];
[1]Neuro/Immuno Discovery Biol., [2]Computat. Biol. and Genomics, Biogen, Cambridge, MA

Abstract: Microglia, the brain's resident tissue macrophages, are intimately involved in brain development and proper function into adulthood. Recent evidence suggests that microglial gene expression and functions are shaped by their location across different brain regions. One of the main genetic regulators of microglia is the chemokine receptor CX3CR1. However, the molecular mechanisms underlying CX3CR1 function in microglia are not well understood. Here, we wanted to characterize the role of CX3CR1 on microglial function at the molecular level by examining how deletion of the receptor affects gene expression and thereby cell function. We also examined if *Cx3cr1* deletion affects microglia differentially in the different microenvironment of gray matter, white matter and cerebellum. We isolated microglia from 2 month old $Cx3cr1^{+/+}$, $Cx3cr1^{GFP/+}$ and $CX3CR1^{GFP/GFP}$ mice (GFP disrupting one or both copies of Cx3cr1) using fluorescence-activated cell sorting, which was immediately followed by RNA isolation. For some experiments, the white matter and cerebellum were microdissected from the remaining gray matter from thick brain sections. For transcriptome analysis, we constructed RNASeq libraries using low-input protocols (SMART-Seq v4 technology) with either 1 or 10 ng of total RNA. *Cx3cr1* deletion resulted in the downregulation of many genes involved in immunity response to pathogens, and chemotaxis. The genes upregulated by *Cx3cr1* deletion are generally associated with chromatin binding and transcription. In contrast to *Cx3cr1* genotype, the brain microenvironment had only a modest effect on global gene expression. Our results raise questions about how *Cx3cr1*-knockout microglia may respond to inflammatory challenges and in neurological conditions with inflammatory component.

Title: A paradigm shift in microglial expression profiles in human brain.

Authors: *D. F. MASTROENI;
Biodesign Neurodegenerative Res. Inst., Arizona State Univ., Tempe, AZ

Abstract: Introduction: Conventional wisdom holds that brain microglia are similar regardless of brain region. Array expression data from many labs, including our own show large changes in expression of many glial-specific genes in Alzheimer's disease (AD) compared to normal controls (NC). The problem is however; homogenates are often used to obtain these data which introduces un-wanted complication because of the number of cell types analyzed. Although selected glial-specific changes are distinguishable, there are thousands of genes that are not cell class-specific but play major roles in cell function.**Methods:** In order to investigate disease and regional effects on gene expression we isolated microglial cells by laser captured micro-dissection from CA1 of hippocampus and substantia nigra (SN) of AD, NC and Parkinson's disease (PD) cases, followed by RNA sequencing.**Results:** Laser captured cells allowed more precise definition of relationships between microglia and their expression profiles based on disease and location. In AD CA1 366 significant ($p<.01$) differentially expressed transcripts were observed and 409 in PD CA1. Of those genes which were differentially expressed, less than 5% overlap was observed between AD and PD; implying that different neurodegenerative diseases affect microglia differently in the same brain region. Expanding the analysis to brain regions (e.g. CA1 vs SN) we show over two-thousand differentially expressed genes. These data show that the expression profile within microglial sub-populations are the equally significant among brain regions.**Discussion:** It has been known for more than a decade that microglia have the

ability to release neurotoxic inflammatory factors. These pro-inflammatory factors or cytokines, have prompted hundreds of studies and clinical trials to suppress their function, but none have been successful to date. Although there are several explanations listed in the literature on why these clinical studies failed to recapitulate *in vitro* findings, we hypothesize that these studies failed due to the inability to address probable heterogeneity among glial cells as a function of brain region. These findings lay the foundation for future development of therapeutic targets, aid in the pursuit of new research leads, and answer fundamental biological questions regarding the interplay between glial types and their function based on location, and disease.

Hamburg-Eppendorf, Hamburg, Germany

Abstract: Microglia, the brain's resident immune cells, have many functions ranging from control of inflammation in brain disease to monitoring synaptic activity. It has been suggested that the adult microglial population is long-lived and maintained by self-renewal; however the precise mechanisms regulating the temporal and spatial control of this population are unknown. To define the mechanisms we studied the density of the microglial population in the healthy postnatal (P0-P21), adult (4-6 months) and ageing (18-24 months) brain. Complementary techniques were used, including intra-liver labelling of embryonic haematopoiesis to analyse the contribution of infiltrating monocytes to the brain during the perinatal period, pulse-chase

experiments to define the time course of microglial proliferation, long-term *in vivo* imaging of microglia and cell-specific apoptosis-deficient mouse models in order to further analyse proliferation and apoptosis. We found circulating monocytes infiltrate the brain during perinatal stages however these do not contribute to the adult microglial population, which is composed exclusively from yolk sac-derived cells. Our data indicates that the adult cell population displays a far more rapid proliferation rate than previously indicated, accounting for at least 6 renewals of the entire population during the lifetime of the mouse. Activation of the colony-stimulating factor-1 receptor (CSF1R) is largely responsible for controlling microglial turnover under homeostatic conditions. We demonstrate that the number of microglia remains relatively constant from early postnatal stages to aged adulthood due to a balance of proliferation and apoptosis of resident cells. These processes are temporally and spatially coupled, evidenced by synchronicity between proliferative events and cell death observed during long-term *in vivo* imaging. The microglial population undergoes a constant and rapid remodelling, with cell density maintained by a subtle balance of proliferation and apoptosis. This challenges the established view of microglia as long-lived cells to a more dynamic scenario, opening new avenues into the understanding of their roles in the maintenance of brain homeostasis.

Title: Microglia responses to chronic sleep restriction in the rat brain

Authors: *S. HALL[1], S. DEURVEILHER[1], K. SEMBA[1,2,3];
[1]Med. Neurosci., [2]Psychology & Neurosci., [3]Psychiatry, Dalhousie Univ., Halifax, NS, Canada

Abstract: Chronic sleep restriction (CSR) has significant consequences on health and cognition, but underlying mechanisms are unclear. CSR is known to elevate brain levels of inflammatory molecules, and microglia, the resident immune cells of the brain, may be involved in this

neuroinflammatory process. In the current study, we examined microglial responses to CSR using immunohistochemistry for several microglial markers. Rats were sleep restricted using motorized activity wheels to impose cycles of 3 h of sleep deprivation and 1 h of sleep opportunity ('3/1' protocol). We previously showed that this protocol over 4 days induced homeostatic and adaptive changes in sleep measures, sustained attention task performance, and brain-derived neurotrophic factor levels. Adult male Wistar rats were assigned to 8 groups (n = 4-9/group): 4 sleep restricted groups underwent the 3/1 protocol for 3 h, 27 h, 99 h, or 99 h followed by 6 days of recovery, and 4 time-matched locked wheel control groups were kept in stationary wheels. Immediately following respective protocols, rats were perfused for immunohistochemistry using antibodies to microglial markers, including ionized calcium binding adaptor molecule-1 (Iba1), with a standard ABC/DAB-Ni method or fluorescent labels. Significant effects of CSR were seen in 4 of 10 limbic and sleep/wake regions examined. Compared to control levels, both the number of Iba1+ cells and the density of Iba1 immunoreactivity were increased in the prelimbic cortex (PrL) after 27 h and 99 h of CSR, and in the perifornical lateral hypothalamic area, central amygdala (CeA), and dorsal raphe nucleus after 99 h of CSR. After 6 days of recovery following 99 h of CSR, the number of Iba1+ cells was at the control levels in all 4 regions, while the density of Iba1 immunoreactivity remained elevated in all 4 regions except the CeA. Sholl analyses of the morphology of Iba1+ microglia in the PrL revealed greater ramification in layer I than in layer II/III, but no significant effect of CSR. The immune phenotype of microglia was assessed in animals that underwent 99 h of the 3/1 protocol (n=2) and a time matched control group (n=2) using antibodies to OX-6, CD68 (both pro-inflammatory) and arginase 1 (anti-inflammatory). Preliminary analyses showed no significant effect of CSR on the expression of these markers in any of the brain regions studied. These results suggest that microglia respond to the 3/1 CSR protocol and these microglial responses might contribute to the cognitive and health impairments associated with CSR. We are currently investigating whether the region-specific increases in the number of Iba1+ microglia are due to cell proliferation or other mechanisms.

Title: Changes in microglia extracellular matrix contribute to age-associated decline in CNS remyelination

Authors: *R. BAROR, R. J. M. FRANKLIN;
Wellcome Trust - MRC Cambridge Stem Cell Institute, Dept. of Clin. Neuro, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Microglia are the immune cells that reside within the central nervous system (CNS) and play important roles in both the healthy and diseased brain. In normal conditions microglia survey their environment in search for new threats, as well as play a role in maintaining synapses homeostasis. During pathological conditions such as demyelination (loss of myelin sheaths) microglia become activated and have an important role in clearing debris, thus contributing to a pro-regenerative environment which can promote remyelination (regeneration of myelin sheaths by newly formed oligodendrocytes). Microglia undergo changes with ageing which render them less effective, specifically in the context of regeneration. In the current study, we have isolated young and aged rat microglia and have discovered that aged microglia increase the production of various proteoglycans. Specifically, we have found that aged microglia increase the expression of NG2 and fibronectin, which are known to inhibit remyelination in the CNS. Our *in vitro* studies show that plating oligodendrocytes progenitor cells (OPC) on de-cellularised aged microglia result in a decrease in the number of cells expressing MBP, a marker of mature oligodendrocytes (OL), suggesting an inhibition of OPC differentiation. Moreover, we have found that these OPC have assumed a different cell fate and mainly differentiated into GFAP+ astrocytes. TGFb levels increase in aged rats serum, and since microglia highly express TGFb receptor, we assessed whether this cytokine can be a potential mechanism for the changes observed in aged microglia. Using qRT-PCR and immunohistochemistry, we have shown that TGFb treated neonatal microglia enhances their expression of NG2 and fibronectin. Furthermore, plating OPC on TGFb-treated neonatal microglia, inhibits their differentiation supporting previously seen effects of aged microglia. In summary, we show that ageing microglia acquire an extracellular phenotype which is inhibitory for OPC differentiation and that potentially contributes to the age-associated decline in remyelination efficiency.

Title: Beyond sex differences: microglial expression of CD36 depends upon estrous stage

Authors: *Y. Y. GRINBERG, C. R. JONAK, R. DILL, D. COSS, M. J. CARSON;
Univ. of California Riverside, Riverside, CA

Abstract: The hippocampus and caudate putamen are two brain structures that are differentially engaged across the estrous cycle of female rodents. Microglia, the brain resident immune cells, are highly plastic cells that influence and respond to physiological changes in neuronal activity. Here we asked whether microglia change in their surveillance and activation state across the estrous cycle. To answer this, we used flow cytometric analysis as a sensitive means to measure cell surface expression of proteins that are markers of microglial activation, in young adult male and female mice. When looking at CD11b, CD45, and Fc receptor (FcR), we found that microglia were largely similar in these healthy unmanipulated animals. However, we did observe modest but significant regional differences in microglial expression of all three molecules, with CD11b and FcR expressed higher in the caudate putamen and CD45 more highly expressed in hippocampus. Further, we observed modest sexually dimorphic expression of CD45 and CD11b, with both higher in females. CD36 is a scavenger receptor that binds to a variety of endogenous and pathogenic ligands. We observed significantly more CD36-positive microglia in the caudate putamen than in hippocampus in both sexes. However, when females were divided into stages of the estrous cycle, this regional heterogeneity in microglial expression of CD36 was lost in the diestrus stage. Thus, CD36 expression was sexually dimorphic in the diestrus stage of the estrous cycle. A cycling of CD36 signaling capacity in the female hippocampus may result in a changing microglial capacity for phagocytosis and initiation of sterile inflammation -processes which can be either neuroprotective or neurotoxic, depending on context.

Title: RNA-seq characterization of mouse and human primary microglia

Authors: *Y. HE[1], X. YAO[2], N. TAYLOR[1], T. LOVENBERG[1], A. BHATTACHARYA[1];
[1]Neurosci., [2]Drug Discovery, Janssen Res. & Develop. LLC., San Diego, CA

Abstract: Microglia, the principal immune cells of the brain, play key roles in neuro-glia interaction, neuroinflammation, neural repair, and neurotoxicity. As such, brain microglia have been an intense area of research, both in academia and industry. To understand the role of these cells (morphology, transcriptome, proteome, secretome) in physiology, and perhaps more importantly in the context of a CNS disease, it is critical to establish microglial cell cultures, both from rodents and humans, that represents physiology in a dish. Currently, there are various protocols for primary mouse microglial isolation, including shaking, mild-trypsin digestion, and CD11b magnetic-associated cell sorting (MACS) without head to head comparison of genomic signatures. In this study, we compared the three isolation methods by using postnatal (P0-P3) mouse brains and applied RNA-sequencing technology to determine transcriptomes of isolated murine microglia. Using bioinformatics platform, we compared the transcriptome from the murine microglia to publicly available data from microglia challenged with LPS and Abeta, to provide insight into the degree of spontaneous activation as a result of differences in isolation methodologies. The data demonstrated that microglia isolated by CD11b MACS exhibited the lowest expression level of the 'activation genes', while the other two methods showed higher levels, thereby implying a resting baseline in mouse microglia from CD11b MACS isolation, which can be potentially used for accurate analysis and comparison of gene expression and function in disease models and testing of compounds. To explore whether these findings could be translated to human microglia, we also performed RNA-sequencing to characterize commercially available human microglia. Surprisingly, a human microglia cell line (SV40) (Applied Biological Materials Inc; catalog # T0251) did not show abundant expression of key microglial markers as seen in human primary microglia from ScienCell (catalog #1900) or Clonexpress (catalog # HMG030). In conclusion, we RNA-sequenced the three human microglia cell types, and compared human and murine transcriptomics.

Title: Simplified procedure for producing large yields of functional microglial cells in culture: application for studying neuroinflammatory responses

Authors: *J. E. SEPULVEDA DIAZ[1], M. O. OUIDJA[2], S. B. SOCIAS[3], S. HAMADAT[1], S. GUERREIRO[1], R. RAISMAN-VOZARI[1], P. P. MICHEL[1];

Abstract: Purified microglial cells in culture are frequently used to model brain inflammatory responses but obtaining large yields of these cells on a routine basis can be quite challenging. Here, we demonstrate that it is possible to achieve high-yield isolation of pure microglial cells from post-natal brain tissue through a simple culture procedure that mainly relies on the adhesion preference of these cells to the polycation polyethyleneimine (PEI) in serum-supplemented DMEM medium. The effects of PEI were not reproduced with other synthetic or biological substrates and they were context-dependent as replacement of DMEM by DMEM/F12 nutrient mixture did not permit microglial cell isolation onto PEI coating. Noticeably, the absence of culture medium renewal during the progression of microglial cell isolation strongly improved cell yield, suggesting that nutritional deprivation was required to make this process as efficient as possible. PEI-isolated microglial cells expressed the macrophage antigen-1 (MAC-1) receptor and also the Fc receptor-like S (Fcrls), a biomarker that specifically distinguishes these cells from other myeloid subsets. When generated in large culture flasks coated with PEI, cultures of microglial cells were easily recovered by trypsin proteolysis to produce subcultures for functional studies. These cultures responded to lipopolysaccharide (LPS, 1-10 ng/mL) treatment by secreting proinflammatory cytokines such as TNF-alpha, IL-6, IL-1beta and by generating nitric oxide and reactive oxygen species. Most interestingly, this response was curtailed by appropriate reference drugs. Microglial cells were also strongly responsive to the mitogenic cytokine GM-CSF, which confirms that the functional repertoire of these cells was well preserved. Because of its high yield and simplicity, we believe that the present method will prove to be especially convenient for mechanistic studies or screening assays.

Title: TSPO ligand regulates activation state of cultured glia

Authors: *M. F. UCHOA, S.-J. KIM, P. COHEN, C. J. PIKE;
Gerontology, USC, Los Angeles, CA

Abstract: Neuroinflammation contributes to the pathogenesis of many neurodegenerative diseases, including Alzheimer's disease. One potential strategy to reduce neuroinflammation is activating translocator protein (TSPO). TSPO is an 18kDa protein located mainly in the outer membrane of the mitochondria. In the central nervous system, it is localized mostly in glial cells. TSPO expression is significantly increased in glial cells during chronic neuroinflammation. In fact, TSPO ligands are increasingly utilized as neuroimaging agents for inflammation detection. Interestingly, administration of TSPO ligands to animals decreases inflammatory response, which reveals a potential usage of TSPO ligands as anti-inflammatory therapy. How TSPO activation regulates the various aspects of glial activation is unclear. Based on prior work with immortalized cell line and primary microglia cultures, TSPO ligands have been hypothesized to modulate microglial activity both by reducing pro-inflammatory cytokine production and promoting phagocytic activity. How these actions may be affected by interactions with astrocytes has not been evaluated. To begin addressing this issue, we investigated the effects of TSPO ligands on microglia activation in the presence of astrocytes. Primary mixed glial cultures generated from neonatal rats were treated with vehicle or the classic TSPO ligand Ro5-4864 in the presence or absence of lipopolysaccharide (LPS), a bacterial wall endotoxin that is widely used as an inducer of microglial activation. Cultures were assessed for four established indices of activation: (i) expression of inflammatory cytokines, (ii) morphological evidence of activation, (iii) phagocytosis, and (iv) proliferation. Overall, we observed that LPS significantly increased measures of microglial activation, effects that generally were reduced by Ro5-4864 in a dose-dependent manner. Interestingly, although TSPO ligands have been reported to increase phagocytosis in isolated microglial cells and immortalized cell lines, we observed that Ro5-4864 decreased phagocytosis in microglia cultured in the presence of astrocytes. Collectively, these data indicate that activation of TSPO largely results in decreased activation of microglia in a model that better mimics the brain environment. These findings support the continued evaluation of TSPO ligands as an intervention against microglial-mediated neuroinflammation, a key component of pathogenesis in Alzheimer's disease and numerous other disorders.

Title: Microglial activation: a tale of two rodent species

Authors: *D. LAM[1,2], S. LIVELY[1], L. C. SCHLICHTER[1,2];
[1]Genet. and Develop., Krembil Res. Inst., Toronto, ON, Canada; [2]Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Microglia, the resident immune cells of the CNS, help maintain homeostasis in the healthy brain, but also respond rapidly to perturbations. After an insult, cells release Damage-Associated Molecular Pattern (DAMP) molecules and soluble mediators (e.g., cytokines, free radicals). The resulting microglial activation evokes a complex reactive phenotype that depends on the severity of damage and can evolve over time. The therapeutic goal should be to maximize the beneficial roles of microglia, while dampening their harmful effects, but not nearly enough is known about the spectrum of microglial activation. *In vitro* studies have largely used a simplified classification scheme based on macrophage responses, with two extremes being a pro-inflammatory or 'classical' (M1) phenotype, which is thought to exacerbate tissue damage, and multiple anti-inflammatory (M2) phenotypes. The best characterized M2 states are 'alternative activation' (M2a) and 'acquired deactivation' (M2c), which are thought to mediate tissue repair and inflammation resolution, respectively. While *in vivo* rodent models are being hotly pursued in an effort to translate potential therapies, we do not know whether rats and mice show the same microglial activation responses. The objective of this comparative study of rodent microglia is to quantify molecular responses and several functional consequences of M1 and M2 stimulation, and address the potential to target two K^+ channels to control their activation. Primary microglia from Sprague Dawley rats and C57BL/6 mice were treated with interferon-γ + tumor necrosis factor-α (I+T) to induce a pro-inflammatory state, or with interleukin (IL)-4 or IL-10 to promote two anti-inflammatory states. After 24 hr, we assessed cell morphology, the expression profile of numerous pro- and anti-inflammatory mediators, expression and activity of two K^+ channels (Kir2.1, Kv1.3), and whether these channels regulate migration, proliferation, and nitric oxide (NO) production under the different activation paradigms. Some responses were similar for rat and mouse microglia; e.g., I+T induced NO production and reduced their migration, while IL-4 and IL-10 increased their migration. However, several responses differed; i.e., morphological changes, inflammatory expression profiles, K^+ channel expression and currents. We conclude that the rodent species can affect the outcome of microglial activation and should be further compared in pre-clinical *in vivo* studies.

Title: Complex molecular and functional outcomes of single versus sequential cytokine stimulation of rat microglia

Authors: T. A. SIDDIQUI, *L. C. SCHLICHTER, S. LIVELY;
Krembil Res. Inst., Toronto, ON, Canada

Abstract: Background. Microglia are the 'professional' phagocytes of the CNS. Phagocytosis is crucial for normal CNS development and maintenance, but can be either beneficial or detrimental after injury or disease. For instance, white matter damage releases myelin debris that must be cleared by microglia in order for re-myelination to occur but phagocytosis can produce damaging reactive oxygen species. Microglia can acquire pro-inflammatory (M1) or anti-inflammatory (M2) activation states but little is known about the consequences for myelin phagocytosis or the effects of a changing cytokine environment that can occur after injury or disease. **Objective.** The objective was to apply several microglial activation paradigms, with or without myelin debris, and assess: (i) gene expression changes reflecting microglial activation and inflammatory states, and receptors and enzymes related to phagocytosis and ROS production; (ii) myelin phagocytosis and production of reactive oxygen species (ROS); and (iii) expression and contributions of several ion channels that are considered potential targets for regulating microglial behavior. **Methods.** Primary rat microglia were exposed to cytokines, individually or sequentially. First, responses to individual M1 or M2 stimuli were compared: IFN-γ plus TNF-α ('I+T'; M1 activation), interleukin-4 (IL-4; M2a/alternative activation), interleukin-10 (M2c/acquired deactivation). Second, sequential cytokine addition was used to assess microglia repolarization and cell functions. The paradigms were: M2a→M1, M2c→M1, M1→M2a, and M1→M2c. **Results.** M1 stimulation increased pro-inflammatory genes, phagocytosis, ROS, as well as expression of Kv1.3, KCa3.1 and Kir2.1 channels. M2a stimulation increased anti-inflammatory genes, ROS production, and Kv1.3 and KCa3.1 expression. Myelin phagocytosis enhanced the M1 profile and dampened the M2a profile, and both phagocytosis and ROS production were dependent on NOX enzymes, Kir2.1 and CRAC channels. Importantly, microglia showed some capacity for re-polarization between M1 and M2a

states, based on gene expression changes, myelin phagocytosis, and ROS production.
Conclusions. In response to polarizing and re-polarizing cytokine treatments, microglial display complex changes in gene transcription profiles, phagocytic capacity, NOX-mediated ROS production, and in ion channels involved in microglial activation. Because these changes might affect microglial-mediated CNS inflammation, they should be considered in future experimental, pre-clinical studies.

Title: Interferon regulatory factor 8 is a major intrinsic determinant of the microglial cell response to sterile nerve injury

Authors: *I. L. CAMPBELL[1], R. D. XIE[2], N. VILLACAMPA[3], B. ALMOLDA[3], B. GONZALEZ[3], B. CASTELLANO[3];
[1]Sch. of Mol. Biosci., [2]Univ. of Sydney, Sydney, Australia; [3]Histology Unit. Fac. of Med., Autonomous Univ. of Barcelona, Barcelona, Spain

Abstract: Interferon regulatory factor (IRF) 8 is an important transcriptional regulator present in many hematopoietic cells including microglia, the resident immune cells of the central nervous system (CNS). We have shown previously(1) that in the normal CNS the properties of microglia are dramatically altered in the absence of IRF8. Here we addressed the question as to whether IRF8 regulates the microglial cell response to sterile nerve injury. Facial nerve axotomy (FNA) was performed in wild type (WT) and IRF8$^{-/-}$ (KO) mice and the brain removed at different days post-injury (dpi). In brains from control IRF8 KO mice, lectin and nucleoside diphosphatase (NDPase) histochemistry revealed gross alterations in the morphology of microglia, which were stunted and hypertrophied but were present in comparable numbers with WT. Following FNA in WT mice, a progressive increase in microglial cell activation was observed peaking at 7 dpi and was accompanied by dense staining for lectin, NDPase and CD11b. By contrast, in IRF8 KO mice, the microglial cell response to FNA was grossly attenuated with the density of staining for lectin, NDPase and CD11b reduced significantly. This diminished microglial cell activation in IRF8 KO mice was paralleled by a significant decrease in microglial cell proliferation at 7 and

14 dpi. The wrapping of individual motor neuron cell bodies in the axotomised facial nucleus by microglia involved in synaptic stripping and phagocytosis was incomplete in IRF8 KO mice and was accompanied by an increase in degenerated neurons at 21 dpi. These findings show that in addition to maintenance of homeostatic properties, IRF8 also has an important role in regulating a number of key processes in the microglial cell response to neuronal injury. Title: Investigating the role of microglia in the spinal cord plasticity observed following peripheral axon injury

Authors: *J. MALONEY, L. G. ISAACSON;
Ctr. for Neurosci. and Behavior, Dept. of Biol., Miami Univ., Oxford, OH

Abstract: Our lab has previously reported that transection of distal axons in the cervical sympathetic trunk (CST) leads to robust retrograde neuronal and glial plasticity in the upper thoracic spinal cord. At one week following injury we observed a marked transient plasticity in the discrete population of parent sympathetic preganglionic neurons housed in the intermediolateral cell column (IML). This plasticity included a decrease in cell body volume, decreased expression of choline acetyltransferase (ChAT), and exclusive expression of activating transcription factor 3 (ATF3) by injured neurons. In addition to neuronal plasticity in the IML, an increase in the number of activated microglia, characterized by aggregation, amoeboid morphology and retraction of cell processes along with increased expression of the pro-inflammatory cytokine interleukin 1β (IL-1β) were observed following peripheral axon injury. Because pro-inflammatory cytokines secreted by activated microglia have been shown to signal to surrounding cells, we hypothesized that microglial activation following injury contributes to

the observed neuronal plasticity. The objective of the present study was to assess the effects of minocycline, a tetracycline-class antibiotic, on microglia activation in the upper thoracic spinal cord following CST transection for use as a model to determine whether activated microglia influence neuronal plasticity. Starting on the day of injury, rats received daily intraperitoneal injections of minocycline (50mg/kg for two days, 25mg/kg for five days; n=6) or vehicle (VEH; saline; 2ml/kg; n=6) for one week. At one week following injury, we found no reduction in the number of microglia cells expressing ionized calcium-binding adapter molecule 1 (Iba1) in the IML. However, the microglia exhibited fewer obvious morphological signs of activation. A blinded quantitative analysis of microglial activation based on cellular morphology revealed that microglia activation in minocycline-treated animals was significantly reduced by 58%. In addition the increased expression of IL-1β typically observed at one week following injury was significantly reduced by 37% in minocycline-treated animals. We conclude that minocycline administration reduces both the extent of microglia activation and the expression of pro-inflammatory cytokines in the vicinity of the injured preganglionic cell bodies in the IML following peripheral axon injury. These results lay the groundwork for future studies examining the role of microglia in the neuronal plasticity observed following injury.

Title: Microglia and monocytes synergistically promote the transition from acute to chronic pain after peripheral nerve injury

Authors: *J. PENG[1,2], N. GU[1], L. ZHOU[1], U. B. EYO[1], M. MURUGAN[1], W.-B. GAN[2], L.-J. WU[1];

Abstract: After peripheral nerve injury, spinal microglia and peripheral monocytes participate in neuropathic pain hypersensitivities. However, the respective function of microglia and peripheral monocytes has not been investigated. Here, using $CX_3CR1^{CreER/+}$:$R26^{iDTR/+}$ mice, in which we can specifically and temporally control the depletion of microglia/monocytes, we examined the role of microglia/monocytes in the initiation and maintenance of neuropathic pain in a mouse model of spinal nerve transection (SNT). Tamoxifen (TM, 150 mg/kg, i.p., 4 injections with 48 hr intervals) was used to induce Diphtheria Toxin (DT) receptor expression in Cx_3CR1^+ cells. In 3 days after the last TM injection, DT (i.p. 50 μg/kg, 2 injections with 48 hr interval) treatment can reliably ablate both central microglia and peripheral CX_3CR1^+ monocytes. We found that, with DT treated 24 hr before and 24 hr after SNT surgery, the neuropathic pain development was fully blocked; with DT treated at Post Operation Day (POD) 3 and POD5, when the neuropathic pain has initiated, the pain hypersensitivities were partially reversed to till at least testing period of 14 days; however, with DT treated at POD7 and POD9, the pain hypersensitivities was only transiently reversed. Therefore, we pinpointed a critical time window that requires microglia/monocytes during the initiation of neuropathic pain. The peripheral blood monocytes have substantially rapid turnover and are replenished frequently. The new generated $CX3CR1^+$ monocytes will not express DT receptor without TM treatment since the progenitor cells do not express CX_3CR1. Therefore, we can ablate the central microglia with DT but leave the peripheral blood monocytes intact at 3 weeks after the TM injection. With this method, we found that the ablation of central microglia can only delay but not prevent the development of SNT-induced neuropathic pain. We then used liposome-encapsulated clodronate to deplete peripheral monocytes, which itself did not affect the neuropathic pain development. However, the combination of clodronate with central microglia ablation was able to completely reverse SNT-induced neuropathic pain hypersensitivities. The results demonstrated that both resident microglia and peripheral monocytes are critical in gating neuropathic pain after SNT. We propose that resident microglia and peripheral monocytes synergistically initiate pain hypersensitivities and promote the transition from acute to chronic pain after peripheral nerve injury.

Title: The role of P2X7 in neuroinflammation: effect on mouse primary microglia and astrocytes

Authors: *N. M. TAYLOR, Y. HE, A. BHATTACHARYA;
Janssen, San Diego, CA

Abstract: P2X7, an ATP-gated cation channel, plays important roles in various inflammatory, immune, and neurologic disorders. Brain P2X7 is thought to be an important mediator of neuroinflammation: to that end, it is well established that activation of P2X7 causes release pro-inflammatory cytokines, IL-1β and IL-18. In this study we addressed the role of P2X7 in modulation of gliotransmitters outside the IL-1/IL-18 family. First, our RNA-seq data showed that P2X7 gene is expressed in glial cells (microglia and astrocytes) in both mouse and human brains. Other than IL-1α and IL-1β, A-804598 (1 μM), a P2X7 antagonist had no significant effect on the panel of gliotransmitters when murine microglia was challenged with LPS and Bz-ATP. To extend the pharmacology, we tested microglia and astrocytes harvested from either P2X7 knockout (Pfizer KO obtained under license from JAX) or wild type (WT) controls. As reported previously, the KO expressed a leaky splice variant at low levels in brain tissue. P2X7-dependent component of IL-1β and IL-18 release was absent in P2X7 KO microglia; the astrocytes did not release these cytokines. We next sought to address the role of P2X7 in microglial activation. Under basal culture condition, WT microglia and P2X7 KO microglia had similar morphology. Under inflammatory conditions induced by LPS or LPS plus IFNγ with or without Bz-ATP, microglia (both WT and KO) responded with morphological changes from a ramified-shape to an amoeboid shape indicating changes in microglial morphology was not dictated by P2X7 activation. Contrary to this, and perhaps more interesting, more P2X7 KO microglia survived with increased Iba1 expression by immunostaining when exposed to LPS plus Bz-ATP or Bz-ATP alone compared with WT microglia, suggesting that P2X7 is involved in ATP-induced microglia cell death. Taken together, our data demonstrate that P2X7 is a modulator of release of IL-1 family, and play a role in microglial cell death.

Title: The difference of microglial activation between in spinal posterior horn and in spinal anterior horn after peripheral nerve injury.

Authors: *T. NISHIHARA[1], J. TANAKA[2], T. YOROZUYA[1];
[1]Dept. of Anesthesia and Perioperative Med., [2]Dept. of Mollecular and cellular physiology, Ehime Univ., Toon, Japan

Abstract: After peripheral nerve injury, microglial cells become activated while directly attaching neuronal somata and eliminating synapses as known as synaptic stripping. Such activated microglia in the posterior horn in the spinal gray matter have been suspected as one of the critical causes for neuropathic pain. In the present study, we have compared the activated microglia in the posterior horn with those in the anterior horn in terms of morphology and the expression of phagocytosis-related factors after chronic constriction injury of the left sciatic nerve. First, we have comprehensively analyzed mRNA expression in the left and the right spinal cord on the 7 days after the constriction utilizing a next generation sequencer. As a result, expression of mRNA for complements C1s and C3 was the most strongly elevated among the whole mRNA species. Next, we compared mRNA expression encoding phagocytosis related factors in the left and the right anterior parts of the cord and those in the posterior parts. Compliments expression in the left cords was higher than in the rights and that in the left posterior was higher than in the left anterior. Expression of CD11b, a C3b receptor, was expressed at a higher level in the left posterior than that in the left anterior, whereas GAS6 and NG2 chondroitin sulfate proteoglycan mRNA expressions were more marked in the left anterior horn than posterior horn. Confocal laser scan microscopy revealed that microglial cells with flattened shape intimately attached to large neurons in the left anterior horn, while those in the left posterior horn displayed amoeboid-like shape and the attachment to neurons was not apparent. These results suggest that the activated microglial cells in the anterior and the posterior horns may have distinct functions in the spinal cord after peripheral nerve injuries.

Title: Microglial impact on KCC2 in the ventral horn after peripheral nerve injury

Authors: *E. T. AKHTER[1], F. J. ALVAREZ[2], A. W. ENGLISH[3];
[1]Cell Biol. & Physiol., [2]Physiol., [3]Cell Biol., Emory Univ., Atlanta, GA

Abstract: Following peripheral nerve injury, spinal cord microglia become activated and proliferate in dorsal horn regions receiving projections from injured sensory afferents and in the ventral horn around the injured motor pool. Microglia activation contributes to the development of neuropathic pain by inducing hyperexcitability in dorsal horn neurons through downregulation of the potassium-chloride cotransporter-2, KCC2, through a BDNF dependent mechanism. Similarly, KCC2 is downregulated in motoneurons axotomized after nerve injury, but its significance and mechanisms of downregulation are unknown. We tested here whether microglia may also drive the downregulation of KCC2 on axotomized motoneurons. To investigate this relationship we injured the sciatic nerve by performing complete nerve transections in transgenic mice in which microglia express EGFP ($CX3CR1^{gfp/wt}$). We then compared the time course, level and distribution of the microglial response in the ventral horn with the degree and distribution of KCC2 depletion on injured motoneuron cell bodies and dendrites fully labeled by transfection with AAV1-mCherry. In addition, we examined the time course of KCC2 expression on the membrane of injured motoneurons (retrogradely labeled from muscle with Fast Blue or cholera toxin subunit b coupled to Alexa 555) at different times after injury, during axon regeneration and muscle reinnervation. Though the number of microglial contacts on motoneuron dendrites does not correlate with the degree of KCC2 loss, the region containing activated microglia closely overlapped with the extension of KCC2 depletion on motoneuron dendrites. The onset of KCC2 downregulation coincides with the microglial response and is restored after the response attenuates. Current experiments are performing cell-specific deletion of BDNF in microglia to test whether this manipulation blocks KCC2 downregulation in motoneurons after peripheral nerve injury.

Title: Polyamidoamine dendrimer-conjugated triamcinolone acetonide attenuates nerve injury-induced mechanical allodynia by inhibiting spinal cord microglia activation

Authors: *K. NOH[1], H. KIM[1], H. LIM[1], H. MIN[1], B. CHOI[1], J. OH[2], S. CHOI[2], J.-S. PARK[2], S. LEE[1];

Abstract: Background: Accumulating evidence on the causal role of spinal cord microglia activation in the development of neuropathic pain after peripheral nerve injury (PNI) suggests that a microglia activation inhibitor might serve as an analgesic drug for neuropathic pain. Studies also show that polyamidoamine (PAMAM) dendrimer may function as drug delivery vehicle to microglia in the central nervous system. In this regard, we developed PAMAM dendrimer-conjugated triamcinolone acetonide (TA) that we have previously screened for microglia activation inhibitor, and tested its analgesic efficacy in the mouse PNI model. **Result**: PAMAM dendrimer is delivered selectively to spinal cord microglia upon i.t. administration. PAMAM dendrimer-conjugated TA (D-TA) inhibits LTA-induced proinflammatory gene expression in primary glial cells. Likewise, i.t. D-TA administration inhibited PNI-induced spinal cord microglia activation and the expression of pain-related genes in the spinal cord such as Nox2, IL-1β, TNF-α, and IL-6. D-TA administration right after nerve injury almost completely reversed PNI-induced mechanical allodynia up to 3 days. Likewise, D-TA administration 1.5 dpi significantly attenuated mechanical allodynia. **Conclusion**: Our data demonstrate that D-TA attenuates neuropathic pain after PNI by inhibiting spinal cord microglia activation, suggesting a therapeutic implication for the treatment of neuropathic pain.

Title: Deafferentation and direct injury cause different microglial response profiles in the adult zebrafish olfactory bulb

Authors: *S. R. VAR, C. A. BYRD-JACOBS;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: The inherent plasticity of the zebrafish olfactory system serves as a useful model for examining the response of immune cells following injury. Microglia are the resident immune cells of the central nervous system that respond to damage by migrating to the site of injury and phagocytizing neuronal debris. Preliminary data suggested that direct injury to the olfactory bulb results in an acute immune response by resident microglia, while further proliferation may be due to migration of microglia from other regions of the brain or peripheral leukocytes entering through the olfactory nerves. We performed peripheral deafferentation and direct injury to the olfactory bulb in the whole fish and compared it to the isolated brain removed of all afferent input and peripheral influence. The olfactory bulbs of adult zebrafish were damaged by either cauterizing the olfactory organ or directly injuring the bulb with a stab wound. Removal of afferent input and peripheral influence was performed by isolating and culturing the brain for 4h. Mouse monoclonal 4C4 antibody was used to label microglia. Comparisons of the whole fish treatment groups to control fish revealed that there was a significant increase in activated microglia in the damaged bulb following peripheral deafferentation ($p<0.01$) and an increase in activated microglia in both the ipsilateral and contralateral bulbs following direct bulb injury ($p< 0.01$). In the whole fish, there were significant differences between active microglial profiles in peripheral deafferentation and direct injury in both the ipsilateral ($p=0.03$) and contralateral ($p<0.01$) bulbs. In the isolated brains, there were significantly more activated microglia in the olfactory bulbs after 4h in culture than in isolated brains immediately after dissection ($p=0.02$). When the isolated brain in culture received a direct injury to the right bulb, there was a significant increase in activated microglia bilaterally compared to the control ($p<0.01$); however, there were no differences between the microglial response profiles following direct bulb injury in the whole fish compared to direct bulb injury in the isolated brain. We found that peripheral deafferentation and direct injury to the olfactory bulb in the whole fish result in different microglial response profiles: a unilateral response to deafferentation and a bilateral response to direct injury. In the isolated brain, there is a significant microglial response following 4h in culture, suggesting that microglia can respond to damage without afferent input or peripheral influence. Further work is required to explore the origin and temporal sequence of the immune cells that respond to injury.

Title: Translocator protein 18 kDa (TSPO) ligands, Ro5-4864 and PK11195, have shown anti-inflammatory effects in diverse neuroinflammatory disease models.

Authors: *J.-W. LEE, L. KIM, H.-J. SHIM, E.-K. KIM, S.-W. YU;
DGIST, Daegu, Korea, Republic of

Abstract: Neuroinflammation is related with activation of the innate immune system involving infiltrating monocytes and macrophages as well as resident microglia. Previously, we reported the anti-inflammatory effects of TSPO ligands in microglial cells in vitro and in vivo. However, the anti-inflammatory mechanisms of TSPO ligands in innate immune system still remain poorly understood. NLRP3 inflammasome activation as a part of the innate immune system, has been implicated in a variety of neuroinflammatory diseases, including Alzheimer's disease, Parkinson's disease, and depression. Here, we demonstrate for the first time that TSPO ligands, especially Ro5-4864, potently inhibits ATP-induced NLRP3 inflammasome activation in microglia and macrophages. Ro5-4864 efficiently suppressed NLRP3 translocation to mitochondria, inflammasome assembly/oligomerization, activation of caspase-1 and subsequent secretion of IL-1β and IL-18. TSPO ligands prevented mitochondrial perturbation upstream of NLRP3 inflammasome activation. Our study can provide novel insight into the anti-inflammatory mechanism of TSPO ligands through regulation of NLRP3 inflammasome activation.

Title: Toll-like receptor 2 has not an important role in an immediate-early microglial reaction to two-photon laser-induced cortical injury *In vivo*

Authors: *H. YOON[1,2], Y. JANG[3], S. KIM[4], S. LEE[3], S. KIM[1];
[1]Dept. of Physiol., Kyunghee Univ. Colledge of Korean Med., Seoul, Korea, Republic of; [2]BK 21 plus, Kyunghee university Col. of Korean medicine, Seoul, Korea, Republic of; [3]Oral physiology and neuroscience, [4]Seoul national university, Seoul, Korea, Republic of

Abstract: Microglia, the resident immune cells in the central nervous system, can be rapidly activated to pathological insults. Toll-like receptor 2 (TLR2) is a pattern recognition receptor that plays a primary role in pathogen recognition and initiate of innate immunity. Although many previous studies have suggested that TLR2 contributes to microglial activation and subsequent pathogenesis following brain tissue injury, it is still unclear whether TLR2 has a role in microglia dynamics in the resting state or in immediate-early reaction to the injury *in vivo*. By using in vivo two-photon microscopy and *Cx3cr1*-^{GFP} knock in/ TLR2-knockout (KO) mice, we first monitored the motility of microglial processes (i.e. the rate of extension and retraction) in the somatosensory cortex of living TLR2-KO and WT mice; Microglial processes in TLR2-KO mice show the similar motility to that of WT mice. We further found that microglia rapidly extend their processes to the site of local tissue injury induced by a two-photon laser ablation and that such microglial response to the brain injury was similar between WT and TLR2-KO mice. These results indicate that there are no differences in the behavior of microglial processes between TLR2-KO mice and WT mice when microglia is in the resting state or encounters local injury. We suggest that TLR2 signaling does not have an essential role in the resting state microglial behavior as well as in the immediate early microglial response to a brain tissue injury *in vivo*.

Title: The effects of minocycline on lps induced cytokine release.

Authors: *I. FRASER, N. TAYLOR, Y. HE, R. WYATT, A. BHATTACHARYA, P. BONAVENTURE;
Janssen, San Diego, CA

Abstract: Minocycline is known to be exhibit anti-neuroinflammatory properties. Current research is examining the possible neuroprotective and anti-neuroinflammatory effects of minocycline against the development and progression of several neurodegenerative disorders. To better understand the possible neuroprotective qualities of minocycline it is important to demonstrate this effect in both in vitro and in vivo models of neuroinflammation, in a systematic evaluation.
To this end, lipopolysaccharide (LPS) was used as an inflammatory agent to induce cytokine and chemokine release from mouse primary microglia in vitro and from rat hippocampus in vivo. We then attempted to block LPS induced cytokine/chemokine release by administering minocycline. Our studies show that minocycline (20 μM) modulates LPS (10 and 100 ng/ml) induced cytokine/chemokine release in the mouse primary microglia in vitro. However, we did not find the same effect of minocycline (80 mg/kg, i.p.) on LPS (10 mg/ml via reverse dialysis) induced cytokine/chemokine release in rat hippocampus, as measured by in vivo microdialysis. Lack of a strong effect of minocycline in vivo was not due to the absence of the compound in the brain as we show that minocycline does indeed cross the blood-brain barrier and is even sufficiently present in the brain (4 μM) during LPS exposure.

Title: Microglia activation occurs early in sustained hypoxia and is necessary for ventilatory acclimatization to hypoxia

Authors: *J. A. STOKES, T. E. ARBOGAST, F. L. POWELL;
Medicine/Physiology, UC-San Diego, La Jolla, CA

Abstract: Ventilatory acclimatization to hypoxia (VAH) is a time-dependent increase in ventilation that persists upon return to normoxia and involves plasticity in central nervous system (CNS) respiratory centers and peripheral chemoreceptors. Plasticity in the CNS increases ventilatory motor output for a given chemoreceptor input but the mechanisms of such plasticity are unknown. Here we tested the role of glial cells, which are known to affect synaptic transmission and central respiratory control. We measured the time course of microglia and astrocyte activation following different durations of chronic sustained hypoxia (CSH, 10% O_2). Three to four male Sprague Dawley rats were exposed to CSH for 0.5, 1, 4 and 12 hours and 1, 4 and 7 days followed by immediate tissue perfusion and brainstem collection. We measured glial cell activation in the nucleus tractus solitarius (NTS; primary synapse in the CNS from carotid body chemoreceptors) and the hypoglossal motor nucleus (CN XII; respiratory motor neurons) using immunohistochemistry and image analysis (FIJI/ImageJ and IMARIS with Filament Tracer). After 1 hour of CSH, microglia in both the NTS and CN XII displayed shorter and fewer branches, indicating activation, but they return to a ramified morphology with more branching and with longer branches after 4 hours of CSH. Astrocytes increased glial fibrillary acidic protein (GFAP) expression in the NTS after 4 hours of CSH, but in the CN XII region GFAP expression was increased only after 7 days of CSH. Similar changes in microglia or astrocytes were not observed in adjacent non-respiratory nuclei. The number of microglia did not change with CSH in the NTS or CN XII, indicating no proliferation. Similarly, the number of astrocytes did not change in the NTS with CSH, but astrocyte number did increase in the CN XII after 7 days of CSH. Systemic administration of a microglia inhibitor (minocycline, 45mg/kg i.p.) during 7 days of CSH blocked the increase in hypoxic ventilation measured with barometric pressure plethysmography in unrestrained rats (n=3). However, once VAH was established with 4 days of CSH, minocycline treatment for 3 more days of CSH did not reverse the increase in

hypoxic ventilation (n=3). Our results support the hypothesis that microglia activation is required for the induction but not the maintenance of plasticity leading to VAH.

Title: Inhibition of astrocytes released IL15 reduces CD8 T cell mediated neuronal apoptosis in experimental traumatic brain injury in rats

Authors: *Y.-M. ZHANG[1], L. WU[1], H. WANG[1], G.-L. ZHANG[2], R. HUA[3];
[1]Jiangsu Province Key Lab. of Anesthesiol., Jiangsu, China; [2]Sch. of Basic Med. Sciences, Anhui Med. Univ., Hefei, China; [3]Dept. of Emergency Medicine, the affiliated hospital of Xuzhou Med. Univ., Xuzhou, China

Abstract: Microenvironmental factors that activate immune cells infiltrating into CNS of rats with traumatic brain injury (TBI) remain elusive. Cytokine IL-15 is crucial in the development and activation of the $CD8^+$ T lymphocyte which is accumulated in brain region of TBI. We examined whether the IL-15 released from astrocytes is able to stimulate $CD8^+$ T lymphocyte response. We found that TBI was associated with astrocytes activation and an increase in the IL-15 level. The distribution of $CD8^+$ T lymphocytes in TBI lesion area were matched to IL-15 positive cells. Furthermore, Gra-b released by $CD8^+$ T lymphocytes induced neuronal apoptosis by activating caspase 3 and cleaving PARP. In addition, pretreatment with fluorocitrate, an inhibitor of astrocytes, decreased the expression of IL-15 positive and $CD8^+$ T cells, improved neurological function and memory, and decreased neuron apoptosis. Pretreatment with rIL-15 upregulated the levels of $CD8^+$ T cells and Gra-b, and induced neuronal death. Our data indicate that IL-15 derived from astrocytes induces neuron apoptosis by enhancing $CD8^+$ T cell function. Key words: IL-15; TBI; astrocytes; $CD8^+$ T cells; neuronal apoptosis. Title: Metabolic stress in microglia dysregulates sirtuin pathway and mitochondrial function

Authors: *S. PUGAZHENTHI[1], A. TYAGI[2], T. CHONG[3];
[1]Res. Services-151, Denver VA Med. Ctr., Denver, CO; [2]Univ. of Colorado, Aurora, CO; [3]Univ. of Colorado, Denver, CO

Abstract: The immune system is recognized as an important sensor of metabolic stress, one of the modifiable risk factors of dementia. We have previously observed that metabolic stress-induced mitochondrial injury activates inflammasome formation in microglia. Sirtuins comprise a highly conserved family of NAD^+-dependent enzymes. They maintain metabolic homeostasis and reduce cellular damage and inflammation. In this study, we examined the effects of nutrient overload-induced metabolic stress on the sirtuin pathway and mitochondrial dysfunction in the Alzheimer's transgenic mouse brain and in cultured microglia.
High-fat feeding induced the expression of inflammatory pathway genes in the brain of both nontransgenic and 3XTg AD mice. Western blot analysis revealed activation of NF-kB, as shown by the decreases in the levels of IkB. Intracellular levels of Aβ in the AD mouse brain increased further following high-fat feeding. Decreases in the levels of SIRT1 and SIRT3 in the AD mouse brain were exacerbated by metabolic stress. Immunofluorescent staining showed the decrease of sirtuins to be specifically in Iba1-stained Microglia.
Palmitic acid treatment on BV2 cells, a mouse microglial cell line, caused mitochondrial fragmentation, decreased the levels of mitochondrial complexes I and II, and NF-kB activation. Examination of mitochondrial respiration measured by high resolution respirometry using Oroboros Oxygraph-2k decreased in response to the carbohydrate substrates in stages 2, 3, and 4. To delineate the role of SIRT1 in the regulation of mitochondrial function, $SIRT1^{-ve}$ BV2 cells were generated. Mitochondrial complexes I and II decreased following the silencing of SIRT1. These cells showed significantly low respiration as compared to control BV2 cells. Palmitic acid-induced NF-kB activation was also exacerbated in $SIRT1^{-ve}$ cells.
Additional studies were performed to determine the role of SIRT3 on the mitochondrial function.

Brain samples from SIRT3 knock-out mice, fed western diet, showed decreased maximum uncoupled respiration rate. SIRT3 silencing in BV2 cells also decreased mitochondrial respiration.
Our findings reveal a novel paradigm that nutrient excess-induced metabolic stress causes mitochondrial injury in the brain, leading to neuroinflammation, an important player in the pathogenesis of Alzheimer's disease. Sirtuin pathway could be a potential therapeutic target to delay cognitive decline.

Title: Microglia participate in the functional maturation of blood-brain barrier by regulating cytokine-chemokine circumstances as members of neurovascular unit.

Authors: *K. SATO, Y. SHIGEMOTO-MOGAMI, K. HOSHIKAWA, Y. SEKINO;
Natl. Inst. Hlth. Sci., Tokyo, Japan

Abstract: There is growing evidence that the blood-brain barrier (BBB) permeability is regulated by various cells comprised of neurovascular unit (NVU). However, the relationship between microglia and BBB is largely unknown. In this study, we investigated the roles of microglia in the functional maturation process of BBB and the underlying mechanisms using in vitro BBB model comprised of endothelial cells, pericytes, and astrocytes (Pharmaco-cell co). When we added non-stimulated microglia to astrocytes in the brain side of the BBB model during the maturation period (DIV1-4), trans-endothelial electrical resistance (TEER) and the

expression level of Claudin-5, a member of tight junction proteins (TJs), were significantly increased. On the other hand, LPS-activated microglia significantly decreased the TEER and the levels of two TJ proteins (Occludin and Claudin-5). We next examined the involvement of cytokines/chemokines in the enhancement of BBB barrier function by microglia. We measured the concentrations of cytokines/chemokines in the brain side of the BBB model supplemented with non-stimulated microglia or LPS-stimulated microglia comprehensively using MAGPIX system (millipore). Among cytokines/chemokines, the concentrations of X showed a correlation with changes of BBB functions, while the concentration of Y showed an inverse correlation with the changes of BBB functions. We have confirmed that X alone significantly increased TEER but had no effects on the expression levels of TJ proteins by 4-day treatment. Currently we are examining the roles of Y. These results so far suggest that microglia regulate BBB barrier function by controlling the dynamics of cytokines/chemokines.

Title: Blockade of potassium channel Kv1.3 ameliorates brain injury in a model of infection-sensitized neonatal hypoxia-ischemia

Authors: *L.-W. JIN[1], M. HORIUCHI[2], H. M. NGUYEN[3], Y.-J. CHEN[3], H. WULFF[3], I. MAEZAWA[1];
[1]M.I.N.D. Inst. UC Davis, Davis, CA; [2]Pathology, [3]Pharmacol., UC Davis, Davis, CA

Abstract: Perinatal hypoxia-ischemia (HI) insult causes major damage to the developing brain and its severity is augmented by perinatal infection. In a rodent model of endotoxin (lipopolysaccharides or LPS)-sensitized hypoxic/ischemic perinatal brain injury (LPS-HI), influx of peripheral T_H17-like lymphocytes and monocytes to the brain as well as persistent microglial activation has been shown to play an essential role in such neonatal brain injury. Because the voltage-gated potassium channel Kv1.3 modulates the migration and activation of a subset of T cells (particularly T_H17 cells), monocytes, and microglia, we hypothesize that Kv1.3 blockade may ameliorate brain injury in newborns suffering from infection-sensitized HI. To test this

hypothesis, we injected P10 C57BL/6J mice with LPS (0.3 mg/kg intraperitoneally) and immediately subjected them to ischemia (left common carotid artery ligation) and hypoxia (10% O_2 at 37^oC for 40 min). We found that IBA1+ microglia/macrophages accumulated in the left (ipsilateral) cortex and hippocampus with associated neuronal loss, but not in the right hemisphere contralateral to the side of ischemia. These microglia/macrophages showed significant upregulation of Kv1.3 transcript and protein, as measured by qPCR and immunohistochemistry, respectively. The enhanced Kv1.3 channel activity/quantity was confirmed by whole-cell patch-clamp conducted on acutely isolated microglia/macrophages. We next assessed the outcomes of the LPS-HI model after Kv1.3 blockade by either administering a specific Kv1.3 blocker PAP-1 (40 mg/kg every 12 h, *i.p.*) or using Kv1.3 knockout mice in C57BL/6J background. We found that both pharmacological and genetic blockade of Kv1.3 significantly mitigated neuronal loss and microglia/macrophage accumulation in LPS-HI mice, reduced the induction of pro-inflammatory cytokines and chemokines, and improved the performance in rotarod and 14-score neurological deficit tests. Flow cytometry showed that Kv1.3 blockade reduced the populations of both CD11b+/CD45^{high} and CD11b+/CD45^{low} cells, suggesting a reduction of both activation of microglia and infiltration of monocyte-derived macrophages. Our results implicate a novel Kv1.3-orchestrated mechanism in neonatal brain injury and suggest a novel therapeutic approach.

Title: Autophagy regulates MAVS signaling activation in a phosphorylation dependent manner in microglia

Authors: *Z. YUAN[1], J. CHENG[2], Y. LIAO[2], Y. XU[3];
[1]Inst. of Biophysics, Beijing, China; [2]Inst. of Biophysics, CAS, Beijing, China; [3]Nanjing Gulou Hosp., Nanjing, China

Abstract: Mitochondrial antiviral signaling protein (MAVS) signaling plays an important role in antiviral immunity and autoimmunity. However, the pathophysiological role of this signaling

pathway, especially in the brain, remains elusive. Here, we demonstrate that MAVS signaling exists in the brain and mediates poly(I:C)-induced inflammation. Importantly, *in vivo* data show that deficiency of *MAVS* prevents MPTP-induced microglial activation and dopaminergic neuron loss. Along with the MAVS signaling activation, there is an induction of autophagic activation. LC3 knockdown or *Atg5* deletion in microglial cells strengthens MAVS-mediated inflammation. Further studies show that MAVS directly binds to LC3 through a classical LIR motif $Y_{(9)}xxI_{(12)}$ Interestingly, we find that c-Abl kinase phosphorylates MAVS and increases its interaction with LC3 and tyrosine phosphorylation of MAVS is indispensible for downstream signaling activation. Together, our findings reveal the molecular mechanisms underlying the regulation of MAVS-dependent microglial activation in the nervous system, thus providing a potential target for the treatment of Parkinson's disease.

Abstract: Alexander disease is caused by mutations in the glial fibrillary acidic protein (GFAP) gene. It remains unknown how GFAP mutations result in astrocyte malfunction and dysmyelination. We have established induced pluripotent stem cells (iPSCs) from Alexander disease (AxD) patients with different GFAP mutations. We have also generated isogenic iPSCs by correcting the GFAP mutations with CRISPR/CAS9. While both AxD and isogenic iPSCs differentiated to astrocytes to a similar degree, AxD astrocytes exhibited GFAP aggregation, a hallmark pathology of the disease. Functional analysis revealed altered calcium wave kinetics and reduced capacity to induce tight junction formation in an *in vitro* model of the blood brain

barrier. These results highlight the utility of iPSC disease modeling as a means to recapitulate human disease *in vitro.* AxD astrocytes provide a tool to reveal how the cytoskeletal protein GFAP functions in astrocytes in both health and disease.

Title: PIP3/AKT activation in $NG2^+$ glial progenitors promotes oligodendrocyte differentiation and regeneration

Authors: *E. GONZALEZ FERNANDEZ[1], M. FUKAYA[2], K. HYUKMIN[1], S.-B. HAN[1], Y.-J. SON[1], S. H. KANG[1];
[1]Shriners Pediatric Hosp. Ctr., Philadelphia, PA; [2]Anat., Kitasato Univ. Sch. of Med., Sagamihara, Japan

Abstract: Oligodendrocytes (OLs) are myelin-forming glia that are critical for rapid axonal conduction and metabolic support for axons in the CNS. In the healthy CNS, homeostatic maintenance of OLs seems to be well supported by abundant $NG2^+PDGF\alpha R^+$ OL progenitors (OLPs), which can give rise to mature OLs not only during early development, but also in later life. In response to OL loss following focal demyelinating injury, OLPs generate new OLs, leading to remyelination in the adult CNS. However, in demyelinating diseases, for unknown reasons such reparative processes do not properly function. Although molecular mechanisms for early OL development have been identified, and knowledge of relevant signaling pathways has accumulated, the effective signaling pathways that can promote the OL regeneration in the mature CNS are yet to be identified.
In search of an effective targetable cell signaling that can promote OL regeneration *in vivo*, we tested the PIP3/AKT/mTOR signaling by deleting *Pten* or *Tsc1*, the two inhibitory upstream regulators of mTOR activity, selectively in OLPs, with tamoxifen-administered *PDGFαR-CreER*

mice. We also performed simultaneous fate analysis of OLPs by adding ROSA26-EYFP reporter to the *PDGFαR-CreER ± Pten (f/f)* mice. The OLP-specific *Pten* deletion resulted in enhanced proliferation $EYFP^+$ OLPs, and facilitated OL development in the two tested age windows, P20 to P41 and P45 to P75, whereas *Tsc1* deletion showed the opposite results. The robust increase in rate of OL differentiation by PTEN inactivation was more prominent in the gray matter areas than white matter areas. Moreover, after focal demyelination of the mature spinal cord (at P60), the *Pten*- deleted OLPs exhibited a significantly enhanced rate of OL regeneration. To better understand the dissimilar outcomes from deletions of *Pten* and *Tsc1*, we crossed *Pten (f/f)* mice with *Mtor (f/f)* mice. Our inducible genetic deletion of *Mtor* alone clearly decreased both the level of p70S6 kinase phosphorylation and the number of mature OLs, confirming effective gene ablation. However, the impact of *Pten* deletion was not reversed by the additional deletion of *Mtor*.
These results suggest that PTEN is an important negative regulator of the rate of OL maturation, and its inhibition (or activating PIP3/AKT) in OLPs can be an effective approach to promote OL differentiation and remyelination. Despite the known importance of mTOR signaling in OL development, the major downstream effectors of PIP3/AKT for the observed enhancement in OL differentiation appear not to include mTOR.

Abstract: Huntington`s Disease (HD) is characterized by striatal and cortical neuronal degeneration, but it is also associated with myelin loss, potentially reflecting dysfunction or failed replacement of oligodendrocytes. Nonetheless, the role of oligodendroglial pathology in HD has not been well explored. We have generated human oligodendrocyte progenitor cells (hOPCs) from embryonic stem cells (hESCs), derived from either huntingtin (mHTT)-mutant hESCs or controls, used fluorescence-activated cell sorting (FACS) to isolate the cells, and performed RNA sequence analysis on their extracted mRNAs to assess mHTT-dependent changes in gene expression. We found that a coherent set of key transcription factors associated with oligodendroglial differentiation (NKX2-2, OLIG2 and SOX10), as well as with myelin biosynthesis (including MYRF, MBP, MAG, OMG, PLP1 and MOG), were significantly, and often severely, down-regulated as a function of mHTT expression (fold change >2.0: corrected $p<0.01$), in a pattern auguring defective oligodendrocytic differentiation and myelin production capacity. We confirmed this observation *in vivo* by using immunodeficient myelin-deficient *shiverer* x *rag2*$^{-/-}$ mice neonatally-engrafted with hESC OPCs, whose glial populations are largely replaced by human donor-derived glia. These human glial chimeric mice, allow the direct *in vivo* comparison of oligodendrocytic differentiation and myelin formation by mHTT vs. control hESC OPCs. We found that the mHTT OPCs manifested significantly delayed and deficient oligodendrocytic maturation, as well as substantially diminished myelination, relative to normal HTT control OPCs, as quantified stereologically by immunostaining at serial time points for OLIG2, Transferrin, and MBP. Together, these data suggest that HD OPCs is a product of an mHTT-dependent block in oligodendrocytic differentiation by affected OPCs, followed by the serial failure of those oligodendrocytes that do develop to express MYRF and those downstream MYRF-dependent mRNAs associated with myelinogenesis. These findings suggest a causal role for defective OPC differentiation in the pathogenesis of HD.

Title: Potential role of G-protein coupled receptor 3 in regulating cytokine gene expression in the T lymphocytes

Authors: *S. TANAKA, K. HIRANO, T. KAMEOKA, T. MIYAGI, Y. YANASE, I. HIDE, T. SHIRAFUJI, N. SAKAI;
Hiroshima Univ. Sch. of Biomed. Sci., Hiroshima, Japan

Abstract: G-protein coupled receptor (GPR) 3 belongs to a member of constitutively active Gs-coupled receptors that activate 3', -5'-cyclic adenosine monophosphate (cAMP). We have previously reported that the neuronal expression of GPR3 enhances neurite outgrowth (Tanaka et al., JBC 2007), modulates proliferation of cerebellar granule cell precursors (Tanaka et al., PLoS One 2009), and associates with neuronal survival (Tanaka et al., Neurobiol Dis 2014); however, the physiological functions of GPR3, especially in other non-neuronal cells, have not been understood. In the present study, we investigated the physiological function of GPR3 in the T lymphocytes. When Jurkat cells were treated with Phorbol 12-myristate 13-acetate (PMA) and ionomycin, the expression of GPR3 mRNA was up-regulated 3 to 6 hours after treatments. Similar results were obtained when mouse splenocytes were stimulated by PMA and ionomycin. We further examined if the induction of GPR3 in the T lymphocytes could modulate the expression of cytokines in the T lymphocytes. The expression of IL-2 mRNA was increased when the CD4+ T lymphocytes from wild-type mice were stimulated by PMA and ionomycin. However, the extent of IL-2 mRNA elevation was up-regulated in these cells from GPR3 knockout mice. To further ask the role of GPR3 in the T lymphocytes. we applied experimental autoimmune encephalomyelitis (EAE) in GPR3 knockout mice and wild-type mice. GPR3 knockout mice developed significantly milder EAE clinical score compared with wild-type mice 13 to 17 days after immunization. These results suggest a potential role of GPR3 in modulating cytokine expression in the T lymphocytes, thereby affecting pathophysiology of autoimmune diseases.

Title: Novel role of protein tyrosine phosphatase sigma in pathogenesis of autoimmune CNS demyelination

Authors: *Y. OHTAKE[1], W. KONG[2], D. GANEA[2], S. LI[1];
[2]Microbiology&Immunology, [1]Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Protein tyrosine phosphatase sigma (PTPσ) is expressed in both the nervous and immune systems and appears to play critical roles in neurodevelopment, axon regeneration and inflammatory responses. Here, we studied the function of PTPσ in mediating inflammatory reactions in the CNS and pathogenesis of demyelination using experimental autoimmune encephalomyelitis (EAE) mouse, a model of multiple sclerosis. PTPσ deletion remarkably increased the clinical EAE symptoms and induced severe demyelination and axonal loss compared with littermate wild-type BALB/c mice immunized with myelin oligodendrocyte glycoprotein (MOG) peptide. Gene expression analysis displayed enhanced levels of several pro-inflammatory cytokines and chemokines in the spinal cord of PTPσ$^{-/-}$ mice after MOG immunization. Ex vivo experiments indicated that splenocytes derived from PTPσ$^{-/-}$ EAE mice produced higher levels of IFNγ and IL17 than those from EAE controls. Importantly, the conventional dendritic cells (cDCs), but not CD4+ T cells, expressed high levels of PTPσ and the cDCs from PTP$^{-/-}$ mice exhibited the inflammatory phenotype characterized by enhanced expression of pro-inflammatory cytokines, chemokine receptors and migration capacity, and decreased expression of anti-inflammatory cytokines. Accordingly, adoptive transfer of PTPσ$^{-/-}$ DCs induced more severe EAE disease than that of wild-type DCs. Moreover, by using a lysolecithin-induced focal demyelination model, we found that PTPσ deficiency prevented remyelination of the spinal cord axons by accumulating microglia and reactive astrocytes and reducing generation of NG2-positive oligodendrocyte progenitors. We conclude that PTPσ plays a critical role in development of autoimmune CNS inflammation by regulating functions of DCs

and other cell types and that it may become a molecular target for treating autoimmune diseases, including multiple sclerosis.

Title: Selective deletion of AMPA receptors on oligodendrocytes prevents excitotoxicity in EAE

Authors: *K. S. EVONUK[1], R. E. DOYLE[2], C. E. MOSELEY[3], H. MONYER[4], T. M. DESILVA[1];
[1]Neurosciences, Cleveland Clin., Cleveland, OH; [2]Physical Med. and Rehabil., [3]Dept. of Pathology, Univ. of Alabama at Birmingham, Birmingham, AL; [4]Clin. Neurobio., Heidelberg Univ. and German Cancer Res. Ctr., Heidelberg, Germany

Abstract: Multiple sclerosis (MS) is a neuroinflammatory disease defined by demyelination and axonal damage. The most common form of MS is relapsing-remitting (RRMS), whereby exacerbations of symptoms are followed by a period of remission. A relapse is defined as a clinical event involving the onset of neurological symptoms caused by CNS inflammation. However, the number of inflammatory events in the CNS of MS patients far outnumbers clinical relapses. Current treatments for the disease are immunomodulatory and fail to fully eliminate these inflammatory events and relapses. Therefore, discovery of treatments that directly protect the CNS during immune cell infiltration is of high importance. Patients with MS have elevated

levels of glutamate in the brain as measured by MRI, implicating excitoxic mechanisms in CNS damage. Our laboratory recently showed that inhibition of a source of excitotoxic glutamate, the system x_c^- transporter, after disease onset in an animal model of MS results in reduced clinical symptoms and demyelination. To further explore the target of excitotoxic glutamate, the AMPA-type glutamate receptors (AMPARs) were selectively deleted on oligodendrocytes since numerous cell types in the CNS and immune system also express AMPARs. Using conditional knockout mice with two different oligodendrocyte promoters, we found that selective deletion of AMPARs on oligodendrocytes in adult C57Bl/6 mice subjected to experimental autoimmune encephalomyelitis (EAE) results in improved clinical scores and reduced myelin damage in the thoracic and lumbar regions of the spinal cord. To confirm that the abrogation of disease activity was CNS-specific, analysis of CNS-infiltrating immune cells by flow cytometry was performed and no changes were found in knockout mice compared to littermate controls. To further exclude changes in peripheral immune cell activity, T cell proliferation in spleens was assessed and no changes were found. These data support that AMPA receptor expression on oligodendrocytes mediates excitotoxic damage in autoimmune demyelination providing potential therapeutic implications for CNS protection in MS.

Title: Efffects of microtubule destabilizing drugs on CNS Myelination

Authors: *I. V. DEYNEKO[1,2], H. M. MORAN[1], M. M. URBANSKI[1], C. V. MELENDEZ-VASQUEZ[1];
[1]Hunter College, City Univ. of New York, Brooklyn, NY; [2]BP-Endure, New York City, NY

Abstract: The glial cells of the central (CNS) and peripheral (PNS) nervous systems, known as oligodendrocytes (OL) and Schwann cells (SC) respectively, wrap axons in a membrane called myelin. Nerve impulses are propagated in myelinated axons via saltatory conduction, which increases the speed of transmission and promotes efficient information processing. Loss of myelin in diseases such as multiple sclerosis in the CNS and Guillain-Barrè Syndrome in the PNS results in significant cognitive and physical impairments. Remyelination by OL and SC has been found to reverse demyelination damage and protect axons from further degeneration. Our

lab focuses on the study of the cytoskeletal proteins as a tool for promoting myelin formation and repair. Specifically, we are investigating the role of Microtubules (MTs) in the process of myelination. MTs are heterodimer polymers made up of α- and β-tubulin, which are involved in the transport of myelin proteins as well as in the formation of processes, and are thus important for the proper assembly of myelin sheaths. We are currently examining a MT-modifying drug that inhibits detyrosination of α-tubulin, a modification that affects the rate of transport along MTs as well as makes the MT more dynamic. We have found that the drug promotes the formation of myelin sheathes by SCs and OLs in co-cultures, with higher rates of branching in OPC-only cultures. Currently we are investigating the mechanisms responsible for these effects.

Title: Myelinogenic plasticity of oligodendrocyte precursor cells following CNS trauma

Authors: *P. L. ASSINCK[1], G. J. DUNCAN[1], J. R. PLEMEL[2], M. J. LEE[1], D. CHUNG[1], D. SYKORA[1], J. LIU[1], D. BERGLES[3], W. TETZLAFF[1];

Abstract: Contusive spinal cord injury (SCI) results in considerable demyelination of spared axons, which impairs signal transduction and may leave axons vulnerable to degeneration. Both oligodendrocytes (OL)s and Schwann cells remyelinate denuded axons in the subsequent weeks and months following SCI. NG2 cells, characterized by the near ubiquitous co-expression of platelet derived growth factor receptor α (PDGFRα) in the uninjured central nervous system (CNS), are oligodendrocyte progenitors (OP)s which may serve as a source of new OLs following SCI. PDGFRα-CreERT mice were crossed with Rosa26-YFP mice and administered tamoxifen to label OPs two weeks prior to contusive thoracic spinal cord injury. In the uninjured spinal cord we found that YFP was expressed in NG2+ OPs at very high efficiency, as well as

αSMA+ pericytes and fibronectin+ fibrocytic cells in the spinal roots. Following injury, many recombined cells continue to express the PDGFRa+, Olig2 and NG2, indicative they have remained as OPs, but substantial differentiation into new mature oligodendrocytes (CC1+) was observed, responsible for de novo ensheathment of >30% of the myelinated axons by three months. Strikingly, the majority of P0+ Schwann cells in the spinal cord expressed YFP, suggesting they originated from central nervous system PDGFRα+ OPs. This result was confirmed using Olig2-CreERT: Rosa26-YFP mice. Furthermore, we found that αSMA+ pericytes did not give rise to myelinating cells after SCI and that only a small proportion of P0+ myelinating cells from the spinal roots migrated into the cord and contributed to Schwann cell myelination after SCI. Overall, this work reveals enormous phenotypic plasticity of PDGFRα precursors following spinal cord injury as a source of the new remyelinating Schwann cells and oligodendrocytes in the injured spinal cord.

Title: Electroencephalographic analysis in a metabolic stress model of Multiple Sclerosis

Authors: *C. R. RICHARDSON[1], D. Z. RADECKI[1], A. GOW[1,2,3];

Abstract: Multiple sclerosis (MS) is a neurodegenerative disease characterized by white and grey matter lesions that contribute to a variety of disabling symptoms. MS has previously been characterized as a primary immune-mediated disease; however, emerging research suggests the involvement of metabolic stress in MS disease progression. Data from MS patient postmortem samples shows multiple phenotypes associated with clinical symptoms, including metabolic stress in white and gray matter. Our *OBiden* (*OBi*) mouse model of MS pathology involves

metabolic stress as the etiology. Through behavioral, humoral, and electrophysiological analysis we compare the pathology of *OBi* mice to that of MS patient autopsy samples to determine if our novel mouse model has pathophysiologic relevance to MS. Common symptoms for MS patients include memory loss, depression, anxiety, sleep deprivation, and lack of thermoregulation. In addition to white matter lesions and innate immune cell activation, we find hippocampal and cortical pathology, memory deficits and depression endophenotypes in *OBi* mice. We have examined the major functions of three hypothalamic nuclei and are able to rule out significant contribution of this brain region to *OBi* phenotypes. We now focus on hippocampal and cortical pathology using electroencephalography (EEG) and demonstrate reduced interhemispheric theta band coherence in 12 but not 6-month old *OBi* mice. Our behavioral testing reveals memory deficits at 12 months and depression-like endophenotype at 6 and 12 months, and we find extensive hippocampal and cortical damage at 12 months in these mutants. Correlations between interhemispheric coherence and behavioral phenotype onset suggest a common source for behavioral and coherence changes, that of hippocampal pathology. Using EEGs to further analyze hippocampus and cortex we aim to better understand the spatial and temporal emergence of pathology in these regions. We hypothesize that disturbances in interhemispheric network theta band activity are associated with the endophenotypes we observe in *OBi* mice. To investigate brain region specific contributions to the pathology we are using microelectrode arrays to interrogate cortical column level activity of layer 5 output neurons for grey matter lesion mapping and site specific identification of coherence changes. Our current data spanning behavioral, humoral, and electrophysiological approaches suggest a disease model arising through metabolic stress that is comparable to MS induction. Thus, this novel model will likely provide insight into MS pathogenesis and new opportunities for the development of disease-modifying therapies for MS patients.

Title: Schwann cell-specific deletion of the endosomal phosphatidylinositol 3-kinase Vps34 leads to impaired radial sorting of axons and failed myelination

Authors: *F. L. ROBINSON[1], A. M. LOGAN[2], D. C. ROBINSON[2], A. F. CONDON[2], E. J. SCHMIDT[2];
[1]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Oregon Heath and Sci. Univ., Portland, OR

Abstract: The PI 3-kinase Vps34 (Pik3c3) synthesizes phosphatidylinositol 3-phosphate (PI3P) on endosomes, where the lipid regulates membrane traffic and macroautophagy. The dysregulation of PI3P (and its derivatives, $PI(3,5)P_2$ and PI5P) is implicated as a cause of hereditary demyelinating neuropathy (Charcot-Marie-Tooth disease; CMT). We have investigated the Schwann cell autonomous role of Vps34 in axonal sorting and myelination using mice. Schwann cells lacking Vps34 are defective in radial axonal sorting, an impairment which leads to prolonged retention of large axons in bundles and delayed myelination. In addition, Vps34-deficient Schwann cells are impaired in the elaboration of myelin, despite having reached the promyelinating stage. Loss of Vps34 in Schwann cells leads to abnormalities in both endosomal-lysosomal trafficking and autophagic flux. We also investigated how the opposed enzymatic activities of PI 3-kinases and 3-phosphatases regulate the levels of PI3P in Schwann cells. Myotubularin-related (Mtmr) 2 and Mtmr13 form a PI 3-phosphatase complex implicated in the regulation of PI3P and $PI(3,5)P_2$ in Schwann cells. Loss of either *MTMR2* or *MTMR13* causes CMT4B, a severe neuropathy characterized by distinctive myelin outfoldings. We find that the elimination of Vps34 from Schwann cells, a manipulation predicted to reduce PI3P and $PI(3,5)P_2$ levels, does not reduce dysmyelination in *Mtmr13*-deficient mice, suggesting that lowering PI3P levels may not be a viable strategy for therapeutic intervention in CMT4B. Our findings indicate that the PI 3-kinase Vps34 is critical for radial axonal sorting and myelination, and also provide insight into the complexities of the regulation of PI3P and its derivatives in Schwann cells.

Title: Altered cholesterol trafficking in mice deficient in peripheral myelin protein 22

Authors: *Y. ZHOU[1], S. LEE[2], A. I. FETHIERE[2], H. TAVORI[3], S. FAZIO[3], A. CORONA[4], G. E. LANDRETH[4], L. NOTTERPEK[2];
[1]Neurosci., [2]Univ. of Florida, Gainesville, FL; [3]Oregon Hlth. and Sci. Univ., Portland, OR; [4]Case Western Reserve Univ., Cleveland, OH

Abstract: In the peripheral nervous system, myelin, a lipid-enriched multilayered insulator of axons, is formed by Schwann cells. The correct expression of specific proteins and lipids is critical for normal myelination and stability. Rodents and humans with haplodeficiency in peripheral myelin protein 22 (PMP22), a Schwann cell glycoprotein, are prone to compression-induced myelin damage, whereas the complete absence of PMP22 in mice is associated with early death. While the precise role of PMP22 in the plasma membrane is not known our recent results indicate involvement in the establishment of lipid rafts (Lee et al., 2014). As cholesterol is a critical component of lipid rafts, here we investigated cholesterol trafficking in the absence of PMP22 using cells and tissue from PMP22-deficient mice. Morphological examination of liver from PMP22-deficient mice shows hepatosteatosis as detected by Oil red O staining, and abnormal clustering of filipin-cholesterol. In cultured primary hepatocytes from wild type animals, filipin-cholesterol is localized at zonula occludens (ZO1) reactive cell junctions, a pattern that is absent in samples from PMP22-deficient rodents. The Low-density lipoprotein receptor (LDLR), the main receptor that functions in extracellular cholesterol endocytosis, is maintained at normal levels in the liver and nerves from PMP22-deficient mice. Furthermore, the tracing of LDL-endocytosis *in vitro* using a BODIPY-LDL complex suggests cholesterol uptake by Schwann cells is not affected in the absence of PMP22. Concerning the cholesterol efflux pathway, the expression of the ATP-binding cassette transporter (ABCA1) is significantly elevated in the liver, in cultured hepatocytes, and in nerves and Schwann cells of affected mice. Conversely, the expression and processing of PMP22 are altered in nerve samples from ABCA1-deficient rodents. At steady-state, in the absence of ABCA1, PMP22 expression is elevated, and only around 50% of PMP22 contains complex carbohydrate modification, in comparison to over 80% in nerve samples from wild-type mice. Taken together these findings suggest a novel role for PMP22 in cholesterol trafficking through the interplay with ABCA1.

Title: Diphenylhydantoin increases proliferation of neural precursor cells and oligodendrocyte differentiation and enhances p-EGFR and p-FGFR expression in the sub ventricular zone.

Authors: *O. GONZALEZ-PEREZ[1], A. GALVEZ-CONTRERAS[2], R. GONZALEZ CASTANEDA[2], T. CAMPOS-ORDONEZ[1], V. LOPEZ-VIRGEN[1], N. MOY-LOPEZ[1], J. GUZMAN-MUNIZ[1], Z. AGUIRRE-TABOADA[1];
[1]Psicologia/University of Colima, Colima, Mexico; [2]Neurosci., Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Diphenylhydantoin, also known as diphenylhydantoin, is an antiepileptic drug that induces cell proliferation in several tissues such as: heart, bone, skin, oral mucosa and neural precursors. Some of these effects appear to be mediated via fibroblast growth factor (**FGFR**) and epidermal growth factor receptor (**EGFR**). These receptors are strongly expressed in the adult ventricular-subventricular zone (**V-SVZ**), the main neurogenic niche in the adult brain. The aim of this study was to determine the proliferating cell lineage and cell fate of V-SVZ neural progenitors expanded by diphenylhydantoin, as well as the effects of this drug on EGFR/FGFR phosphorylation. Male Balb/C mice received 10 mg/kg diphenylhydantoin by oral cannula for 30 days and 100 mg/kg BrdU i.p. 24 h before sacrifice. We analyzed the proliferation of V-SVZ neural progenitors by immunohistochemistry and western blot. diphenylhydantoin-treated animals showed ~two-fold increase in the phosphorylation in the V-SVZ as compared to controls. We also found that diphenylhydantoin treatment increases the number of BrdU+/Sox-2+ and BrdU+/DCX+ cells in the V-SVZ and expands the population of Olig2-expressing cells around the lateral ventricle. After diphenylhydantoin removal, we found a high number of BrdU+/RIP+ in the olfactory bulb of the diphenylhydantoin group. In conclusion, diphenylhydantoin enhances the phosphorylation of FGFR and EGFR and promotes the expression of neural precursor markers in the V-SVZ. Upon diphenylhydantoin removal, the number of BrdU+ oligodendrocytes increases, whereas the proportion of BrdU+/NeuN+ neurons decreases in the olfactory bulb. In conclusion, diphenylhydantoin enhances the phosphorylation of FGFR and EGFR and promotes the expression of neural precursor markers in the V-SVZ. In parallel, the number of oligodendrocytes increases significantly after diphenylhydantoin removal. **Keywords:** Neural stem cells; Epidermal growth factor receptor; Fibroblast growth factor receptor; Sox2; oligodendrocyte; Olig2; Diphenylhydantoin.

Abstract: Remyelination, the restoration of myelin sheaths around axons denuded by a demyelinating insult, is a unique regenerative process occurring in the Central Nervous System (CNS) of vertebrates. At the core of this process is the adult oligodendrocyte progenitor cell (aOPC), a multipotent cell widespread throughout the CNS. Although the presumed default fate of the aOPC is to become a myelinating oligodendrocyte, fate-mapping studies have shown that in the appropriate environment, the OPC is also capable of becoming an astrocyte or a Schwann cell. How and why these fate choices arise is currently unknown. We hypothesized that each OPC responding to a demyelinating insult will have a pattern of gene expression reflecting and in part determining its ultimate fate. Therefore, interrogating the transcriptional profile of single OPCs would not only reveal their fate, but also provide clues about the mechanism of fate determination.

Using a rodent focal toxic demyelinating model (the rat ethidium bromide caudal cerebellar peduncle lesion), we have designed a protocol to acutely interrogate gene expression in single remyelinating aOPCs using single cell RNAseq and single cell high throughput qRT-PCR. We have compared these expression profiles to those of aOPCs residing within unlesioned white matter of the the same animal, and the white matter of unlesioned animals.

Our studies have revealed marked heterogeneity within remyelinating aOPCs, and revealed both

similarities and differences in gene expression between aOPCs in the immediate and distant demyelinated environment, and those in intact white matter. We have identified a subpopulation of aOPCs expressing markers typical for astrocytic and Schwann cell fate. We are currently analyzing their transcriptome in search for mechanistic determinants and pathways associated with this fate choice, and are hoping to confirm these findings in the immediate future.

Title: The function of microRNA-33 in the brain and its implication for brain diseases

Authors: ***H. YOON**[1,2], J. KIM[2], K. C. BELMONTE[2], J. KIM[2];
[1]Neurobio. of Dis., Mayo Grad. Sch., Jacksonville, FL; [2]Dept. of Neurosci., Mayo Clin., Jacksonville, FL

Abstract: MicroRNAs are small noncoding RNAs that regulate gene expression either by inducing mRNA degradation or by inhibiting translation. ATP-binding cassette transporter A1 (ABCA1) is a cholesterol transporter that has been studied as a therapeutic target for Alzheimer's disease (AD). Recently, we demonstrated that microRNA-33 (miR-33) regulates the expression of ABCA1 in the peripheral tissues and in the brain. More importantly, we also found that

inhibition of miR-33 increased the ABCA1 level and cholesterol efflux, leading to decrease in the cortical Aβ level. Our *in vivo* and *in vitro* data strongly suggested that inhibition of miR-33 may be a promising therapeutic strategy for AD. To further investigate the novel functions of miR-33 in the brain, we performed an unbiased large scale gene expression study. Microarray data analysis of the mir-33 gene deficient brain samples revealed that 42 genes were up-regulated and 168 genes were down-regulated (fold change>1.35, p-value<0.05). The systemic analyses of the differentially expressed genes suggested that mir-33 may be involved in the regulation of myelination. Furthermore, we were able to predict putative direct targets of miR-33 based on the publicly available prediction algorithms and the up-regulated genes from our array data. Our studies may provide a new insight into the role of miR-33 in the brain.

Title: Pericyte deficiency leads to white matter demyelination and axonal degeneration

Authors: *A. M. NIKOLAKOPOULOU, A. MONTAGNE, Z. ZHAO, G. SI, D. LAZIC, A. P. SAGARE, B. V. ZLOKOVIC;
Physiol. and Biophysics, USC, Los Angeles, CA

Abstract: White matter damage is a characteristic of a plethora of neurodegenerative diseases, such as Alzheimer's disease (AD) and Multiple Sclerosis (MS). Pericytes play an important role in sustaining blood brain barrier (BBB) permeability and cerebral blood flow (CBF), while they participate in the clearance of toxic byproducts. Pericyte loss has been implicated in BBB breakdown, neuronal degeneration, cognitive impairment, inflammation, synaptic loss and has negative effects on CBF. In this study, we used $Pdgfr\beta^{F7/F7}$ mice to examine the effects of pericyte deficiency on white matter integrity, and more specifically, in the corpus callosum. Our data show that pericyte deficiency leads to early BBB leakage, which precedes demyelination and axonal degeneration; at early stages in adulthood (4wks old) animals present accumulation

of blood byproducts (IgG and fibrin), however they show no defects in myelin and axonal integrity yet. On the other hand, adult *Pdgfrβ*$^{F7/F7}$ mice (12-16wks old) exhibit a decrease in myelin thickness, as shown by electron microscopy, and a reduction in axonal and myelin-related protein expression, both of which deteriorate with aging. Furthermore, these animals exhibit behavioral deficits related to white matter damage. Previous studies have shown that hypoxia can induce coagulation and thus the formation of fibrin deposits, events that are responsible for oligodendrocyte death. Our in vitro oligodendrocyte studies show that oxygen/glucose deprivation (OGD) and fibrin accumulation can cause mature oligodendrocyte death, hence implying that the events following BBB leakage are responsible for myelin destruction. To strengthen our results, we show that fibrinogen depletion can restore myelin integrity and reverse axonal damage. Taken together, our results show that pericyte deficiency causes BBB leakage at very early stages, followed by myelin destruction and axonal degeneration, thus emphasizing the importance of the neurovascular unit in health and disease.

Title: A co-ultramicronized N-palmitoylethanolamine/luteolin composite promotes oligodendrocyte precursor cell survival and development and improves outcome in experimental autoimmune encephalomyelitis

Authors: ***S. D. SKAPER**[1], M. BARBIERATO[2], L. FACCI[2], G. CONTARINI[2], C. MARINELLI[2], M. ZUSSO[2], P. GIUSTI[2];
[1]Univ. of Padua, Padova, Italy; [2]Pharmaceut. and Pharmacol. Sci., Univ. of Padua, Padua, Italy

Abstract: Oligodendrocytes, the myelin-producing cells of the CNS have limited ability to repair damage either to themselves or to other nerve cells. Such is the case in multiple sclerosis (MS), a chronic CNS neuroinflammatory demyelinating disorder. MS lesions are characterized by the presence of a compromised pool of undifferentiated oligodendrocyte precursor cells

(OPCs) which fail to mature into myelin-producing oligodendrocytes. An attractive strategy may thus be to replace lost oligodendrocytes and/or promote their maturation or proliferation. N-palmitoylethanolamine (PEA), an endogenous fatty acid amide signaling molecule possesses analgesic, anti-inflammatory, and neuroprotective actions. Recent studies show a co-ultramicronized composite of PEA and the flavonoid luteolin (co-ultraPEALut, 10:1 by mass) to be more efficacious that PEA alone in improving outcome in CNS injury models. Here, we examined the effects of co-ultraPEALut on the survival and development of OPCs isolated from newborn rat cortical mixed glial cell cultures. OPCs were maintained under conditions which favored either proliferation (FGF-2 and PDGF-AA-supplemented serum-free medium ('SFM')) or differentiation (Sato's medium containing T3 and T4). OPCs cultured in SFM displayed high expression of PDGF receptor alpha gene and improved survival in the presence of 10 μM co-ultraPEALut and down-regulation of *Apoe*, whose deletion reportedly leads to a later time of peak symptoms/disease severity and less severe demyelination/axonal damage in myelin oligodendrocyte glycoprotein (MOG35-55)-induced experimental autoimmune encephalomyelitis (EAE) in female C57BL/6 mice. In Sato's medium OPCs showed a rapid decrease in PDGF receptor alpha expression and time-dependent rise in myelin basic protein (MBP) expression. In these conditions co-ultraPEALut (10 μM) enhanced OPC morphological complexity, protein content, and gene expression for MBP, proteolipid protein and 2',3'-cyclic nucleotide 3'-phosphodiesterase, as well as genes coding for enzymes involved in cholesterol and fatty acid synthesis. Co-ultraPEALut also increased OPC content of MBP, while protecting against TNF-α-induced suppression of MBP gene expression. Moreover, co-ultraPEALut improved the clinical score in this EAE mouse model, which is often used as a chronic first-pass model of MS. Hence, strategies intended to promote endogenous remyelination in MS should focus on both enhancing the long-term survival of OPCs and on stimulating these cells to proliferate and differentiate into remyelinating oligodendrocytes. Within this context, co-ultraPEALut may represent a novel pharmacological approach.

Title: The TAM receptor Tyro3 is a regulator of central nervous system myelination

Authors: ***M. D. BINDER**[1], R. AKKERMANN[2], A. A. PERERA[1], H. BUJALKA[2], A. APRICO[1], J. FIELD[1], T. J. KILPATRICK[1];
[1]Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia; [2]Anat. and Neurosci., Univ. of Melbourne, Parkville, Australia

Abstract: There is an emerging consensus that the progression of disability in MS correlates with the accumulation of axonal degeneration, which in turn is influenced by the extent of demyelination and the loss of oligodendrocytes. Therefore there is a clear need to identify and validate targets that can form the basis for the development of novel treatments that can potentiate remyelination and either slow or prevent disability progression in Multiple Sclerosis. We have previously identified that Gas6, a ligand for a family of tyrosine kinase receptors known as the TAM (Tyro3, Axl and Mertk) receptors, directly increases myelination *in vitro*, and that loss of Gas6 leads to increased disease severity and to delayed recovery in an animal model of CNS demyelination. We therefore hypothesised that the pro-myelinating effect of Gas6 is mediated through Tyro3. In order to test this hypothesis we utilised mice which were deficient in this receptor ($Tyro3^{-/-}$). We found that developmental myelination was delayed in these mice compared with WT littermates, and that oligodendrocytes derived from these mice have a reduced capacity to myelinate neurons *in vitro*. Further, we identified extracellular signal related (Erk) 1 as downstream target of the Gas6-Tyro3 axis in oligodendrocytes. In summary, we have shown, for the first time, that Tyro3 is an important regulator of myelination by oligodendrocytes, and this effect may be mediated by activation of Erk1.

Title: The selective mGluR group I agonist, 2-chloro-5-hydroxyphenylglycine, increases BDNF and oligodendrocyte differentiation following cuprizone-induced demyelination

Authors: *K. S. SAITTA[1,2], Y. HUANG[1], C. VARGHESE[1,3], C. DREYFUS[1];
[1]Dept. of Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; [2]Joint Grad. Program in Toxicology, Rutgers Univ., Piscataway, NJ; [3]Rutgers Grad. Sch. of Biomed. Sci. at Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: The demyelinating agent cuprizone (0.2%) causes a decrease in brain-derived neurotrophic factor (BDNF) and myelin proteins in mice after 4 weeks of treatment. Similarly, patients with relapsing-remitting multiple sclerosis have decreased levels of BDNF in addition to decreased myelin proteins. Therefore, an intriguing therapeutic approach for these types of demyelinating diseases may be to enhance the endogenous source of BDNF. In previous studies, we found that the Group I and Group II mGluR agonist, ACPD, was able to enhance the expression of BDNF and myelin proteins when injected directly into the corpus callosum following demyelination. The aim of this study was to expand this concept to the selective mGluR Group I agonist, 2-chloro-5-hydroxyphenylglycine (CHPG), by using the more clinically relevant approach of a peripheral injection. Cuprizone or identically processed control feed was fed to mice for 4 weeks starting at 8 weeks of age prior to intraperitoneal injections of saline vehicle or CHPG (20 or 40 mg/kg). Western blot was used to analyze the levels of BDNF, myelin proteins, and oligodendrocyte progenitor cell markers. CHPG increased levels of BDNF and myelin proteins 24 hours after injection and this effect lasted up to 3 days. Myelin proteins increased without increases in CC1+ oligodendrocytes, suggesting that CHPG increases myelin proteins per cell. Additionally, cuprizone treatment causes an increase in oligodendrocyte progenitor cell markers NG2 and PDGFRα, which were reduced after CHPG administration. Interestingly, CHPG did not alter these proteins or myelin proteins in control-fed mice. Taken together, these data suggest that selective mGluR Group I agonists such as CHPG may be a therapeutic approach for treating demyelinating diseases by increasing the levels of BDNF and myelin proteins possibly by promoting differentiation of oligodendrocyte progenitor cells.

Abstract: The G-protein-coupled receptor (GPCR) GPR17 is a key player in oligodendrogenesis and a promising target for demyelinating diseases [Fumagalli et al, 2015 Neuropharmacology]. A spurious pharmacology has been reported for both GPR17 and some phylogenetically related GPCRs, including chemokine receptors (CXCRn). Specifically, GPR17 can be activated by several different molecules, including extracellular nucleotides, cysteinyl-leukotrienes and oxysterols acting as emergency signals in local reparative processes, inflammatory reactions and neurodegenerative disorders [Ciana et al 2006, Embo J; Sensi et al 2014, Cell Signal]. Whether GPR17 can be also activated by typical CXCRn ligands like Stromal Derived Factor 1 (SDF1) has not been studied before. Of note, GPR17 is necessary to start oligodendrocyte precursor cells (OPC) differentiation, but, at subsequent maturation stages, it has to be downregulated to allow cells to start myelination.
Here, we analyzed the potential interaction between SDF1 and GPR17 and its involvement in demyelinating diseases. In vitro studies, in both a classical reference assay for GPCR activity and in a model of primary OPCs maturation, showed that SDF-1 can indeed promote OPC transition to fully mature cells by directly acting as a GPR17 agonist. This interaction was further unveiled by computational approaches showing two distinct binding sites for SDF1 on GPR17, like for peptide receptors.
These data provide the basis for deciphering our in vivo data obtained in the multiple sclerosis (MS) murine model of experimental autoimmune encephalomyelitis (EAE). In EAE mice, we found a marked and persistent upregulation of GPR17 in the OPCs accumulating at demyelinating lesions; in a similar way, in autoptic samples from MS patients, many GPR17-positive activated cells accumulated at the border of active lesions in parallel with a marked increase of SDF1 levels [Calderon et al 2006, J Neuroimmunology]. Conversely, no GPR17 upregulation was found in a model characterized by a much lower degree of inflammation, i.e., cuprizone-induced demyelination model. Thus, SDF1 may represent one of the key inflammatory factors triggering a persistent upregulation of GPR17 in both rodent EAE and human MS. We speculate that, as a results of chronic inflammation, SDF1 accumulating at demyelinating lesions markedly upregulates GPR17, thus preventing its physiological downregulation, that would, in turn, inhibit terminal OPC maturation to myelinating cells. These findings may have implications for the design of novel pharmacological approaches aimed at overcoming the re-myelination block typical of chronic demyelinating diseases.

Title: Lipid abnormalities in myelinated nerves of Trembler J neuropathic mice

Authors: ***A. I. FETHIERE**, Y. ZHOU, E. SOTO, L. NOTTERPEK;
Neurosci., McKnight Brain Inst., Gainesville, FL

Abstract: The Trembler J (TrJ) mouse harbors a non-conservative leucine to proline mutation in peripheral myelin protein 22 (PMP22) and models early onset dysmyelinating neuropathy. Peripheral nerves of young heterozygous animals contain abnormally thin myelin, which progress to demyelination in adulthood. Reduced expression and altered localization of Schwann cell and axonal proteins have been described in affected nerves, however much less is known about potential changes in lipid metabolism related molecules. In this study we investigated the expression and localization of cholesterol metabolism related proteins and the distribution of various myelin lipids. Sciatic nerves from young adult genotyped male and female mice were collected and used for morphological and biochemical studies. Western blot analysis of whole nerve lysates identified significant increases in the levels of apolipoprotein E (ApoE), ATP-binding cassette protein A1 (ABCA1), and lipoprotein receptor-related protein 1 (LRP1) in affected nerves, as compared to wild-type (WT). To investigate the cellular source for the elevated ApoE, we double immunolabeled nerve sections with anti-ApoE and anti-CD11b antibodies. In agreement with previous studies, there is an increase in the number of CD11b positive macrophages in affected nerves, as compared to age-matched WT, and these immune cells are reactive for ApoE. Microscopic analysis of polar and non-polar lipids using Nile Red, a lipophilic stain, on nerve sections revealed substantial decrease in overall lipid-associated signal, which can be attributed to the hypomyelinated state of the TrJ nerves. In addition, we observed clumped, irregular distribution of lipids in the neuropathic nerves. Utilizing filipin, a fluorescent dye that specifically binds to cholesterol, we observed irregular and clustered cholesterol distribution on affected TrJ nerves. Furthermore, filipin staining on TrJ Schwann cells shows

limited transport of cholesterol to the plasma membrane with the majority localized around the perinuclear area, as compared to WT. Together, the upregulation of proteins involved in lipid trafficking and the irregular lipid distribution in TrJ nerves suggest that the intracellular aggregation and altered trafficking of the mutant PMP22 impacts lipid homeostasis.

Title: A model of failed remyelination demonstrates a crucial role of new oligodendrocytes on motor recovery and preservation of axons.

Authors: ***G. J. DUNCAN**[1], B. J. HILTON[2], P. ASSINCK[3], J. R. PLEMEL[7], F. G. W. MUIR[4], R. HIRATA[5], S. NADERI-AZAD[3], A. LIM[3], M. WEGNER[6], D. E. BERGLES[8], W. G. R. MOORE[4], W. TETZLAFF[2];

Abstract: Demyelinating inflammatory lesions are the hallmark of multiple sclerosis (MS). Remyelination can occur but this process is often incomplete resulting in the chronic demyelination of axons. The failure to remyelinate, has been correlated with increased axonal damage which is thought to underlie progressive disability. In contrast to MS, remyelination in rodents following chemical demyelination is typically rapid and efficient. Therefore, there is need of an animal model that selectively inhibits oligodendrocyte maturation while leaving other cellular responses to demyelination unaltered. Such a model would allow for the exploration of the role of remyelination in axonal health, the mechanisms by which chronically demyelinated axons are lost, and for testing the effectiveness neuroprotective therapies on preserving demyelinated axons. Remyelination requires the recruitment and maturation of oligodendrocyte precursor cells (OPCs) into new oligodendrocytes, and selectively blocking this process would

halt remyelination. Previously, we found the inducible deletion of a crucial transcription factor for myelination from OPCs, myelin regulatory factor (Myrf), inhibits new oligodendrocyte production and impairs subsequent remyelination. These mice, combined with cuprizone/rapamycin demyelination, should permit the modelling of impaired remyelination *in vivo* without altering inflammation or astrogliosis directly. $Myrf^{fl/fl}$ PDGFRa CreER (Myrf iCKO) and $Myrf^{fl/fl}$ controls were injected daily with rapamycin (10mg/kg) and fed a diet containing 0.3% cuprizone for six weeks to induce near complete demyelination of the medial corpus callosum, then returned to a normal diet to permit remyelination. In the fifth week of cuprizone intoxication, the mice were injected with tamoxifen to delete Myrf from OPCs. In contrast to tamoxifen-treated control mice, Myrf iCKO mice did not demonstrate accumulation of new oligodendrocytes when returned to a normal diet. Electron microscopy and immunohistochemical stains reveal little evidence of remyelination. Myrf iCKO mice exhibited reduced motor coordination as assessed on the Rotarod following cuprizone demyelination. The number of SMI31+ axons was decreased in the corpus callosum of Myrf iCKO mice, suggesting new oligodendrocytes are crucial for preservation of phosphorylated neurofilament positive axons. The density of microglia and astrocyte reactivity was examined, as was the number of SATB2+ neurons. Myrf iCKO mice combined with cuprizone demyelination will offer new insights into the mechanisms and consequences of failed remyelination on axonal preservation and functional outcomes.

Title: Axon initial segment changes in a potential new mouse model of Multiple Sclerosis

Authors: *D. Z. RADECKI[1], C. R. RICHARDSON[1], A. BROWN[6,2], S. PERRINE[3], A. GOW[1,4,5];
[1]Ctr. for Mol. Med. and Genet., [2]Summer Undergraduate Res. Program, [3]Psychiatry and Behavioral Neurosciences, [4]Dept. of Neurol., [5]Carman and Ann Adams Dept. of Pediatrics, Wayne State Univ. Sch. of Med., Detroit, MI; [6]Loyola Marymount Univ., Los Angeles, CA

Abstract: Multiple Sclerosis (MS) is a demyelinating disorder of the CNS for which secondary gray matter (GM) damage, including lesions and progressive neurodegeneration, is reemerging as an integral component of the pathophysiology. To investigate this secondary GM damage, our laboratory developed the novel *OBiden* (*OBi*) mouse model of MS pathology. In *OBi* mice, we generate primary, episodic metabolic stress in oligodendrocytes (OLs), whereby this primary white matter (WM) pathology damages neurons and causes GM changes reminiscent of MS. First gliosis, defined by significant activation of microglia, is observed in multiple WM tracts, likely arising as these cells remove cellular debris from stressed or dying OLs. Second, we observe similar overall degenerative changes in MS normal appearing GM (NAGM) and *OBi* cortex, such as increases in non-phosphorylated neurofilaments without changes to general neuronal or synaptic integrity markers. We also find changes to the axon initial segment (AIS), the trigger zone for action potentials, which comprises shortened AISs in rostral entorhinal and perirhinal cortices of *OBi* mice. Also, we observe changes to the specific ion channel variant, potassium channel 7.2 (Kv7.2), a modulator of basal firing rate in neurons. However, the predominant change is seen in the CA1 layer of dorsal and ventral hippocampus, with a significant decrease in Kv7.2 signal on western blots and diminished fluorescence staining in the AIS. These changes appear to manifest as behavioral changes in *OBi* mice. Specifically, a learned helplessness (LH) depression-like endophenotype develops by 6 months of age and is maintained until at least 12 months, indicating dysfunction in hippocampal processing pathways. 12 month old *OBi* mice show deficits in two tests specific for short term memory function; novel object (N.O.) testing and a win-shift T-maze foraging paradigm. In N.O. testing, *OBi* mice fail to distinguish a novel object from a familiar object. The win-shift T-maze trains mice to alternate between goal arms of a standard T-maze to follow a food reward. Twelve month *OBi* mice show an inability to shift (alternate) arms on successive trials, again suggesting a deficit in working or short term memory. Together, this data demonstrate that *OBi* mice develop significant secondary GM changes from primary WM pathology in OLs with parallels to MS molecular and cognitive pathology.

Title: Behavioral recovery due to knock out of alpha-synuclein in a mouse model of Krabbe disease

Authors: *M. S. MARSHALL[1], Y. ISSA[2], V. ELACKATTU[2], B. JAKUBAUSKAS[2], F. CARDOZO-PELAEZ[3], E. R. BONGARZONE[2];
[1]Univ. of Illinois At Chicago COM, Chicago, IL; [2]Anat. and Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [3]Dept. of biomedical and pharmaceutical sciences, Univ. of Montana, Missoula, MT

Abstract: Infantile Krabbe disease is a devastating genetic disorder, which causes progressive demyelination of the central and peripheral nervous system, neurosensory deficits, muscle atrophy, and early death. Krabbe disease is due to loss-of-function mutations in the gene encoding for the lysosomal enzyme Galactosylceramidase (GALC). This results in the toxic accumulation of one of its lipid substrates, galactosyl-sphingosine (or psychosine).
We have recently identified the presence of psychosine-induced intraneuronal aggregates of mis-folded alpha-synuclein (α-syn) in the brains of both the Twitcher (TWI) mouse, the natural murine model of KD, and human KD patients. This finding is remarkable because KD patients show movement symptoms similar to many of the hallmark symptoms in another adult movement disorder and alpha-synucleinopathy, Parkinson's disease (PD). Additionally, the accumulation of these aggregates within the substantia nigra of the TWI prompted us to examine the levels of dopamine (DA) in the TWI, which we found to be significantly reduced in the caudate at postnatal ages 15 and 30 days. This suggests that aggregations of alpha-synuclein may be a contributing factor to the pathology of KD.
Alpha-synuclein is known to have influences over the production of dopamine and its synaptic release. To isolate the role alpha-synuclein aggregates play in KD, we created a new mouse model that crosses the twitcher with a knock out of *SNCA*, the gene for alpha-synuclein. This TWI/SNCA-KO animal shows a significant increase in lifespan, body weight, grip strength, and

nesting ability when compared to the twitcher. These mice also displayed an improvement in locomotion and gait. These results suggest that the effects of alpha-synuclein compound the pathophysiology of KD in addition to the already toxic effects caused directly by psychosine. These results provide a new therapeutic target for the treatment of KD and potentially open a new model for studying the detrimental effects of alpha-synuclein aggregation.

Title: Loss of the *Drosophila* khc-73, kinesin-3 family member, causes age-dependent neurodegeneration

Authors: *E. MAKSOUD, E. LIAO, P. HAGHIGHI;
The Buck Inst. For Res. On Aging, Novato, CA

Abstract: Neurodegenerative diseases are currently incurable and are characterized by a progressive loss of neuronal cells. Dysregulation of endosomal dynamics has been suggested as one of the common causes of a number of degenerative disorders such as Parkinson's disease, amyotrophic lateral sclerosis and hereditary spastic paraplegia. Tight regulation of endosomal trafficking is essential for appropriate signaling at the synapse and efficient transport of cellular cargoes from the soma to the processes and vice versa. We have recently generated mutations in the fly *Khc-73* gene, a member of the kinesin superfamily and a homolog of the human *Kif13B*, which leads to defects in the retrograde routing of late endosomes from synaptic terminals to the retrograde pathway in motoneurons. *Khc-73* loss of function mutant flies appear normal in the first few days following hatching, but soon develop climbing and flying defects. One of the hallmarks of neurodegeneration is the detection of lesions in the brain that appear as vacuoles in histological sections. Compared to age-matched control flies, *Khc-73* mutant flies showed strikingly increased numbers of vacuoles and larger vacuoles in histological brain sections. This severe degeneration was fully reversed in *Khc-73* mutant flies when we genetically introduced a genomic copy of the *Khc-73* gene. In order to determine the tissue requirement for *Khc-73*, we took advantage of a transgenic RNA interference approach, and showed that knock down of *Khc-73* in neurons, but not in glial cells, was capable of recapitulating the phenotype in *Khc-73* loss

of function mutants. Finally, to rule out a developmental role for *Khc-73* we verified the temporal requirement of *Khc-73* by knocking it down only after birth in adult flies. Temporally restricted knock down of *Khc-73* in adult neurons also led to a severe neurodegeneration reminiscent of the loss-of-function phenotype. These results indicated that *Khc-73*'s function is required in neurons to ensure their healthy aging and to prevent early onset neurodegeneration in adult flies. Based on the role of *Khc-73* as a regulator of endosomal trafficking, our findings provide strong evidence that disruptions in endosomal trafficking during aging may result in accumulative damage in neurons and ultimately trigger neurodegeneration.

Title: Banking the brain & blood: A Sri Lankan emerging era of collaborative research; what East can offer the West

Authors: *R. DE SILVA;
Univ. of Sri Jayewardenepura, Nugegoda, Sri Lanka

Abstract: Introduction: Variations in the genetic dispositions, influenced by environmental factors including diet, natural products, lifestyle factors, ethnicity and culture have profound influence in: differential responses in clinical settings, neurobiologic biomarkers that may be associated with neurological diseases. The human brain bank and DNA repository established in Sri Lanka, is one of the largest bio-banks in the Indian subcontinent that could facilitate as a cornerstone in translational neuroscience. **Objectives**: To facilitate the access of biological resources of South Asia and support high-quality multidisciplinary research collaborations in neuroscience understanding the diversity of neurological disorders, bridging the East and the West. **Method:** Anatomico-pathological studies performed in cerebral arteries of 447adult and 34 fetal postmortem brains and gene expression studies in 6 cerebral arteries. Age-related cytoskeletal pathologies in 76 aging and diseased human brains using histopathological/ immunohistochemical techniques for tau and β-amyloid biomarkers, and vascular genetic variants: apolipoprotein E, angiotensin converting enzyme, methylenetetrahydrofolatereductase (MTHFR C677T) and Factor V Leiden (FVL G1691A). A bio-repository of DNA bank

established with socio-demographic and clinical data of over 2,000 patients with; [Stroke n=1200, Parkinson's Disease (PD) n=250, Duchenne Muscular Dystrophy (DMD) n=130, Spinal Muscular Atrophy (SMA) n= 40, Huntington's Disease (HD) n=41, Spinocerebellar Ataxia (SCA) n= 49] and controls n=500. We possess unique samples; genetically confirmed monozygotic DMD twins (7th reported worldwide), PD patients with heavy metal & pesticide exposure and three villages located in the southern part of Sri Lanka with SCA type 1. **Results:** Burden of Alzheimer's disease related pathologies in aging brains did not show a significant difference between the East and West, significant anatomical variations in the circle of Willis and vascular genetic variants were seen among intra and inter ethnic groups, will be discussing how the bio-bank could offer novel insights in determining the ateiology of neurodegenerative and neuromuscular disorders, stroke and suicide. **Conclusion:** Anatomical, pathological and genetic variation between East and West is possibly due to genetic, racial, regional, environmental and dietary factors or a combination of any of the above, warrants further multidisciplinary collaborative studies between West and East, culture unique to East may lead to the development of preventive therapeutics, nutraceuticals that could promote healthy brain aging.

Title: Do over-the-counter brain supplements alleviate neurodysfunction? An extensive trial using the spastic Han Wistar rat, a model of ataxia

Authors: *R. A. HERNANDEZ[1], C. T. LAO[2], M. GARCIA[2], D. A. DICKEY[2], R. W. COHEN[2];
[1]California State Univ. Northridge, Granada Hills, CA; [2]California State Univ. Northridge, Northridge, CA

Abstract: As an alternative to current drug, stem cell, and physical therapies, there are numerous forms of over-the-counter brain supplements. The projected benefits of using these brain supplements for numerous of brain injuries, including concussion, Parkinson's and Alzheimer's, have been proclaimed by their manufacturers to augment the effectiveness of pharmaceutical

drugs. The brain supplement we utilized in our project is made up of natural compounds such as niacin, acetyl- L-carnitine, phosphatidylserine, inositol, and choline that have been found to increase neuroprotection in many disorders. The goal of our project was to evaluate the effectiveness of an over-the-counter brain supplement on an animal model of cerebellar ataxia. The *spastic* Han-Wistar rat carries an autosomal gene mutation that induces various symptoms of ataxia, including forelimb tremor and hind limb rigidity. Studies in our laboratory have shown that the symptoms of the spastic Han Wistar rat originate from progressive Purkinje cell death. The symptoms of the spastic Han Wistar rat are evident beginning at age 25-30 days. Progression of the disorder eventually leads the rats to malnutrition and dehydration, due to aforementioned symptoms of ataxia that ultimately leads to their death at 65-70 days. Utilizing this animal model, we tested one over-the-counter brain elixir or vehicle on both normal and mutant rat groups (n=10 for treatment; equal mix of males and females). We randomly chose Han-Wister rats at 28 days old (control mutant and normal siblings) and began feeding elixir or vehicle (sucralose) daily (0.7mg/kg; per os). Rats were dosed daily until the mutant's date of death. We tested the decline in motor activity of the treated animals weekly using the rotorod and open field activity tests. Our results showed that mutants treated with a brain supplement had a slightly longer lifespan and had a slight incline for Rotorod test. For the Open field, the mutant groups showed signs of decline overtime. The effects of brain supplements on this animal model of ataxia show low impact on performance.

Title: Effect of bexarotene on locomotor activity, learning and memory and dendritic morphology in old mice

Authors: *E. MONROY HERNÁNDEZ, ESQ[1], F. DE LA CRUZ[3], G. FLORES[2];
[2]Inst. de Fisiología, [1]Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [3]Dept. de Fisiologia, Escuela Nacional de Ciencias Biologicas, Inst. Politecnico Nacional, Mexico, Mexico

Abstract: Bexarotene, a compound has been suggested as a neuroprotective in Alzheimer's disease. However its mechanism of action has not been fully described. Increasing age, leaves individuals at risk for neurodegenerative disorders like Alzheimer's disease. Although the vast majority of older adults do not develop dementia, usually some degree of cognitive change is experienced. The main objective of this work was to investigate changes in behavior and its correlation with neuronal morphology of the hippocampus, nucleus accumbens (NAcc) and prefrontal cortex (PFC) caused by the administration of bexarotene in old mice. For this, we administered intraperitoneally with repeat doses of bexarotene (0.0, 0.5, 2.5 and 5 mg/kg) for 21 days to 18 months male mice. A behavioral level, locomotor activity, and learning and memory was evaluated in the Morris water maze test. Neuronal morphology was evaluated using Cox Golgi staining. The results showed that mice administered with 5 mg/kg of bexarotene had increased locomotor activity, there is no significant differences in memory and learning test between animals administered with bexarotene; whereas in dendritic arborization, NAcc hypertrophy was found in the group with administration of 2.5 mg/kg of bexarotene, without differences in the density of spines compared with the control group and there were no change in hippocampal neuronal cytoarchitecture and PFC. The administration of bexarotene in senile mice did not offset the effects associated with aging in learning and in memory, although there was greater locomotor activity in the group administered with the dose of 5 mg/kg of bexarotene compared to the control group.

Title: FTO gene and BMI interact to predict white matter integrity in late middle age and older adults

Authors: ***A. STICKEL**[1], K. WALTHER[3], M. HUENTELMAN[4], L. RYAN[2];
[1]Psychology, [2]Univ. of Arizona, Tucson, AZ; [3]Psychology and Neuropsychology, Ludwig Maximilians Univ., Munich, Germany; [4]Translational Genomic Res. Inst., Phoenix, AZ

Abstract: Unhealthy weight affects approximately two-thirds of Americans. In addition to lifestyle factors, genetics may contribute to unhealthy weight. The Fat Mass and Obesity (FTO) gene was one of the first to be linked to weight and is highly expressed in the brain. Both FTO and body weight have been associated with individual differences in brain structure and cognition (Ryan et al., 2014; Ho et al., 2010), but few studies have considered the combination of these two factors. The present study examined the combined contributions of FTO allele (rs1421085) and body mass index (BMI) on white matter integrity, controlling for age. Diffusion MRI scans (25 directions) were obtained from 128 adults (ages 52-92) on a 3T Skyra with a 32 channel head coil. In order of increasing risk for increased body weight, the study included FTO T-homozygotes (n = 43), T heterozygotes (n = 62), and C-homozygotes (n = 23). FTO groups were matched on gender, age, education, and percent hypertension. Phenotype was controlled by matching the groups on BMI (average BMI = 26, range = 18 to 45). Fractional anisotropy (FA), radial diffusivity (RD), and axial diffusivity (AD) values were calculated and compared on a voxel-by-voxel basis across segmented white matter maps in SPM8. Clusters were identified that showed a significant interaction between FTO and BMI, while controlling for age ($p < .05$, $k > 50$). While no interactions were observed for FA, an interaction was found for AD in the splenium: as BMI increased, AD decreased in the CC group but not the T carrier groups. Interactions were also observed for RD within the corticospinal tract, the splenium, and the anterior cingulate. Contrary to expectations, as BMI increased in each region, radial diffusivity decreased in the CCs, while T carrier groups showed no association between BMI and RD. The results suggest that CCs – individuals with the highest risk for obesity – have greater BMI-related changes in white matter diffusion relative to T carriers, beyond the changes associated with normal aging and BMI alone. The pattern of change is surprising. In most studies, damage to white matter is associated with increases in RD. Here, we find the opposite – increasing BMI is associated with decreased RD values. This finding might suggest enhanced myelin in these individuals (Song et al., 2003). Alternatively, at least one study (Elvsåhagen et al., 2015) has reported decreases in RD after sleep deprivation, and note that RD may be sensitive to other aspects of white matter including cell membrane permeability, axon diameter, tissue perfusion or glial processes. Our findings warrant future investigations into the pattern of white matter change associated with the FTO gene.

Title: The effects of long term treatment with withania somnifera on cognitive function

Authors: *S. ALI[1], A. LI[2], J. MARTINEZ[2], G.-A. LETICIA[2], I. VASQUEZ[2], A. MADIRA[2], E. CUELLAR[2], M. CANDELARIO[2], J. M. REYES-RUIZ[3], A. RUSSO-NEUSTADT[2];
[1]Biol., [2]California State University, Los Angeles, Los Angeles, CA; [3]Univ. of California, Irvine, Irvine, CA

Abstract: *Withania somnifera* is an adaptogenic herb that has been traditionally used in the Indian Ayurvedic medical system for thousands of years. It has been found to have many beneficial properties, such as promoting relaxation, improving muscle strength, and exhibiting neuroprotective characteristics. Previous studies have suggested that *Withania somnifera* protects the brain against neurodegeneration. We hypothesize that, during the course of aging, long-term treatment with *Withania somnifera* will improve the performance of older rats in cognitive/behavioral tasks, and will also increase the expression of genes associated with learning and memory. The novel object recognition test, which assesses recognition memory through the identification by distinguishing a novel object from a familiar one, was employed in our studies. Briefly, Sprague-Dawley rats were placed in an open field arena in the presence of either two identical objects, or two different objects, one of which was novel after a 24-hour delay. Sprague-Dawley rats that were treated with *Withania somnifera* for fourteen months showed an increase in environmental engagement and higher discrimination index during the novel object recognition test. It was found that *Withania somnifera* treated rats had a mean discrimination index of 0.36 ± 0.05, while the mean discrimination index of the control group was 0.12 ± 0.03. A two-tailed unpaired *t*-test revealed a *p*-value of 0.0013. In order to assess the changes in gene expression during the course of the treatment, RTqPCR analysis of hippocampi from these animals were conducted. RNA was isolated from hippocampal using the RNeasy Kit (Qiagen) and cDNA was generated using the BioRad's iScript cDNA synthesis kit. The resulting cDNA was used as a template to perform qPCR with the SYBR Green mix from Bio-Rad and an iCycler real-time PCR machine. Our analysis revealed an elevation in the expression of glutamate AMPA receptor 2 (about twice the number of transcript vs. control, $p=0.015$, n=8). These results suggest that long term *Withania somnifera* treatment preserves recognition memory and environmental exploration/engagement, and may also enhance gene expression associated with excitation/inhibition balance in the CNS.

Title: The c-terminal domain of the heavy chain of tetanus toxin effects in performance deficits and morphology in aged mice

Authors: *M. PACHECO-FLORES[1], R. VAZQUEZ-ROQUE[2], G. FLORES[2], J. C. PENAGOS-CORZO[4], J. AGUILERA[5], A. DÍAZ[3];

Autònoma de Barcelona, Barcelona, Spain

Abstract: The deficits associated to aging involve a progressive decline in cognitive processes along with morphological alterations, in case of neurological and morphological deficits it has been showed that the prefrontal cortex and hippocampus are altered in aged mice, given the decline observed during aging of systems as learning and memory that correlate to these structures, several studies had target to shown if age-related changes could be offset by certain pharmacological compounds. It has been suggested that the C-terminal domain of tetanus toxin (Hc-TeTx) could be used as a neurotrophic factor involved in the activation of cascades responsible for trophic actions and neuroprotection that results in the amelioration of neurodegenerative processes. In this study we aimed to evaluate the effects of the (Hc-TeTx) treatment on behavioral and neuronal alterations. To assess the behavioral effects we used a paradigm that has been widely used to evaluate attentional and executive functions in rodents, the 5-choice serial reaction time task (5-CSRTT), for morphological evaluation we analyzed the changes in pyramidal neurons of the PFC (Layers III and V) and dorsal Hippocampus (DH), CA-1 and CA-3 regions of 18 month-old mice by using the Golgi-Cox method. In addition, mice were intraperitoneal injected with the recombinant Hc-TeTx protein (40µg/Kg, weekly, for two months). Furthermore, behavioral data showed that the Hc-TeTx group had an improvement in performance compared to the Control group, besides histological analysis showed a recovery effect induced by the Hc-TeTx in PFC and DH neurons. In conclusion, our results suggest that Hc-TeTx could serve as a potential therapy for age-related deficits considering the beneficial effects in behavioral deficits and morphological alterations.

Title: Interactive effects of weekly binge alcohol and exercise on the female brain

Authors: *R. WEST, J. I. WOODEN, E. A. BARTON, J. L. LEASURE;
Univ. of Houston, Houston, TX

Abstract: Mounting evidence substantiates a positive association between physical activity and alcohol consumption, with alcohol drinkers being more physically active. The interactive effects of binge alcohol and exercise on the brain therefore warrant investigation. We focused on the female brain, as binge drinking is a common alcohol use disorder (AUD) among American women and girls. According to the Centers for Disease Control, 1 in 8 report binge drinking three times a month (6 drinks per binge). We have previously shown that a single 4-day binge results in a 10-15% decrease in granule neurons in the hippocampal dentate gyrus (DG) in female rats. We have also shown that 2-4 weeks of post-binge exercise restores the damaged DG. In the present study, we hypothesized that weekly binge alcohol would cause a significant loss of DG granule neurons, and that weekly exercise would prevent this. Female adult Long-Evans rats (n=45) were randomly assigned to either control or alcohol groups and given a once-weekly alcohol (5 g/kg) or isocaloric control dose via intragastric gavage for 11 weeks. Following the alcohol dose, rats either remained sedentary or were given access to exercise wheels (2 hours/3 consecutive days). Behavioral intoxication and blood alcohol content were measured weekly and did not differ between binged groups. All rats were behaviorally tested periodically throughout the experiment. Exercised rats, regardless of binge exposure, were more exploratory in the open field and performed better on the rotarod in comparison to sedentary rats. We found no difference between groups on a water maze task, however sedentary binged rats had impaired object recognition compared to all other groups. Brain tissue was stained for the neuronal marker, NeuN, and remaining granule cells in the DG were counted using unbiased stereology. Rats that remained sedentary had a 19% reduction in remaining granule neurons compared with sedentary controls, and exercise reversed this effect. Our results indicate that weekly binge alcohol causes detectable hippocampal damage and cognitive impairment, and that exercise counteracts these effects. Our next step is to determine whether weekly binge alcohol influences exercise-driven neuroplasticity.

Title: Ventriculomegaly and periventricular pathology correlate with cognitive impairment in the aging brain

Authors: *K. TODD[1], E. NORTON[1], T. BRIGHTON[1], S. SCHICK[1], S. RESNICK[2], W. ELKINS[2], J. TRONCOSO[3], O. PLETNIKOVA[3], J. CONOVER[1];
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [2]Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Expansion of the brain's fluid-filled ventricles, termed ventriculomegaly, is a condition commonly found in the aging brain. We have previously shown that expansion of the lateral ventricles is linked to ventricle surface gliosis in which areas of the ciliated ependymal cell monolayer that lines the ventricles are replaced with dense astrocytic patches. Loss of ependymal cells would compromise trans-ependymal bulk flow mechanisms required for clearance of harmful toxins and metabolites from the parenchyma. However, the interplay between age-related ventricle expansion and decline in ependymal integrity and its effect on periventricular fluid homeostasis, pathological protein accumulation and cognitive impairment has not been examined. In collaboration with the Baltimore Longitudinal Study of Aging and Alzheimer's Disease Neuroimaging Initiative, we analyzed longitudinal structural MRI scans to map spatiotemporally the progression of ventricle expansion in healthy aging individuals and those with varying degrees of cognitive impairment. Accompanying subject-matched FLAIR-(fluid-attenuated inversion recovery) MRI scans and biospecimens were used to investigate the relationship between periventricular white matter hyperintensities and loss of ependymal layer functions in areas of ventricle expansion. We found that the trajectory of ventricle expansion correlated with degree of cognitive impairment in both speed and severity, and confirmed that in areas showing longitudinal expansion ependymal cells were replaced with regional gliosis. The relative size of periventricular white matter hyperintensities increased with worsening cognitive performance. This was accompanied by accumulation of protein aggregates in periventricular tissue, further suggesting impaired clearance mechanisms in these regions. These findings provide valuable and highly relevant information for the development of improved diagnostic tools and treatments for the healthy and cognitively impaired aging population.

Title: Making American Football Safer: changing the NFL's policy on the type of helmets allowed on the playing field

Authors: ***R. J. COLELLO**[1], I. COLELLO[3], M. GRASSO[2], O. KEMP[2], S. MUFFLY[2], K. OIU[2], A. SCHLOE[2];
[1]Anat. and Neurobio., [2]Virginia Commonwealth Univ., Richmond, VA; [3]Virginia Tech., Blacksburg, VA

Abstract: Helmet-to-helmet collisions are considered one of the primary means by which concussions occur in American Football. With over 1,500,000 people playing football nationwide, helmet-to-helmet contact accounts for a significant proportion of the over 100,000 concussions that occur yearly. Not surprisingly, this represents a health concern of such magnitude that many have questioned whether the game can survive. In an effort to evaluate helmet safety, the STAR System was developed in 2011 that rated helmets based on their ability to reduce g forces experienced by the head across a range of impact forces measured on the field. Using a helmet drop assay to measure linear forces, helmets were rated 1-5 Stars, with a 5-Star rating being the best available helmets and a 1-Star the worst. Although this was a major step in making the game safer, litigation concerns made the NFL, in 2014, adopt the position of allowing players to wear any helmet provided it is, "of a suitably protective nature" and "designed and produced by a professional manufacturer". This led us to ask: 1.) what helmets do NFL players wear and, 2.) does the current NFL helmet policy make the game safer? To address this, we identified the specific helmets worn by 1000 NFL players on Week 13 of the 2015 season. Using stop motion footage for each of the16 games played and helmet air vent patterns to identify helmets worn, we found that players wore a wide range of Star Rated Helmets, from the 5-Star Riddell Revolution Speed (44%) and Schutt Air XP Pro (33%) to the 3-Star Riddell Revolution (6%) and 1-Star Riddell VSR4 (worn by Tom Brady, Drew Brees and 2% of players). Using a helmet-to-helmet impactor system, we next sought to determine the g forces

experienced by the head when helmets of varying Star rating collided through the range of impact forces recorded on the field. We found that, when two 5-Star helmets collided, the g forces experienced by the head were roughly 25% less than that observed for two 3-Star helmets colliding and roughly 50% less than that observed for two 1-Star helmets colliding. Surprisingly, when a 5-Star helmet collided into a 1-Star helmet, the 5-Star helmet's ability to protect the head was significantly reduced, with g forces experienced by the head in the 5-Star helmet increasing by an average of 40% at all impact forces tested. Together, these results suggest that the NFL policy of allowing players to wear any helmet put players at increased risk of receiving a concussion during helmet-to-helmet collisions. Thus, the simplest and most straightforward way to reduce concussions in American Football is to mandate that players only wear helmets that receive the highest safety rating.

Title: Nuts and brain: Walnuts, pecans, and cashews increase power spectral density (μV^2) of EEG gamma wave band frequency (31- 40 Hz) relative to nut antioxidant concentration - beneficial for enhancement of recall, memory and brain wellness.

Authors: *L. S. BERK[1,2,3], E. LOHMAN[2], G. BAINS[1], N. DAHER[4], J. LEE[2], J. BRADBURN[5], R. MOLINA[7], S. JUNEJA[2], R. MOHITE[2], N. VIJAYAN[2], S. MORE[2], P. DESAI[2], D. MALI[6], S. SHAH[2];
[1]Allied Hlth. Studies, [2]Physical Therapy, [3]Sch. Med., [4]Res. & Statistics, [5]Clin. Lab. Sci., [6]Loma Linda Univ., Loma Linda, CA; [7]Global Hlth. & Digital Educ, Sch. Publ. Hlth, Loma Linda Univ., Loma Linda, CA

Abstract: Nuts are a major source of flavonoids. They are potent antioxidants with known mechanisms that provide cardioprotective, anticarcinogenic, and anti-inflammatory properties. Studies have shown that absorbed flavonoids penetrate and accumulate in brain hippocampal regions involved in learning and memory. Neurobiological correlates of flavonoids cascade an expression of neuroprotective and neuromodulatory proteins that promote neurogenesis, blood-flow improvement, and angiogenesis supporting brain wellness. However, the correlates of neuroelectric activities that are associated with nut flavanoid effects on neurocognition, neuronal

synchronization, memory, recall, mood and behavior are not well known. Purpose: Provide evidence of a relationship between antioxidant concentration in nuts and electroencephalography (EEG) brain state frequency modulation, specifically gamma wave band frequency 31-40 Hz (γBA). Methods: A pilot study was conducted using walnuts, pecans, and cashews. EEG Power Spectral Density μV^2 (PSD) was acquired during a sequence of enhancing sensory awareness tasks ranging from cognition of past experience, visualization, olfaction, taste, and finally consumption of nuts. EEG wave band activity was recorded from 9 cerebral cortical scalp regions F3, Fz, F4, C3, Cz, C4, P3, Pz and P4 using the FDA approved EEG B-Alert 10X System™, Carlsbad, CA. Second by second 9 bandwidths (BW) were recorded through the study. The PSD BW data were referenced to eyes closed baseline task, and then Z-scored. Results: Z-scores were graphed and analyzed for each task along with BW across 0-40 Hz. The overall respective BW were collapsed across all 9 EEG channels. γBA for PSD was greatest in all 9 brain regions for all sensory tasks ($p<0.01$). The most profound observation was the composite of sensory tasks for γBA. It was observed that γBA was the highest for walnuts (PSD 4.5), with an antioxidant concentration of 2772 μmoles; followed by pecans (PSD 3.0), with an antioxidant concentration of 1743 μmoles; and next for cashews (PSD 1.4), with an antioxidant concentration 48 μmoles. Conclusion: This pilot study provides evidence that EEG γBA can be initiated by cognitive, sensory and consumption of nuts. It appears that the PSD γBA intensity is associated with anti-oxidant concentration. We propose this protocol as a potential assessment tool in determining the efficacy of nuts dose response modulation of PSD γBA 31-40 Hz for support of brain wellness. Further research is needed to support and expand these important preliminary findings.

Title: The role of CD36 in atherosclerosis and vascular cognitive impairment

Authors: ***K. CHO**[1], Y. KIM[2], J. KIM[1], G. KIM[1];
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Pomfret Sch., Pomfret, CT

Abstract: CD36, a platelet receptor bound thrombospondin, contributes to normal and also various pathologic processes such as apoptotic cell death, fatty acid transport, atherosclerosis, and Alzheimer disease (AD) by initiating different signaling responses. The multi-ligand recognition of CD36 can allow exerting several functions depending on the different cell type. In Alzheimer brain, CD36 has been implicated to involve in neuronal degeneration and interruption of CD36 signaling pathways by blocking the recruitment of microglia to amyloid deposits. Here this study primarily (1) investigates the expression of peripheral CD36 and brain CD36 to age with cerebrovascular damge; (2) also examine the role of CD36 that works in initiating autophagy which may relate to atherothrombus forming and progessing; (3) Furtherly we examine how the blockage of MAPKinases involves and regulates the CD36 of endothelial and microglial cells with age. By the physiological aging process and vessel damage, CD36 expression in the human serum was increased contrast young and middle-aged group and also CD36 expression level was higher in aged group with cerebrovascular damage than without damaget. And also the aged who showed higher level of CD36 were relatively reduced cognitive function (MMSE, CDR). To further investigate the role of peripheral blood CD36 and brain CD36, we assessed the expression level in endothelial CD36 and microglial CD36. By inhibiting MAPKinases, we evaluate the changing downstream signal regulation and autophagy and apoptotic cell death.This study demonstrates that CD36 can promote MAPKinse signaling that may drive authophagic and apoptotic cell death in endothelial cells and microglial cells. This study suggest that increased CD36 with age leading age-related diseases could be prevented the consequences by not only treating antagonist (up-stream) but also blocking MAPKinase signals (down-stream).

Title: Gender-specific associations of cardiovascular risk with brain structure across the lifespan

Authors: *A. ISENBERG, J. PA;
Inst. for Neuroimaging and Informatics, USC, Los Angeles, CA

Abstract: Declines in brain health with age are a major public health issue and may occur in men and women differently. In addition to the devastating emotional and physical caregiving burden placed on families worldwide, the cost of caring for the elderly is causing ever increasing

societal and economic burden. Despite great advances in investigating factors associated with cerebrovascular disease and dementia, progress towards effective prevention and treatment has been discouraging. Modifiable lifestyle interventions are promising for decreasing the risk associated with declines in brain health, with the potential for delaying disease onset and slowing decline in cognition. Known contributions of vascular risk factors associated with Alzheimer's disease (AD) may differ significantly by gender, but these effects have not been studied well in the context of cardiovascular disease. In the present study we hypothesized that cardiovascular risk factors may impact brain structures differently in men and women. Cardiovascular risk was assessed using the Framingham Risk score for cardiovascular disease (CVD) in the adult population of the publicly available Rockland NKI dataset (Ages 22-85 years old, N=426). CVD risk scores were calculated with a model based on the following factors: age, systolic blood pressure, treatment of hypertension, body mass index, diabetes, and smoking. Analyses were performed on the subset of these data with available MRIs (N=335) to assess the correspondence of cardiovascular risk with brain structure across the lifespan. Increased risk of cardiovascular disease across the lifespan was associated with smaller gray matter volume in men, particularly in superior frontal cortex, the hippocampus, parahippocampal gyrus, and the amygdala. In contrast, greater risk of cardiovascular disease in women was only associated with smaller thalamic grey matter volume. These data suggest gender may be a significant factor in how cardiovascular risk is associated with brain volume over the lifespan.

Title: The effects of heavy cannabis use during adolescence on hippocampal sub-region morphology in an aging population

Authors: Z. MAHMOOD[1], A. M. KARACOZOFF[1], T. M. HARRISON[2], S. Y. BOOKHEIMER[1], *A. C. BURGGREN[3];
[1]Psychiatry and Biobehavioral Sci., [2]Neurosci. Interdepartmental Ph.D. Program, UCLA, Los Angeles, CA; [3]Semel Neuropsychiatric Inst., Univ. California @ Los Angeles, Los Angeles, CA

Abstract: Adolescents and young adults of the 1960's and 70's, a time during which cannabis (CB) use expanded rapidly, are now entering their senior years when age-related cognitive decline may begin. There is growing evidence of the adverse effects of CB use on cognition, brain structure and function, specifically with earlier exposure during adolescence (1), but the long-term effects of heavy adolescent CB use in early life and its interaction with brain aging are not well understood. The current study used retrospective assessment in older adults to investigate CB use during adolescence and age-related changes in hippocampal complex (HC) morphology in late-life. We enrolled 22 subjects, 10 participants who used CB > 20x/month for at least a year during adolescence ('CB+'; M_{age} = 62 years old) and 12 subjects who did not report CB use during adolescence ('CB-'; M_{age} = 65 years old) based on self-report on the Marijuana Smoking History questionnaire (2) and an extensive Drug Use History Battery. No participants used CB at the time of testing, as verified by a urine test on the day of testing. High resolution hippocampal structural scans (TR:3s; TE:41ms; FOV=20mm, 512x512, 3mm thick, 0mm spacing) were acquired and a cortical unfolding method was used to measure thickness of HC subregions (3-4). Light cigarette smoking and alcohol use was allowed and matched across groups (5). Participants in the CB+ group had thinner cortex within Cornu Ammonis (CA) fields 2,3 and the dentate gyrus (11.9% thinner, p=0.004), CA1 (9.8% thinner, p=0.009), entorhinal cortex (7.9% thinner, p=0.0003) and subiculum (7.2% thinner, p=0.008). Across the whole HC, subregions averaged together showed 8.9% thinner gray matter in CB+ compared to CB- (p=0.005). The results suggest that chronic use of CB in adolescence has long-lasting effects on HC structure, which may underlie and exacerbate age-related cognitive decline. Our findings suggest that CB use has a neurotoxic effect on the adolescent brain that persists well into adulthood. These findings, when expanded to a larger sample size, may help to identify persons more likely to decline than their age-matched counterparts and suggest early life CB use may have long-lasting effects on brain morphology in the HC.

Title: UCP2 haplotype establishes a novel genetic link between mitochondria and mood disorders

Authors: *V. HEISE[1,2], E. ZSOLDOS[1], S. SURI[1,2], N. FILIPPINI[1], A. MAHMOOD[1], A. SINGH-MANOUX[3], M. KIVIMÄKI[3], A. C. NOBRE[2], C. E. MACKAY[1,2], K. P. EBMEIER[1]; [1]Dept. of Psychiatry, [2]Oxford Ctr. for Human Brain Activity, Univ. of Oxford, Oxford, United Kingdom; [3]Dept. of Epidemiology and Publ. Hlth., Univ. Col. London, London, United Kingdom

Abstract: Objective: Uncoupling protein (UCP) 2 is a proton carrier found in the inner mitochondrial membrane where it plays a role in regulating the membrane potential. UCP2 is expressed in neurons in various brain areas and plays a role in functions from lipid/ glucose metabolism to calcium signaling and the generation of reactive oxygen species. In humans several polymorphisms of UCP2 exist and they have been linked to body mass index variability and obesity. However, there are no studies to date showing links between UCP2 polymorphisms and the human brain.
Methods: Data from the Whitehall II imaging sub-study was investigated. Participants are former civil servants who are mostly male and now aged between 60 and 85 years. They were genotyped for two polymorphisms of the UCP2 gene, -866G>A (rs659366) and Ala55Val (rs660339). There is linkage disequilibrium between these polymorphisms and -866G is strongly linked to Ala55. Therefore, we investigated three different UCP2 haplotypes: homozygotes for -866G / Ala55 (called haplotype1 (HT1)), homozygotes for -866A / 55Val (HT3), and heterozygotes (HT2). We investigated their risk of developing neurodegenerative or psychiatric disorders. In addition, we investigated magnetic resonance imaging (MRI) data to determine the effect of UCP2 haplotypes on grey matter structure and functional brain connectivity using resting-state functional MRI.
Results: There was a significant UCP2 haplotype effect on the occurrence of mood disorders. There was a gene-dose effect with the highest occurrence of mood disorders in the HT3 group and a stepwise decrease to HT2 and HT1. The neuroimaging data showed a trend to decreased size of the thalamus for HT3 compared with the other two haplotypes. Additionally, this group showed significantly decreased functional connectivity of the thalamus with several cortical areas compared with the two other groups.
Conclusions: This is the first study to report an association between UCP2 haplotype and mood disorders in humans. The polymorphisms investigated here affect levels of UCP2 mRNA expression and thus mitochondrial function *in vitro*. While some evidence points towards the role of mitochondria in psychiatric disorders, we show a more direct genetic link between mitochondrial function and the occurrence of mood disorders. UCP2 haplotype effects on size and connectivity of the thalamus indicate that this region might be particularly susceptible to differences in mitochondrial function. As the thalamus is an integral part of the cortico-limbic

mood regulating circuit, differences in thalamic size and connectivity might lead to higher risk of mood disorders in the HT3 group.

Title: How the emotional motor system controls the pelvic organs

Authors: *G. HOLSTEGE;
The Univ. of Queensland, Herston Qld 4006, Australia, Haren, Netherlands

Abstract: The brain has two goals, survival of the individual and survival of the species. Its most important tool is its motor system, which consists of the voluntary and the emotional motor system. The pelvic organs are very important parts of the body systems, because the bladder and rectum play a crucial role in micturition and defecation, while the prostate, testicles, vagina and uterus are the organs that take care of survival of the species.
The emotional motor system controls these pelvic organs, which are innervated by the sacral parasympathetic motoneurons. These motoneurons, in turn, are controlled by a specific group of neurons in the pontine brainstem, the pelvic organs stimulating center (POSC). Via long descending pathways the POSC generates micturition, defecation, parturition and sexual activities by stimulating different groups of sacral parasympathetic motoneurons. In turn, the POSC is driven by the periaqueductal gray (PAG), and pre-optic area (POA), which receive, via long ascending pathways from the sacral cord, precise information regarding the situation in all pelvic organs. The PAG and POA also receive instructions from higher brain regions as amygdala, and bed nucleus of the stria terminalis.
In humans the most important brain region having access to the PAG is the medial orbitofrontal cortex. This part of the prefrontal cortex receives information from many other cortical regions regarding the situation of the individual. Is the situation appropriate for micturition, defecation, sexual activities, or parturition to take place? If not, the orbito-frontal cortex will send a message to the pre-optic area and PAG not to activate the POSC in order to activate one of the pelvic

organs.
It has been shown that cerebral infarctions can cause urge-incontinence. In all likelihood the cause of urge-incontinence, in the very many elderly suffering from this disease, leading to healthcare costs of $85 billion a year, is interruption of the pathway of the orbitofrontal cortex to the PAG. The reason is the many small infarctions in the brains of these elderly.
In women suffering from hypoactive sexual desire disorder (HSDD), but not in healthy women, the medial orbitofrontal cortex is de-activated during watching erotic movies. This de-activation causes major problems, because the pre-optic area and the PAG are not activated in order to generate vaginal vasocongestion and lubrication, leading to decreased sexual behavior in general.
Conclusion, the orbitofrontal-POA-PAG-POSC-sacral parasympathetic motoneuronal pathway plays a crucial role in survival of the individual and species and problems in this system causes great problems in very many humans.

Title: Determination of neurite isolation method and identification of neurite specific proteins in hydrogen peroxide-treated N1E-115 cells

Authors: *O. SHUNSUKE[1], K. FUKUI[2], Y. OFUCHI[2], H. TSUMOTO[3], Y. MIURA[3];

Abstract: Reactive oxygen species (ROS) increase the risks of several diseases, such as Alzheimer's disease (AD), cancer and diabetes. In these severe ROS-related diseases, we are focusing on the relationship between ROS-related brain dysfunction and aging. Accumulation of oxidative damage in the brain, the neurotransmission systems gradually attenuate. Although the brain is susceptible to damage by ROS, it is difficult to recover the neuronal network after induction of cell death. In order to prevent ROS-related neuronal cell death, we are trying to find an early sign of neurons before induction of cell death. Previously, we found that treatment with a low concentration of hydrogen peroxide induced axonal degeneration in cultured cells, and co-treatment with vitamin E protected its deterioration. Furthermore, collapsing response mediator protein (CRMP)-2, which one kind of microtubule-related protein phosphorylated in normal aged-mice brain. In this study, we tried to determine other neurite specific proteins in hydrogen

peroxide-treated N1E-115 cells using Liquid Chromatography-Mass Spectrometry/Mass Spectrometry (LC-MS/MS) technique. Before start of this study, we tried to separate neurite and cell soma using cell-culture insert system. A few days after the culture cells using this system, we collected neurite, and checked tubulin and actin protein expressions by western blotting. Histone which is nucleus specific protein was not detected at all. Next, these proteins were purified and were labeled cyclopaedically by iTRAQ. At the result of LC-MS/MS, several protein expressions significantly increased in the isolated neurite from hydrogen peroxide-treated cells. Some proteins which we identified have already reported to be associated with neurodegeneration disorders. These results show the possibility that ROS-derived neurite degeneration is induced in the early stage of neurodegeneration disorders. However, it is difficult to obtain the reproducibility, we are continuing to study the identification of proteins and the elucidation of its function.

Title: Maternal choline supplementation as a preventive therapeutic strategy for reducing AD-like pathology

Authors: ***R. VELAZQUEZ**[1], A. CACCAMO[1], E. FERREIRA[1], A. TRAN[1], N. DAVE[1], S. ODDO[1,2];
[1]Neurodegenerative Res. Ctr., Biodesign Inst. At Arizona State Univ., Tempe, AZ; [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Over the next few decades, the advancing age of the global population will dramatically increase the prevalence of Alzheimer’s disease (AD), the most prevalent neurodegenerative disorder worldwide. Currently, there are no effective treatment options;

therefore, there is an urgent need for novel, safe, and efficacious strategies to mitigate this disorder. Recent work in a mouse model of Down syndrome, which develops some aspects of AD-like phenotype, has shown that maternal choline supplementation (MCS), during gestation and lactation leads to an improvement in cognitive function in 12-month-old offspring. Here, we examined MCS effects on learning and memory in APP/PS1 mice, a widely used mouse model of AD. Specifically, APP/PS1 breeding pairs were kept on a CTL diet (choline normal diet, with standard choline content of 1.1 g/kg choline chloride) or on a MCS diet (5 g/kg choline chloride) from conception through postnatal day (PND) 21. At PND 21, all offspring were put on the CTL diet for 11 months, after which they were tested in spatial reference memory using the Morris water maze task (MWM). We found that APP/PS1 mice whose mothers were on the MCS diet performed significantly better than APP/PS1 mice whose mothers were on the CTL diet. The cognitive improvement was associated with reduced Aβ plaques and β-secretase activity. Collectively, our results provide preliminary support suggesting that simply modifying the diet of pregnant mothers with additional choline might help reduce the risk of developing AD and/or delay the onset of the disease for offspring in late adulthood; benefits which may be carried over throughout subsequent generations.

Title: p62 gene transfer improves AD-like pathology by increasing autophagy

Authors: ***A. CACCAMO**, E. FERREIRA, C. BRANCA, S. ODDO;
Arizona State Univ., Tempe, AZ

Abstract: The multifunctional protein p62 is associated with neuropathological inclusions in several neurodegenerative disorders, including frontotemporal lobar degeneration, amyotrophic lateral sclerosis, and Alzheimer’s disease (AD). Strong evidence shows that in AD, p62 immunoreactivity is associated with neurofibrillary tangles and is involved in tau degradation. However, it remains to be determined whether p62 also plays a role in regulating amyloid-β aggregation and degradation. Using a gene therapy approach, here we show that increasing brain

p62 expression rescues cognitive deficits in APP/PS1 mice, a widely used animal model of AD. The cognitive improvement was associated with a decrease in amyloid-β levels and plaque load. Using complementary genetic and pharmacologic approaches, we found that the p62-mediated changes in Aβ were due to an increase in autophagy. To this end, we showed that removing the LIR domain of p62, which facilitates p62-mediated selective autophagy, or blocking autophagy with a pharmacological inhibitor, was sufficient to prevent the decrease in Aβ. Overall, these data provide the first direct *in vivo* evidence showing that p62 regulates Aβ turnover.

Title: Dissecting the role of Nrf2 in Alzheimer’s disease

Authors: ***C. BRANCA**, A. CACCAMO, C. A. NEGRICH, N. DAVE, S. ODDO;
Biodesign Inst., Arizona State Univ., Tempe, AZ

Abstract: Alzheimer's disease (AD) is the most common type of dementia in the elderly. Growing evidence links oxidative stress and free radical damage to the initiation and progression of AD; however the molecular mechanisms underlying the link between oxidative stress and AD pathogenesis remain elusive. Nrf2 is a master transcriptional regulator that controls the expression of several genes involved in antioxidant response. To investigate the involvement of Nrf2 in AD pathogenesis, we used a crossbreeding strategy to remove the Nrf2 gene from the brain of APP/PS1 mice, a widely used model of AD. We found that removing both copies of the Nrf2 gene from the APP/PS1 mice increased behavioral deficits in several tasks, such as Morris water maze, radial arm water maze, and contextual fear conditioning. These deficits correlated with an increase in amyloid beta (Aβ) pathology, without affecting the APP processing. Mechanistically, we found that the increase in Aβ levels was not due to changes in turnover, as we found that autophagy induction and proteasome activity were similar between APP/PS1 with and without Nrf2. In contrast, we found that APP/PS1 mice lacking Nrf2 had higher levels of activated microglia and astrocytes, suggesting that the increase of Aβ might be mediated by an increase in brain inflammation.These results provide a better understanding of the role of Nrf2, and oxidative stress in general, in the progression of AD.

Title: Targeting phosphodiesterase 2 for treatment of memory loss by regulating neuroplasticity

Authors: ***Y. XU**[1], G. WANG[2], L. CHEN[2], Q. MA[1], Y. XIAOKAITI[1], H.-T. ZHANG[3], J. M. O'DONNELL[1];
[1]Dept. of Pharmaceut. Sci., State Univ. of New York at Buffalo, Buffalo, NY; [2]Clin. Pharm., Hangzhou First People's Hosp., Hangzhou, China; [3]West Virginia Univ., Morgantown, WV

Abstract: Alzheimer's disease (AD) is characterized by progressive cognitive impairment, which is the most common cause of dementia in the aging population. AD is the sixth leading cause of death in the United States and the mortality rate has increased by 70% in during the last ten years. To date, no treatments are available to cure or halt the progression of AD. Synaptic loss, a detectable trait in patients with mild cognitive impairment, is the major neurobiological substrate of cognitive dysfunction. The dysfunction of cAMP and/or cGMP signaling in the progress of AD reduces synaptic firing and rapidly affects cognitive function. In the present study, we investigated the effects of PDE2 inhibitor Bay 60-7550 on memory performance in a mouse model of AD by microinfusion of beta amyloid peptide 1-42 (Abeta-42) into CA1 subregions of the hippocampus. Memory performance was measured by Morris water maze and passive avoidance tests, which are sensitive to evaluate PDE2 inhibitors. The results showed that Bay 60-7550 rescued memory deficits induced by Abeta-42, as evidenced by shorter latencies and more platform crossings in the target quadrant of the probe trails and longer step-down latency to avoid electric footshock tested 24 h after training in Morris water maze and passive avoidance tests, respectively, following treatment with Bay 60-7550. Bay 60-7550 also reversed Abeat-42-induced synaptic and neuronal dysfunction, i.e. increases in the number of dendrites and the total length of neuritis, as well as the spine density in the hippocampus. Immunoblot analysis revealed that Bay 60-7550 also reversed decreased CREB and BDNF expression in the hippocampus induced by Abeta-42. These findings provide evidence for the role of PDE2 in mediating cognitive impairment associated with AD by regulating synaptic and neuronal plasticity, which implicate potential novel therapeutic strategies for treating AD.

Title: SUVN-D4010, a novel 5-HT_4 receptor partial agonist: preclinical profile demonstrating symptomatic and disease modifying effects in the treatment of alzheimer's disease

Authors: ***V. BENADE**, S. DARIPELLI, G. AYYANKI, V. KAMUJU, R. MEDAPATI, S. IRAPPANAVAR, A. MOHAMMED, N. BOGARAJU, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: SUVN-D4010 is a potent, selective and orally bioavailable 5-HT_4 receptor partial agonist being developed for the treatment of Alzheimer’s disease. The effect of SUVN-D4010 on the cholinergic neurotransmission was studied using brain microdialysis technique. The procognitive effect of SUVN-D4010 was evaluated using object recognition task (ORT). The effect of SUVN-D4010 on the oscillatory activity in the hippocampus of anesthetized rats was evaluated using EEG. The effect of SUVN-D4010 on the toxic beta amyloid and the neuroprotective sAPPα were evaluated in the preclinical species using ELISA kits. SUVN-D4010 increased cortical acetylcholine levels in freely moving rats and the effects were blocked by GR 125478, a selective 5-HT_4 receptor antagonist. Similarly, the procognitive effects in ORT were blocked by GR 125478. This indicates that the observed efficacy is mediated through the target receptor. Co-administration of SUVN-D4010 potentiated donepezil’s effects on extracellular acetylcholine levels. SUVN-D4010 also potentiated the effects of donepezil on stimulation elicited theta oscillatory activity in anesthetized rats. At therapeutically effective doses, significant increase in cortical sAPPα and decrease in toxic beta amyloid protein levels were observed in preclinical species. SUVN-D4010 also demonstrated antidepressant like effects in animal models of depression such as forced swim test. These findings in preclinical animal models suggest that SUVN-D4010 exhibits both symptomatic and disease modifying properties together with antidepressant properties which may be beneficial in the treatment of Alzheimer's disease. Phase-1 studies have been completed under US IND and SUVN-D4010 was found to be safe and well tolerated in healthy adult subjects.

Title: The effects of thymoquinone in the amyloid beta-induced sporadic alzheimer models in rats

Authors: *M. KARAKAS BEKER[1], T. AYDOGAN[1], S. TERZIOGLU-USAK[1], F. AKBAS[1], U. KILIC[2], B. ELIBOL[1];

Abstract: Alzheimer’s Disease is the most common neurodegenerative disease in aged population. This disease characterized by synaptic deficiency, neuronal damage and neuron loss in the hippocampus, a brain region specific for memory formation, has no effective treatment. It was known that existing molecules for treatment of Alzheimer’s Disease provide only symptomatic recovery. Nowadays, the investigations of neuroprotective substances preventing Alzheimer’s disease-induced neuronal damage gain importance. One of these candidate molecules is Tymoquinone (TQ), an aromatic hydrocarbon which is found in the *Nigella Sativa*. In literature, the effectiveness of TQ in the treatment of Alzheimer’s Disease was investigated *in vitro* without any *in vivo* studies. Therefore, the aim of the present study was to examine the molecular principles of the neuroprotective effects of TQ in the hippocampus of rats which have

sporadic Alzheimer's disease. In the current study, a micro-osmotic pump which include aggregated amyloid beta was placed to the hippocampus of 6 month-old rats. During 15 days, TQ at a dosage of 20 mg/kg/day were intubated intragastrically as a treatment. After behavioral tests (Morris Water Maze (MWM) and Passive Avoidance Test (PAT)), the rats were decapitated and their brains were removed for histological and molecular analysis. The formation of amyloid plaques was visualized by anti-amyloid beta antibody fluorescently. To confirm the results, a congo red staining were performed to the brain sections. The neuronal loss in the hippocampus was determined by cresyl violet staining. Lastly, the RT-PCR were used to determine the changes in the expression levels of selected microRNAs (mir26b, mir29a, mir29c, mir124) to obtain the molecular effect of TQ in the treatment of Alzheimer pathology. In the TQ-treated Alzheimer rats, there was a functional recovery in the memory performance which was obtained from probe trial of MWM while there was no significant difference in the escape latency in both PAT and MWM learning compared to untreated rat with Alzheimer's disease. According to immunohistochemical analysis, TQ decreased amyloid beta plaques in the hippocampus. Interestingly, TQ increased the expression of mir124 gene whose concentration is altered in the neuronal plasticity in the hippocampus of Alzheimer rats. In conclusion, TQ may be a candidate molecule in the treatment of Alzheimer's disease due to its capacity to recover AD-related neuropathology and to increase the expression of synaptic plasticity molecules.

Title: Significant Aβ42 lowering in PS1-E280A knock-in mouse brain following γ-secretase modulator administration

Authors: *K. M. WOOD, M. SHEEHAN, C. GONZALES, N. I. POZDNYAKOV, M. CAI, S. HASSON, M. PETTERSSON, E. HAJOS-KORCSOK, K. R. BALES;
Neurosci., Pfizer, Inc, Cambridge, MA

Abstract: We developed a mouse model utilizing CRISPR technology to knock-in the familial Alzheimer's Disease (FAD) mutation, Presenilin 1-E280A (PS1-E280A). In humans, the PS1-E280A mutation results in an aggressive, early onset form of AD caused by a shift in Aβ cleavage, leading to an increase in the production and deposition of Aβ42 in brain. We

investigated the impact of the PS1-E280A mutation on mouse brain Aβ production and assessed the effect of γ-secretase modulator (GSM) treatment on the various forms of Aβ. Previously published efficacy data from multiple preclinical models provided evidence for a potentially beneficial effect of GSM treatment in AD by shifting cleavage away from amyloidogenic forms Aβ42 and Aβ40 toward production of carboxy-terminal truncated forms Aβ37 and Aβ38; these shorter fragments are considered less amyloidogenic with reduced neurotoxicity. The PS1-E280A mutation in mouse resulted in modulation of brain Aβ production, with increased Aβ42 and decreased Aβ37 and Aβ38. GSM treatment in PS1-E280A mice had a beneficial effect by correcting the abnormal Aβ cleavage shift caused by the FAD mutation.

Title: Combination therapies with γ-secretase modulator for alzheimer's disease

Authors: *O. PRIKHODKO[1], M. Y. VO[2], P. NGUYEN[3], K. RYNEARSON[3], L. MONTE[3], R. E. TANZI[4], R. RISSMAN[3], S. L. WAGNER[3];
[1]Biomed. Sci., [2]Biol. Sci., [3]Neurosci., UCSD, La Jolla, CA; [4]Genet. and Aging Res. Unit, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Alzheimer's disease (AD) is the most prevalent form of dementia in the elderly, which affects about 5.4 million individuals in the US. Current AD treatments are limited to temporary and mild alleviation of cognitive and behavioral symptoms in a subset of patients; there is no cure, effective prevention therapy or treatment which alters the course of AD. The pathological features of AD include β-amyloid (Aβ) plaques and neurofibrillary tangles in cerebral cortex and hippocampus. Aβ peptides are the product of the amyloid precursor protein (APP) cleavage by BACE1 (β-site APP cleaving enzyme 1) to produce the membrane-bound C-terminal fragment C99, which is further processed by γ-secretase to generate Aβ fragments. Aβ40 is the most abundant secreted Aβ peptide; however, the more fibrillogenic Aβ42 is the primary constituent of Aβ plaques. Our group developed and tested a series of small molecule γ-secretase modulators (GSMs), with BPN15606 emerging as the leading candidate for clinical development. BPN15606 demonstrates excellent in vivo PK/PD properties, highly significant dose-dependent biochemical efficacy and dose proportional exposures. At higher doses, this compound can almost completely eliminate Aβ42 levels in both brain and in CSF. In the current study, we evaluated the benefit of two distinct combinational therapies. The first therapy uses BPN15606 and a BACE1 inhibitor, LY2886721, in multiple in vitro assays and in an animal study currently in progress. The second therapy combines BPN15606 and a CRFR1 inhibitor (cotricotropin-releasing factor receptor 1, which modulates cellular activity in many AD-relevant brain areas, and has been demonstrated to impact both tau phosphorylation and Aβ pathways) in an in vivo study. Collectively, the presented data demonstrates the improved efficacy of combination therapies over single-therapy treatments for AD.

Title: Effects of uric acid on the cellular changes caused by amyloid beta

Authors: *B. YE[1], D. KIM[3], P. LEE[2];
[1]Dept. of Neurol., [2]Neurol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]Severance Biomed. Sci. Institute, Yonsei Univ., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD) is the most common cause of degenerative dementia, which is characterized by the accumulation of beta-amyloid plaques and tau tangles. Uric acid (UA), the final product of purine metabolism, is a well-known natural antioxidant that reduces oxidative stress and protects cells against free radicals. Recent studies raised a possibility that UA could have beneficial effects on the cognitive decline in patients with AD pathology. However, it is currently unknown whether UA protects neurons from the toxic effects of AD pathology. In this study, we investigated the protective effects of UA using in vitro models of AD. UA increased the survival of neurons from cell death induced by amyloid beta. UA also reversed the elevation of ROS induced by amyloid beta. Furthermore, UA increased the activity of SOD, and maintained the potential of mitochondrial membrane. These results suggest that UA protects cells against cell death induced by amyloid beta.

Abstract: The endocannabinoid system has emerged as important modulator of memory processing and changes in the endocannabinoid system have been correlated to cognitive deficits in Alzheimer's disease (AD). However, it remains unknown how the exogenous administration of anandamide (ANA) could modulate the development of memory impairments in AD subjects. This study aimed to investigate the preventive effects of ANA in a sporadic AD model induced

by streptozotocin (STZ; which promotes brain resistance to insulin) on recognition and emotional memories tasks. Adult male Wistar rats (300-400g) received intracerebroventricular injections of ANA (100 ng) and/or STZ (2.0 mg/kg) or vehicle (groups: Veh/Veh, Veh/STZ, ANA/Veh and ANA/STZ). After 30 days, animals were submitted to object recognition task and two days later, they were trained in fear conditioning paradigm and tested 24 hours (contextual) and 48 hours late (tone). No differences were observed in locomotion or exploration in STZ and/or ANA treated animals. STZ impaired short-term recognition memory and ANA prevented STZ-induced deficit because animals treated with STZ demonstrated a lower recognition index compared to all groups. ANA *per se* did not affect object recognition memory. Emotional memory evaluated by contextual and tone fear conditioning was not affected by STZ and/or ANA. Our data showed that, after 30 days, STZ disturbs recognition but not fear memories, suggesting that hippocampus but not amygdala memory systems are more sensitive to cognitive deficits showed by AD model used in this study. Importantly, ANA prevented this impairment on recognition memory induced by STZ. Molecular analyses (tau, p-tau and co-chaperones) are in progress to understand underlying biological processes related to our results.

Title: Zinc and pyrithione exposure prevents 2,2’-dithiodipyridine-induced varicosity formation in rat primary cortical neurons

Authors: *C. QIAN, R. A. COLVIN;
Biol. Sci., Ohio Univ., Athens, OH

Abstract: Varicosities along neurites are early-stage traits of degenerating neurons found in AD and ALS. One common trigger of these swellings is microtubule disruption, leading to microtubule-associated protein dissociation and disruption of axonal transport. Zinc has been reported to stabilize microtubules and regulate axonal transport, but mechanisms remain

unknown. Visualizing tau by immunofluorescence (IF) showed tau colocalized with varicosities formed in rat primary cortical cells after 15min treatment with 60μM 2,2'-dithiodipyridine (DTDP), which has been reported to undergo thiol-disulfide exchange reaction with cysteines (thiol) on either tau or tubulin. Imaging analysis showed that the number of tau-positive varicosities increased by 841 ± 21%. DTDP increased tau fluorescence by 159 ± 22% in cell bodies and 166 ± 8% in neurites (mean ± SEM, n = 3). Western-blots after DTDP treatment showed high molecular weight βME-sensitive bands of presumptive tau aggregates. Furthermore, IF showed that tubulin and MAP2 were co-localizing with tau in the varicosities. DTDP treatment (15min) did not cause accumulation of transporting cargoes mitochondria or postsynaptic markers PSD-95 in the varicosities - the overall distribution could not be distinguished from control. Hydrogen peroxide (200μM) did not lead to varicosity formation after 15min treatment, suggesting that DTDP's general oxidative capacity is not the causation, and varicosity formation is not simply a morphological sign caused by common pathways leading to cell death. In addition, the role of DTDP-induced intracellular free zinc and calcium increase was studied - either zinc-specific chelator TPEN (100μM) or zinc/calcium chelator BAPTA-AM (10μM) failed to prevent varicosity formation. Surprisingly, exposing cells to zinc entry mediated by zinc ionophore pyrithione (10μM zinc/5μM pyrithione) prevented DTDP-induced varicosity formation, increases in tau immunofluorescence, but did not alter tau aggregation. Adding zinc lower than 10μM or in the absence of pyrithione was not protective. In conclusion, DTDP-induced tau dissociation (increased tau immunofluorescence) and aggregation are likely triggered by tau disulfide-crosslinking directly, or by microtubule disruption indirectly. Intriguingly, intracellular free zinc released from physiological binding sites attacked by DTDP is not a mediator of the observed effects, but adding zinc prevents varicosity formation implying zinc somehow protects critical cysteines on tubulin. However, adding exogenous zinc did not block tau aggregation, suggesting zinc may not interfere with the DTDP-induced disulfide-crosslinking of tau.

Title: sAPPα is an allosteric inhibitor of BACE1 and potential therapy for Alzheimer's disease.

Authors: *P. SPILMAN[1,2], J. CAMPAGNA[1], C. PETERS-LIBEU[2], M. P. ALAM[1], M. ARBING[3], S. CHAN[3], M. COLLAZO[3], D. CASCIO[3], D. BAI[1], V. JOHN[1];
[1]Neurol., Mary S Easton Ctr. for Alzheimer's Dis. Res. at UCLA, Los Angeles, CA; [2]Bredesen Lab., Buck Inst. for Res. on Aging, Novato, CA; [3]Inst. for Genomics and Proteomics, Univ. of California, Los Angeles, CA

Abstract: Amyloid precursor protein (APP) may be processed via an amyloidogenic pathway wherein it is cleaved sequentially by β-secretase BACE1 (BACE) and γ-secretase to form amyloid-β (Aβ), the major component of the amyloid plaques that characterize Alzheimer's disease (AD). Alternatively, APP may be cleaved by α-secretase to generate sAPPα and αCTF. As sAPPα supports synaptic and cell survival, we focused our drug discovery efforts on identification sAPPα enhancers as new potential therapeutics for AD. We observed sAPPα increases in brain induced by F03 (Spilman et al. 2013) and analogs after 28-day oral delivery at 4 mkd to J20 AD model mice correlated well with decreases in sAPPβ, suggesting sAPPα may affect BACE cleavage of APP. In 2012, Obregon et al. revealed sAPPα did indeed interact with and inhibit BACE; and we showed by small-angle X-ray scattering (SAXS) and tryptophan fluorescence studies that this inhibition was conformation-dependent and allosteric in nature, that is, sAPPα interacts with an exosite remote from the active-site of BACE. The latter was revealed by sAPPα's inhibition of BACE cleavage of a longer MBP-APPC125, but not a shorter P5-P5', substrate (Peters-Libeu et al. 2015). To further elucidate the sAPPα:BACE interaction, we have undertaken co-crystallization studies using recombinant sAPPα and rBACE (Sussman et al. 2013). In addition, as our ultimate goal is to develop sAPPα as a potential therapeutic for AD and as a protein fragment it is not suitable for conventional delivery, we have encapsulated rsAPPα in small, uniform, BBB-targeted elastic liposomes using a microfluidic reactor to allow delivery to brain after peripheral injection. sAPPα's ability to inhibit BACE cleavage of APP - the first and rate-limiting step in Aβ production - by a physiologically relevant mechanism makes it a potential biologic therapeutic for AD. In addition, the allosteric mechanism provides the potential for both greater enzyme- and substrate specificity, lowering the risk of off-target effects. Elucidation of the nature of the interaction would provide information to support therapeutic development. Furthermore, early results indicate liposomal encapsulation may provide a method for successful peripheral delivery of sAPPα.

Autònoma de Barcelona (UAB), Barcelona, Spain

Abstract: The C-terminal domain of tetanus toxin (Hc-TeTx) is a nontoxic fragment of the tetanus toxin that has a protective action against excitotoxicity *in vitro* and *in vivo*. The efficacy of Hc-TeTx fragment it has been demonstrated in several animal models of neurodegeneration. For this reason, the Hc-TeTx fragment it has been proposed as a molecule with neuroprotective and neurorestaurative potential. The $A\beta_{25-35}$ fraction mimics the toxic effects of the full complete peptide Aβ. This fraction modify the cholinergic system in magnocelular nucleus and results in cognitive impairments. The aim of this study was evaluate the neuroprotective effect of Hc-TeTx fragment against toxicity of $A\beta_{25-35}$ fraction into NBM in rats. Male Wistar rats were administered bilaterally with 2μL of $A\beta_{25-35}$ peptide at a concentration of [1μg /μL] (n = 12) into NBM by stereotaxic surgery estereotáxica (AP: -0.6, L: ±2.7, P: -6.5) and Hc-TeTx [2μM]+$A\beta_{25-35}$ [1μg/μL] group. Animals were tested for spatial learning and memory in the eight arm radial maze. The brains were obtained to assess expression and phosphorylation such as Akt (Ser 473), GSK-3β (Tyr 216), Trk-A receptor (Tyr 674/675) and vesicular acetylcholine trasporter (VAChT) by western-blot in NBM, frontal and temporal cortex (CxF, CxT). Finally a group of animals was designed to evaluate the activity of acetylcholinesterase (AChE) by the Ellman assay in Cx-F and CxT. We found that the administration of Hc-TeTx+$A\beta_{25-35}$ prevents a decrease in phosphorylation of Trk-A receptor and Akt protein, on the other hand decreases the phosphorylation of GSK-3β and maintains expression of VAChT compared with $A\beta_{25-35}$. All these improvements could be reflected on spatial learning and memory performances. In summary, our findings suggest that Hc-TeTx fragment promotes Trk-A signaling and improves the spatial learning and memory process in rats with $A\beta_{25-35}$ peptide.

Title: The effect of phloretin, a phytoestrogen, on amyloid beta 1-42 induced toxicity in primary cortical neurons and *In vivo* models

Authors: *P. J. GHUMATKAR, JR[1], V. PESHATTIWAR, Jr[1], D. WHITFIELD[2], S. SATHAYE[1], P. FRANCIS[2];
[1]Inst. of Chem. Technol., Mumbai, India; [2]King's Col. London, London, United Kingdom

Abstract: The aggregation of amyloid beta (Aβ1-42) that results in formation of extracellular senile plaques is the major pathological hallmark of Alzheimer's disease (AD). Aβ1-42 has been shown to produce deleterious effect on hippocampal adult neurogenesis, synaptic proteins and cognition. Phloretin, a phytoestrogen found in apple leaves has previously been shown to enhance spatial memory and to demonstrate strong antioxidant, anti-inflammatory and neurotrophic actions in a scopolamine induced amnesia mouse model. The objective of this study was to evaluate the effect of phloretin on Aβ1-42 induced pathological alterations *in vitro* as well as *in vivo*. In this study, we examined the ability of phloretin to protect primary cortical neuronal cells exposed to oligomeric Aβ1-42 as well as investigated a potential modulatory role on adult neurogenesis in Aβ1-42 injected Wistar rats. In the in vitro study, primary rat cortical neurons were treated with phloretin 10μM and then further exposed to Aβ1-42 oligomers 3μM concentration. For the in vivo study, male Wistar rats were pre-treated with phloretin 5mg/kg, followed by intra-hippocampal injections of 2 μL of aggregated Aβ1-42 at 200 μM/L concentration. Following sacrifice, perfused brains were removed and subjected to immunohistochemical analysis for BrdU, Ki67 and doublecortin (DCX). Exposure of primary neuronal cultures (n=3) for 24 hours to Aβ1-42 significantly ($P \leq 0.01$) decreased the cell viability by 19% as compared to the vehicle control cells. However, 3 days pretreatment with phloretin significantly ($P \leq 0.001$) protected the neuronal cells from the Aβ1-42 toxicity. The preliminary results of the in vivo study demonstrated that 21 days phloretin treatment elevated the number of BrdU, Ki67 and DCX positive neurons in the dentate gyrus as compared to sham control rats by 70%. Aβ1-42 injections decreased cells stained for BrdU and Ki67 as well as DCX in the sub

granular zone (sgz) of the hippocampus by a minimum of 35%. Pretreatment of Aβ1-42 injected rats with phloretin increased the number of DCX positive cells by 42% in the sgz of when compared to Aβ1-42 rat brains. The above experimental findings point to a neuroprotective role of phloretin in Aβ1-42 exposed primary cortical neurons and an ability to enhance adult hippocampal neurogenesis in normal as well as Aβ1-42 injected rats. While further work is required these encouraging preliminary findings highlight the potential of phloretin as a dietary supplement targeting key therapeutic mechanisms in AD.

Title: Neurosteroid metabolites of testosterone and progesterone are protective against amyloid β-induced neurotoxicity

Authors: *A. L. MENDELL, C. E. CREIGHTON, N. J. MACLUSKY;
Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Androgens, estrogens, and progestogens have all been reported to have neuroprotective properties. It has been suggested that the protective effects of androgens and progestogens may involve conversion to neurosteroid metabolites in the brain. 5α-androstane-3α,17β-diol (3α-diol) and 3α-hydroxy-5α-pregnan-20-one (allpregnanolone; ALLO), metabolites of testosterone and progesterone, respectively, have been shown to allosterically potentiate the activity of GABA at the $GABA_A$ receptor ($GABA_AR$). Intriguingly, elevated free levels of these hormones have been correlated with a reduction in the risk for Alzheimer's disease. Dysregulation and prolonged phosphorylation of extracellular signal-regulated kinase (ERK) is an indication of oxidative stress, and has been implicated in amyloid-induced neurotoxicity. In this study, we sought to determine whether 3α-diol and ALLO could protect against prolonged ERK phosphorylation induced by hydrogen peroxide (H_2O_2) and amyloid β peptide 1-42 (Aβ42) in SH-SY5Y human neuroblastoma cells and primary cortical neurons cultured individually from

male and female mice. Both 3α-diol and ALLO prevented prolonged ERK activation induced by 24 hour H_2O_2 treatment and 48 hour Aβ42 treatment in SH-SY5Y cells and primary cortical neuron cultures from male or female mice. However, the concentration required for these effects differed drastically - a final concentration of 100nM was necessary to achieve neuroprotection with ALLO, while 3α-diol was able to produce the same apparent protection at a final concentration of only 10nM, below the threshold for its potentiation of $GABA_A$ signaling. Additionally, antagonism of the $GABA_AR$ prevented the protective effect of ALLO, but not 3α-diol. These results suggest that neurosteroids may play a role in the prevention of amyloid-induced neurotoxicity, and may therefore contribute to the neuroprotective effects of androgens and progestogens. The mechanisms and concentration requirements for ALLO- and 3α-diol-mediated protection appear, however, to be different. The potency of 3α-diol suggests that it may contribute to the apparent reduction in risk of Alzheimer's disease in men with high circulating free testosterone levels (Hogervorst *et al* Exp Gerontol. 2004;39:1633).

Title: Secreted APP alpha overexpressing neural stem cells as a therapeutic for dementia-linked insulin signaling dysfunction

Authors: *B. AULSTON, G. GLAZNER, G. ODERO;
St. Boniface Res. Ctr., Winnipeg, MB, Canada

Abstract: Aberrant insulin signaling is present in the Alzheimer's brain and may underlie disease-associated cognitive dysfunction. Moreover, the administration of exogenous insulin has shown promise as a treatment for Alzheimer's disease (AD) suggesting that activation of brain insulin signaling is a therapeutically viable strategy. Despite mounting evidence that the neurotrophic factor secreted amyloid precursor protein alpha (sAPPα) may activate insulin signaling pathways and reverse diabetes and AD-associated pathology, the therapeutic potential

of sAPPα as a treatment for dementia-linked insulin signaling dysfunction has yet to be explored. Furthermore, there is currently no clinically viable sAPPα delivery system suitable for human patients. Therefore, we tested the effects of sAPPα overexpressing neural stem cells (NSCs) on cognitive dysfunction and disease-induced pathology in mouse models of AD and diabetes. 6 month old, non-transgenic SAMP8 AD mice were made diabetic by i.p. injections of STZ and wild-type or sAPPa-overexpressing NSCs implanted into the hippocampus 2 months later. 8 weeks after NSC implantation, cognitive performance was evaluated in these mice via Morris Water Maze. Mice were then sacrificed and hippocampi were analyzed for activation of insulin signaling, presence of amyloid beta and phosphorylation of tau. Some hippocampi were reserved for analysis of mitochondrial function, LTP and characteristics of NSC transplants. In total, the work presented here supports the development of sAPPα-overexpressing NSCs as a therapeutic for the treatment of dementia-linked insulin signaling dysfunction.

Title: Annexin A1 can restores Aβ1-42 induced blood brain barrier disruption

Authors: *J. PARK, S. BAIK, S.-H. HAN, H. CHO, H. CHOI, H. KIM, H. CHOI, W. LEE, D. KIM, I. MOOK-JUNG;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The blood brain barrier (BBB) is composed of brain capillary endothelial cells and has an important role in maintaining homeostasis of the brain separating the blood from the parenchyma of the central nervous system (CNS). It is widely known that disruption of the BBB occurs in various neurodegenerative diseases, including Alzheimer’s disease (AD). ANXA1 (ANXA1), an anti- inflammatory messenger, is expressed in brain endothelial cells and there were some reports that it can regulates BBB integrity. However, its role and mechanisms for protecting BBB in AD have not been identified. We found that β-Amyloid 1-42 (Aβ42)-induced BBB disruption was rescued by human recombinant ANXA1 (hrANXA1) in the murine brain endothelial cell line bEnd.3 and the capillaries of 5XFAD mice. In addition, we verified that the RhoA signaling pathway was activated in the Aβ42 treated bEnd.3 cells and the capillary of 5XFAD mice. Therefore, we suggest that ANXA1 can restore Aβ42-induced BBB disruption through inhibition of RhoA-ROCK signaling pathway and propose ANXA1 as a therapeutic

reagent, protecting against the breakdown of BBB in AD. **Keywords:** Annexin A1; blood-brain barrier; Alzheimer's disease; RhoA-GTP

Title: Intensive brain training intervention fails to reduce amyloid pathologies or cognitive deficits in transgenic mouse models of Alzheimer's disease

Authors: *M. ANDERSON[1,2], F. XU[1], M. OU-YANG[1], J. DAVIS[1], W. VANNOSTRAND[1], J. ROBINSON[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Farmingdale State Col., Farmingdale, NY

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder that is the leading cause of dementia in the elderly. Amyloid β protein (Aβ) depositions in both the brain parenchyma and the cerebral vasculature are recognized as important pathological components that contribute to the cognitive impairments found in individuals with AD. Because pharmacological options have been minimally effective in treating cognitive impairment to date, interest in the development of preventative lifestyle intervention strategies has increased in the field. One controversial strategy, cognitive-specific stimulation, has been studied previously in human participants and has been widely commercialized in the form of 'brain-training games.' In the present study, we developed a highly controlled, isolated cognitive training intervention program for mice. Two transgenic mouse lines, one that develops Aβ deposition largely in brain parenchyma, and another in the cerebral microvasculature, progressed through a series of domain-specific tasks for an average of 4 months. Following the intervention, spatial memory and exploratory behavior were assessed in the Barnes maze and the DigiScan. Brain tissue was harvested for quantitative ELISA and immunostaining for Aβ species. Despite the high intensity and duration of the intervention, we found little evidence of positive benefits for AD amyloid pathologies and post-training cognitive testing in these two models. Taken together, these results

support the current evidence in human studies that cognitive-specific stimulation does not lead to a measureable reduction in AD pathology or an improvement in general brain health.

Title: Design of inhibitor against amyloid toxicity

Authors: ***C. LIU**, D. LI, C. WANG;
Chinese Acad. of Sci., Shanghai City, China

Abstract: Alzheimer disease (AD) is one of the major forms of neurodegenerative disorders. Currently, over 50 million patients are suffering from AD worldwide. The abnormal aggregation of amyloid-beta (Aβ) into plaques in brain is the hallmark of AD[1,2]. The most widely used strategy for drug development against AD is to prevent the formation of pathogenic Aβaggregates[3,4]. In this study, we performed two different strategies of structure-based inhibitor design against Aβtoxicity. One is to develop peptide-based beta-sheet mimics to target the nucleus of Aβaggregates. By blocking the nucleation process, beta-sheet mimics efficiently inhibited Aβaggregation and reduced its cytotoxicity in mammalian cells. The second strategy is to design small molecules capable of stabilizing Aβfibrils. From structure-based rational design, several compounds were identified as tight fibril binders. The compounds were able to detoxify Aβby accelerating the formation of non-toxic amyloid fibril. Further in vivo studies would be necessary to evaluate the potential of these inhibitors as drug candidates. 1. Chiti, F. & Dobson, C. Title: Selective targeting of three repeat tau for the treatment of neurodegenerative disorders

Authors: *B. J. SPENCER[1], E. ROCKENSTEIN[2], A. ADAME[2], P. DESPLATS[3], E. MASLIAH[3];
[1]Neurosciences, UCSD, LA Jolla, CA; [2]Neurosciences, [3]Neurosciences & Pathology, UCSD, La Jolla, CA

Abstract: Neurodegenerative disorders with Tau accumulation are a common cause of dementia in the aging population. Alternative splicing can generate two different major forms of Tau containing either 3 or 4 32 amino acid repeats. These 3R or 4R Tau species are differentially expressed in neurodegenerative diseases with Corticobasal degeneration (CBD) and Progressive supranuclear palsy (PSP) primarily expressing the 4R Tau isoform while Pick's Disease (PiD) primarily expresses the 3R Tau isoform. Immunotherapy may prove to be effective at reducing total Tau protein; however, studies with Tau knock out mice and have shown that this strategy might have deleterious effects. Furthermore, down-regulation of Tau in oligodendrocytes by siRNA results in reduced expression of MBP protein leading to reduced myelination. To date, there has been little or no effort to specifically target the 3R Tau protein. We developed a single chain antibody (scFV) specifically recognizing 3R Tau and then further modified this with proven brain transport peptide to facilitate trafficking into the brain. Non-tg and 3R Tau-tg mice receive IP injections of a lentivirus expressing the 3R Tau scFV, LV-3RT-apoB, or LV-control and after 4 weeks were evaluated behaviorally, biochemically and neuropathologically. 3R Tau-tg mice treated with the brain penetrating LV-3RT-apoB displayed improvements in behavior comparable to the non-tg mice in contrast to mice treated with control vector or the non-brain-penetrating scFV expressing vector. By western blot with an antibody against the scFV, mice treated with LV-control or LV-3RT without the brain penetrating apoB tag showed low or no immunoreactivity, in contrast mice treated with LV-3RT-apoB displayed higher levels of immunoreactivity in brain homogenates. Next, brain sections were immunolabeled with antibodies against the scFV. Likewise, mice treated with LV-control or LV-3RT showed low or no immunoreactivity, in contrast mice treated with LV-3RT-apoB displayed immunoreactivity in neuronal cells in the neocortex and hippocampus. To evaluate the beneficial effects of the 3RT-apoB, brain sections were immunostained with antibodies against 3R Tau. The highest levels of 3R Tau were detected in tg mice treated with the LV-control or LV-3RT. In contrast, tg mice

treated with LV-3RT-apoB showed decreased levels of 3R Tau accumulation in neuronal cells in the neocortex and hippocampus. Thus, we have developed the first 3R Tau specific antibody for the treatment of PiD that can reduce Tau accumulation, prevent neuronal degeneration and reverse behavioral deficits in a mouse model of PiD.

Abstract: Neurodegenerative disorders are the leading cause of death and disability in the elderly population. The number of people living with neurodegenerative diseases continues to rise due to increased life expectancy, therefore, finding effective prevention and treatment strategies is becoming increasingly important. The aggregation and accumulation of the microtubule-associated protein, tau, are pathological hallmarks of many neurodegenerative diseases known as tauopathies such as Alzheimer’s disease, Parkinson’s disease and many others. For a long time, neurofibrillary tangles (NFTs)—aggregates of hyperphosphorylated tau—were assumed to be the cause of neuronal toxicity since they correlate with cognitive decline and neuronal loss. Recent studies by our lab and others demonstrate that tau oligomers are the true toxic and propagating species in these diseases. Tau oligomeric structures, aggregates of an intermediate size between monomers and NFTs, are a heterogeneous group of biophysically and conformationally distinct tau multimers that can be present in numerous

conformations termed tau oligomeric strains. Due to the dynamic nature of these strains, studies focusing on the mechanisms underlying their formation and characteristics are challenging. Importantly, different strains could potentially explain how the aggregation of the same protein causes different diseases, progression rates and phenotypes, even between individuals within the same disorder. Thus, depleting the disease-relevant structures by using small molecules could be a powerful therapeutic strategy that targets toxicity regardless of the diverse factors involved in the formation of tau oligomeric strains. We hypothesize that small molecules targeting and specifically binding to tau oligomeric strains can neutralize their formation and toxicity, thus preventing the spread of pathology. We used biochemical and biophysical methods to characterize tau oligomeric strains and their reactivity with tau oligomer-specific polyclonal and monoclonal antibodies, T22 and TOMA respectively, in the presence and absence of our first small molecule, CA. Interestingly, CA binds and significantly decreases levels of both 3R and 4R oligomeric tau. We identified the first leading compound that is capable of modifying tau oligomeric structures and we are currently developing new compounds based on CA structure. Moreover, we are screening additional compounds for their ability to target and modulate tau oligomeric strains toxicity and/or formation in order to develop disease-specific and personalized therapeutics and imaging reagents.

Abstract: Neurodegeneration and cognitive decline in Alzheimer disease is paralleled by the spread of neurofibrillary tangles or tauopathy that may be initiated but not halted by Abeta directed therapies. Tangles comprised of microtubule-associated protein tau are a tauopathy hallmark, but preclinical studies have implicated smaller, more soluble toxic tau aggregate species including ptau and tau oligomers in the spread of tauopathy and cognitive deficits. Because most aggregation inhibitors have off-target effects that have historically prevented successful drug development, a selective tau aggregation inhibitor, D-TLKIVW (D-peptide), was designed that very specifically targets the aggregate-forming steric zipper region of tau (Sievers et al. 2011). To test *in vivo* efficacy, D-peptide or its TAT-analog (TAT-D) were fed to Drosophila expressing human non-mutant human tau (htau Tg+ Dr) with a degenerative rough eye phenotype. D-peptide reduced tau dimer and protected from rough eye while TAT-D was more protective. Next D-peptide or its scrambled form (d-TAKIVW) as a control were intra-cerebroventricularly infused for two weeks into aged htau Tg+ mice on a mouse tau knockout background (17-20 month, n=14). The ipsilateral hemisphere containing the infusion cannula was used for immunocytochemistry, while the contralateral hippocampus, frontal subcortex and posterior subcortex were selected for biochemical measurements. D-peptide infusion reduced soluble tau dimer, insoluble tau aggregates in subcortex, and phosphorylated tau (pTau, CP13) by ICC in pyramidal neurons of hippocampal CA3. D-peptide increased subcortical tyrosine hydroxylase (TH) and parameters involved in or impacted by anterograde fast axon transport (FAT), a putative tau aggregate target. These included the motor protein kinesin and the mitochondrial marker porin evaluated by Western as well as the perikayal accumulation of amyloid protein precursor (APP) in CA3 and globus pallidus evaluated by ICC. D-peptide also resulted in an increase of post-synaptic protein PSD95 in frontal subcortical fractions. These results suggest that acute D-peptide treatment can limit candidate toxic tau aggregate species *in vivo* to protect neurons in mice and flies with no reduction in total soluble tau. While the present proof of principle study used invasive intraventricular infusion to deliver the drug to mice, if brain penetrant D-peptide or related drugs can be further developed, this structure based drug design may be a viable approach to treating tauopathy, including AD.

Title: Phenotypic screening for novel inhibitors of Tau aggregation in human iPSC-derived neurons

Authors: *B. VOLETI, M. USENOVIC, L. WARREN, A. WALJI, S. SUR, P. YI, J. LI, H. ZHOU, J. SCHACHTER, B. LUO, L. LUBBERS, S. P. BATTEUR;
Neurosci., Merck and Co, West Point, PA

Abstract: Tauopathies are neurodegenerative diseases characterized by the presence of aggregates of abnormally hyperphosphorylated tau. Due to the intrinsic differences in clearance mechanisms between neuronal and non-neuronal cells, we used human iPSC-derived neurons to develop a biologically relevant cellular model that recapitulates the disease. AAV8-mediated overexpression of both wild type (hu tau WT) and an aggregation-prone construct of tau (hu Tau-mod) in iPSC-neurons resulted in disease-relevant phenotypes such as tau phosphorylation, misfolding, aggregation and subsequently neuronal death. Phenotypic screening of a selected library of annotated compounds in the *in vitro* model of human iPSC-derived neurons resulted in ~7% hit rate with targets spanning across different functional classes such as autophagy, kinase inhibition, inflammation etc. Dose-response evaluation of the hits and confirmatory screening assays are ongoing to identify novel targets/pathways and support target identification efforts. In addition, we have established the translation of this model in vivo and overexpression of both WT and aggregation-prone construct of tau in rat hippocampus showed increased tau phosphorylation, misfolding and neurodegeneration at 6 weeks post AAV infusion. Behavioral, biochemical and immunohistochemical analyses are ongoing to further characterize the *in vivo* model of tauopathy. Our goal is to uncover key targets involved in the clearance of tau aggregates that could become potential strategies to cure neurodegenerative disorders associated with tau.

Title: Chronic Angiotensin IV administration rescues cerebrovascular deficits and memory retention in a mouse model of Alzheimer's disease

Authors: *J. ROYEA, M. LACALLE-AURIOLES, P. MARTINOT, X.-K. TONG, E. HAMEL; Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: Background: Hypertension increases the risk of developing Alzheimer's disease (AD) with increasing age. Cohort studies have shown lower incidence and progression to AD in elderly patients treated with anti-hypertensive medications targeting the renin-angiotensin system. The mechanism initiating these benefits is unknown; yet, blockade of angiotensin II (AngII) type 1 receptors (AT1Rs) may favor conversion of AngII to angiotensin IV (AngIV). AngIV receptors (AT4Rs) have been implicated in cognitive performance and cerebrovascular dilatory function. Objective: We investigated whether chronic intracerebroventricular (icv) administration of AngIV could restore cerebrovascular and cognitive function in transgenic mice overexpressing the Swedish and Indiana mutations of the human amyloid precursor protein (APP mice). Methods: APP mice (4.5 months old) were administrated (icv, 1 month) artificial CSF or AngIV (~1.3 nmol/day, AT4R agonist), delivered using osmotic minipumps. At endpoint, a MWM was performed to assess spatial learning and memory. Neurovascular coupling response to whisker stimulation was measured using laser Doppler flowmetry and cerebrovascular vasodilatory function was measured in segments of isolated and pressurized posterior cerebral arteries. Blood pressure was monitored by non-invasive tail-cuff plethysmography. Results: Chronic AngIV administration rescued neurovascular coupling and dilatations of cerebral arteries to acetylcholine, calcitonin gene-related peptide, ATP-sensitive potassium channel opener levcromakalim and transient receptor potential vanilloid 4 channel opener GSK1016790A, as well as baseline production of nitric oxide measured by incubating vessel segments with N^{ω}-nitro-$_{L}$-arginine. The impaired spatial learning capacity of APP mice was not

rescued following 1 month of AngIV delivery. However, memory retention was improved for the time and distance swam within the target quadrant despite a non-significant number of crossings over the hidden platform, suggesting a deficit with precision. Blood pressure was comparable in all groups. Conclusions: The AngIV/AT4R cascade rescued impairments in neurovascular coupling, cerebrovascular dilatory function and memory retention in APP mice. Our findings identify the AngIV/AT4R cascade as a promising target for restoring cerebrovascular deficits in AD.

Abstract: Amyloid containing neuritic plaques and Tau containing neurofibrillary tangles are characteristic of the neuropathology that appears in the brains of Alzheimer disease (AD) patients. By combining two innovative technologies, induced pluripotent stem cells (iPSCs) and three-dimensional (3D) human neuronal culture, we have created cellular model systems representing five individual AD patients. We developed iPSCs from human peripheral blood mononuclear cells taken from each patient and differentiated these iPSCs into 3D human neuronal cultures. We validated the differentiation status of our 3D neurons by immunocytochemical staining to characterize neuronal markers. We treated these 3D neurons

either with inhibitors targeting β- or γ-secretase, two enzymes that cleave amyloid precursor protein (APP) to generate amyloid β peptide (Aβ), or with inhibitors targeting glycogen synthase kinase 3β (GSK3β), which phosphorylates Tau at multiple sites. We confirmed the drug exposure of 3D neurons and quantified the levels of these inhibitors inside of neurons at the end of treatment by quantitative liquid chromatography/tándem mass spectrometry. The β- and γ-secretase inhibitors blocked generation of Aβ in cultured neurons derived from all five AD patients. However, the GSK3β inhibitor exhibited variation among 5 AD patients' neuronal lines. Specifically, GSK3β efficacy for blocking Tau phosphorylation at residues threonine 181 versus threonine 231 varied among the individual patients' neurons. Furthermore, a different class of GSK3β inhibitor also demonstrated the same pharmacological inhibition profile for Tau phosphorylation in our individual AD patient derived neuronal systems. In conclusion, our 3D human neuronal cultures, differentiated from iPSCs derived from individual AD patients, represents the most physiologically relevant model for testing drug efficacy in vitro.

Title: TFEB-mediated cellular clearance as a potential therapy for Alzheimer`s disease

Authors: *H. SUN[1], Y. LI[2], H. LUO[2], H. ZHENG[2,3];
[1]Inst. of Neurosci., Xiamen Univ., FUJIAN, China; [2]Inst. of Neurosci., Xiamen Univ., Xiamen, China; [3]Huffington Ctr. on Aging, Baylor Col. of Med., Houston, TX

Abstract: Autophyagy is the basic catabolic mechanism that involves cell degradation of unnecessary or dysfunctional cellular components through the actions of lysosomes. Its dysfunction has been implicated in multiple neurodegenerative diseases with abnormal protein aggregates. The transcription factor EB (TFEB) can activate the autophagy-lysosome pathway (ALP) through coordinated expression of autophagy and lysosomal target genes. It also plays crucial roles promoting cellular clearance through transcriptional activation of endocytosis and membrane repair and lysosomal exocytosis. Our data has shown a highly efficacious effect of TFEB in ameliorating pTau and NFT pathology in rTg4510 mutant Tau transgenic mice. In

addition, it leads to the improved synaptic plasticity and cognitive improvements in this mouse model. Thus, TFEB is an attractive therapeutic target due to its ability to simultaneously activate autophagy and lysosomal biogenesis, its activity can be modulated through kinase inhibition. So we hypothesize that activation of TFEB by novel kinase inhibitors will be effective in clearing pTau and NFT pathology and improves cognitive outcomes. We propose to identify new TFEB activators by performing high-throughput screening of selected small molecule libraries using a TFEB-specific luciferase reporter assay and test the effect of the inhibitors on TFEB activity and tau/NFT pathology in rTg4510 mouse model. Above all, our study holds promise for intervening protein aggregate pathologies in AD and other neurodegenerative diseases.

Title: Hypercaloric diet-induced metabolic syndrome increases white matter inflammation and cognitive deficits in a transgenic rat model of Alzheimer's disease

Authors: ***N. IVANOVA**, N. WEISHAUPT, S. WHITEHEAD, D. CECHETTO;
Anat. and Cell Biol., Western Univ., London, ON, Canada

Abstract: Alzheimer's disease (AD) is a debilitating progressive incurable neurodegenerative disease. Metabolic disorders including obesity, metabolic syndrome (MS) and type 2 diabetes represent a risk factor for dementia including AD later in life. Unhealthy lifestyle choices, particularly the intake of high-caloric Western diet rich in saturated fat and simple carbohydrates, is a common risk factor for the development of metabolic syndrome and is associated with incidence of clinical dementia. The existence of a common basis for these two pathologies raises the possibility of a contribution of metabolic disorders to the course of the dementia when these conditions are co-morbid, however, the underlying mechanisms of this interaction are yet to be elucidated. And this knowledge may be crucial for defining a new therapeutic target and, moreover, may point out a possible preventative strategy.
In this study we investigate the effect of diet-induced metabolic disturbances on neuropathology, specifically examining the consequences of its chronic course on neuroinflammation, and cognitive function in a transgenic rat model carrying a human β-amyloid precursor protein gene

with Swedish and Indiana mutations, implicated in early-onset AD.
Wild type with intact genotype and transgenic rats 8.5-9 month old were fed either a hypercaloric (HCD) or a control diet for 12 weeks. Diet consumption and caloric intake were measured twice a week throughout the experiment. Assessed physiological parameters included body weight, glucose and insulin levels, serum lipid profile and blood pressure. Cognitive function was assessed using Morris water maze. Immunohistochemistry was used to examine neuroinflammation including staining for markers of activated microglia and astrocytes.
Rats maintained on the HCD developed significant obesity, visceral adiposity, dyslipidemia and hyperinsulinemia, but did not become hypertensive. Glucose metabolism was altered only in wild type rats on the HCD. Memory consolidation was impaired in the co-morbid model of AD and MS. Immunohistochemistry has shown greater white matter neuroinflammation in the co-morbid model in comparison to MS alone. Our data suggests that neuroinflammation might be one of the key elements linking early brain pathology to the neurodegeneration observed in AD and indicates anti-inflammatory agents may be a potential treatment strategy.

Title: Cathepsin B is a validated drug target for traumatic brain injury (TBI), Alzheimer's disease (AD), and related neurodegenerative brain disorders

Authors: ***V. Y. HOOK**[1], J. JACOBSEN[2], K. GRABSTEIN[3], M. KINDY[4], G. HOOK, 92037[5]; [1]Skaggs Sch. of Pharmacy, and Dept. Neurosciences, LA Jolla, CA; [2]AstraZeneca, Cambridge, MA; [3]Univ. of Washington, Seattle, WA; [4]Univ. of South Florida, Tampa, FL; [5]American Life Sci. Pharmaceuticals, La Jolla, CA

Abstract: There is an urgent, unmet need for new drug targets in neurodegenerative diseases. Animal models and clinical correlates show that the cysteine protease cathepsin B is such a target. Mice lacking the cathepsin B gene in traumatic brain injury (TBI), Alzheimer’s disease

(AD), ischemia (IS), chronic inflammatory pain (CIP), epilepsy (EP) and multiple sclerosis (MS) all have improved behavioral deficits, neuropathologies, or biomarkers relative to sufficient animals. Specifically, TBI of cathepsin B deficient mice results in less neuromotor dysfunction, brain tissue loss and neuronal cell death than that which occurs in wild-type (wt) animals. Transgenic AD mice expressing human APP containing the wt beta-secretase site sequence and London mutation develop memory deficits and brain amyloid plaque and deleting the cathepsin B gene in such animals reduces the memory deficits, amyloid plaque and neurotoxic brain amyloid-beta, including the pernicious pyroglutamate amyloid-beta. IS in a cathepsin B gene knockout mouse results in less brain injury and inflammatory TNF-alpha, IL-1beta, IL-10 cytokine production than occurs wt animals. In a CIP model, deleting the cathepsin B gene reduces chronic inflammatory pain and inflammatory cytokines IL-1beta and IL-18. Removing the cathepsin B gene in an EP mouse model reduces the brain neuronal cell death that occurs in cathepsin B sufficient EP mice. In a MS model, deleting the cathepsin B gene and that encoding cathepsin S, which is another cysteine protease, increases the age of onset, improves the clinical score and reduces spinal cord leukocyte infiltration. Increased cathepsin B levels also correlate with worse outcomes in patient groups. Plasma cathepsin B is elevated in polytrauma patients and higher levels correlate with increased organ failure and death. AD patients have higher brain and plasma cathepsin B levels than controls and higher plasma levels correlate with reduced cognitive function. Patients with the chronic inflammatory neurological diseases Guillain-Barre syndrome, chronic demyelinating polyneuropathy and MS have higher cerebrospinal fluid cathepsin B levels than controls. Cathepsin B expression is higher in spinal tissue from amyotrophic lateral sclerosis patients than in control patients. Cerebral aneurysum results in vascular wall cathepsin B levels that are much higher than normal vascular tissue. These data from a variety of neurodegenerative models and clinical correlates strongly support cathepsin B as a new drug target for many neurodegenerative diseases.

Title: Small molecule APP processing inhibitors lower Aβ peptide levels via cKit signaling

Authors: *C.-D. CHEN[1], E. ZELDICH[1], K. CAMARA[3], L. E. BROWN[3], J. A. PORCO[3], C. R. ABRAHAM[1,2];
[1]Biochem., [2]Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [3]Chem., Boston Univ., Boston, MA

Abstract: Alzheimer's disease (AD) is characterized by the accumulation of neurotoxic amyloid beta (Aβ) peptides, which are proteolytically derived fragments of the amyloid precursor protein (APP). Inhibiting Aβ production may reduce neurodegeneration and cognitive dysfunction associated with AD. Ample evidence suggests that dimerization of APP plays a role in Aβ production; however, the mechanism involved is not fully understood. We have previously used an APP-firefly luciferase enzyme complementation assay to conduct a high throughput screen for inhibitors of APP dimerization, and have identified a compound that inhibits APP dimerization and reduces Aβ levels. In the present study, we have identified a number of analogs with improved efficacy in reducing Aβ, and identified a lead compound, Y10. A kinase-profiling assay identified the cKit receptor tyrosine kinase as a possible Y10 target. To elucidate the precise mechanism involved, APP phosphorylation was examined by IP-western blotting. We found that Y10, in addition to inhibiting cKit phosphorylation increases APP phosphorylation on tyrosine residue Y743 (APP751 numbering). A second specific cKit inhibitor was also found to increase APP phosphorylation. Next, we investigated the effects of compounds that target cKit downstream signaling molecules on APP phosphorylation and Aβ reduction. Our results suggest that the cKit signaling pathway is involved in APP phosphorylation, surface localization, dimerization, and Aβ production. Thus, reduction of Aβ *via* regulation of APP phosphorylation should be considered as a novel therapeutic strategy for AD.

Title: Expression of the stress response regulatory protein Dual Leucine Zipper Kinase (DLK) during the development of the neuropathology in Alzheimer's disease

Authors: *V. BUGGIA-PREVOT, S. GOODWANI, C. CHAKRABORTY, R. SHIN, P. ACTON, W. RAY;
IACS Neurodegeneration Consortium, MD Anderson Cancer Ctr., Houston, TX

Abstract: Patients affected by Alzheimer's disease (AD) develop amyloid plaques and neurofibrillary tangles long before cognitive deficits and neuronal loss can be measured in the brain. However the precise mechanism and pathways leading to the progressive yet ultimately massive neuronal death during AD remain elusive. Modulating such pathways to promote neuroprotection would be an attractive therapeutic strategy to slow the progression of AD and preserve patients' cognitive function. Activation of c-jun N-terminal kinase (JNK) pathway is a critical player in triggering neuronal death in response to acute neuronal stress and injury. The neuron-specific mixed lineage kinase member Dual Leucine Zipper kinase (DLK, *Map3k12*) is required for JNK pathway activation in response to acute neuronal damage such as axonal injury, excitotoxicity, and toxin-induced neurodegeneration. Despite evidence of the JNK pathway activation in slowly progressing degenerative condition, DLK expression in the CNS and its potential contribution to neuronal loss in AD hasn't been evaluated. In the present study, we examined DLK, the activated phosphorylated form of JNK (pJNK), and the target of JNK, p-c-Jun, by immunofluorescence at various ages in multiple models of AD (APP TTA, 5XFAD, rTg4510, p25/cdk5). In control brains, DLK is expressed exclusively in neurons throughout most brain regions with a predominant localization to axons. However, DLK localization is affected early in the pathological process and followed by JNK pathway activation in all AD models examined. Both DLK and p-JNK accumulates in dystrophic neurites surrounding amyloid deposits in the brain of both amyloid models tested, whereas in p25/cdk5 and rTg4510, DLK accumulates in damaged axons. We propose that DLK might play a critical role in triggering JNK-dependent neurodegeneration in AD in addition to its well-known role regulating the acute neuronal stress response.

Title: Characterizing p53 oligomers in neurodegenerative disease

Authors: *K. FARMER[1], C. LASAGNA-REEVES[2], R. KAYED[1];
[1]Univ. of Texas Med. Br., Galveston, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: The homotetrameric tumor suppressor, p53, is known as the “guardian of the genome” due to its role as a master regulator of cell cycle control, apoptosis, and DNA repair. P53 is the most frequently mutated gene in cancer cells and its loss of function is associated with over 50% of cancers, but p53 also plays a substantial role in aging. An increase in p53 can lead to premature aging, the primary risk factor for the most prevalent neurodegenerative diseases. Impaired proteostasis is implicated as an etiological factor in a growing number of diseases, notably neurodegenerative disorders and recently, cancer. When proteostasis is dysregulated, proteins misfold, aggregate, lose biological function, and eventually form large fibrils that disrupt the normal physiological function of nearby cells. Our lab and others have shown that p53 can aggregate into oligomers and fibrils similarly to other prion-like proteins implicated in neurodegeneration. The extent to which p53 oligomerizes in cancer has been shown to be dependent on the p53 mutation. This suggests that specific alterations to p53 may be critical to its propensity to form potentially toxic aggregates. Mutant p53 aggregates have been shown to seed the aggregation of wildtype p53 and also its paralogs, p63 and p73. This has led to the more alarming notion that P53, like the aggregant proteins associated with neurodegeneration, may have prion-like properties. Thus, we hypothesized that p53 oligomers may play a critical role in neurodegenerative disease. We demonstrated that p53 oligomers are the most toxic species in basal cell carcinoma, similar to findings for other amyloid proteins. We then evaluated p53 aggregation status in Alzheimer’s disease (AD) for the first time using brain tissue from AD patients and mice overexpressing mutated amyloid precursor protein (Tg2576 mice) by immunohistochemistry using novel antibodies with conformational epitopes common to oligomers of aggregant proteins and specific to oligomeric tau, F11G3 and T22, respectively. Our findings suggest that P53 oligomers may play a role in the progression of both cancer and Alzheimer’s disease and may interact with other aggregant proteins in disease. These results may

have implications for a number of other neurodegenerative disorders. Thus, it will be critical to understand which P53 mutations increase oligomerization and whether they are associated with different neurological disorders. Further research is needed to determine whether p53 may provide a new route for treatment of AD.

Title: PPP3CB catalytic isoform mediated signaling of Calcineurin is significantly altered in Alzheimer’s disease.

Authors: *M. THAKER[1], E. HUDRY[3], S. HOPP[2], B. T. HYMAN[4];
[1]Neurol., Res. Associate At MGH, Revere, MA; [2]Neurol., Res. Associate At MGH, Boston, MA; [3]Neurol., Instructor At MGH, Boston, MA; [4]Neurol., Professor At MGH, Boston, MA

Abstract: Calcineurin (CN), the only Calcium-dependent protein phosphatase, mediates diverse physiological processes including neuronal differentiation, axonal transport, long term depression (LTD), inflammation, and autophagy by dephosphorylating critical signaling proteins and transcription factors. The holoenzyme is composed of a catalytic and a regulatory subunit. Three catalytic (PPP3CA, PPP3CB, PPP3CC) and three regulatory (RCAN1, RCAN2, RCAN3) isoforms of CN are described. Accumulating evidence suggests that CN inhibition is a specific target for alleviating symptoms associated with early synaptic changes in Alzheimer’s disease (AD). However the mechanism of CN action remains poorly characterized in the brain. Moreover nothing is known about which catalytic and regulatory isoform reveal altered expression and signaling in AD. Therefore we developed a series of assays to examine the CN deregulation in AD by comparing its three catalytic isoforms PPP3CA, PPP3CB, PPP3CC and two regulatory isoforms RCAN1 and RCAN2 using immunohistochemical and biochemical assays. Cytosolic, nuclear and synaptoneurosomal fractions from the frontal cortex of AD brains were compared to age-gender matched control brains. Strikingly, among the three catalytic isoforms only the truncated and constitutively active form of PPP3CB was upregulated, while PPP3CC was downregulated and PPP3CA remained unchanged in AD brains. Both RCAN1 and RCAN2 expressions were reduced in AD brains. My data implies that increased activation of CN

in AD is due to both increased truncation of PPP3CB and decrease in endogenous CN inhibitors RCAN1 and RCAN2. Notably the altered expressions of catalytic subunit as well as the regulatory proteins were significant mainly in the cytosolic fractions in AD brains. Immunohistochemistry demonstrated that the catalytic isoforms exhibit differential sub-cellular localizations in human brain; PPP3CA and PPP3CB are cytoplasmic and PPP3CC is axonal while RCAN1/RCAN2 localize both in the cytoplasm and nucleus. Taken together, these data suggest that the catalytic isoforms PPP3CB and PPP3CC reveal altered cleavage and regulatory isoforms show altered expression affecting the overall activity of CN in AD brains which certainly is linked with the pathogenesis of AD.

Title: Formation of toxic oligomeric assemblies of RNA-binding protein Musashi in Alzheimer’s disease and other tauopathies

Authors: ***U. SENGUPTA**[1], K. LIN[2], G. MINUESA[3], M. G. KHARAS[4], R. KAYED[1]; [1]Neurol., [2]Univ. of Texas Med. Br., Galveston, TX; [3]Sloan Kettering Inst., New York, TX; [4]Sloan Kettering Inst., New York, NY

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disorder associated with structural and functional alterations of brain cells causing progressive deterioration of memory and other cognitive functions. While neurofibrillary tangles (NFT’s) and amyloid beta plaques are the classical pathological hallmarks of AD, existing findings suggest that an intermediate species in the aggregation process, oligomers, are the prime neurotoxic entities in this disease and other neurodegenerative diseases. Recent studies demonstrate that in addition to amyloid-β, tau and α-synuclein aggregation, AD pathology also exhibits aggregates of transactive response DNA binding protein (TDP-43) and some RNA-binding proteins. The two isoforms of MUSASHI (MSI1 and MSI2) are important proteins in the mammalian central nervous system (CNS), and have been studied in stem cells and in various cancers. Preliminary studies indicate that MUSASHI1 (MSI1) is ectopically present in lesion-bearing neurons in AD and other neurodegenerative tauopathies. Here we have investigated the expression and

accumulation of MUSASHI, as well as their possible interactions with other cellular proteins in neurodegenerative diseases. We have carried out biochemical and biophysical assays with recombinant MUSASHI and have also performed immunohistochemical (IHC) and biochemical analyses of post-mortem brain tissues from AD and other tauopathies using our conformation-based anti-oligomeric antibodies in combination with commercially available MSI1 and MSI2 antibodies.
Our data, for the first time, demonstrate that MUSASHI are present in an oligomeric state in AD brain compared to the control. Normally, MUSASHI is found to be monomeric, but higher concentration of these proteins may lead to their aggregation. More interestingly, we found nuclear localization of MUSASHI oligomers in the diseased brains. Despite being similar in function, MSI1 and MSI2 tended to aggregate and associate with other cellular proteins in different manner. MSI2 was found to associate with TDP43 and tau more evidently than MSI1.

Title: Palmitoylation in neurodegeneration

Authors: *C. DIEZ ARDANUY;
Strathclyde Inst. of Pharm. and Biomed. Sci., Univ. of Strathclyde, City of Glasgow, United Kingdom

Abstract: Neuronal Ceroid Lipofuscinoses (NCLs) are a group of hereditary, neurodegenerative disorders characterized by the accumulation of autofluorescent storage material in neurons. Depending on the age of symptomatic onset, NCLs are broadly classified infantile, juvenile and adult. Mutations in the *DNAJC5* gene encoding Cysteine-String Protein alpha (CSPα) have been identified as the cause of autosomal-dominant adult-onset NCL (ANCL) [1]. The disease-causing mutations (L115R and ΔL116) occur within the cysteine-string domain, a region of the protein that is extensively palmitoylated. Palmitoylation is a post-translational modification consisting of the attachment of fatty acids to cysteine residues through a thioester bond. We previously described that the ANCL mutations cause CSPα to form SDS-resistant aggregates, which are induced and maintained by S-acylation[2]. This observation is interesting as protein aggregation is a common feature of different neurodegenerative disorders. Using different proteasomal and

lysosomal inhibitors, we have been able to identify the degradation pathway of the CSP protein. Moreover, in order to investigate the role of palmitoylation and the cysteine string domain in aggregation, we transfected PC12 cells with previously generated mutant CSP proteins. With that purpose, we have been able to identify the residues involved in the aggregation process. Thus, the present study aims to identify the potential mechanisms involved in aggregation of ANCL mutant CSPα proteins and to further investigate how disruption of CSPα might cause the disease. Having identified the role of the cysteine-string domain in aggregation and the cellular pathways that mediate degradation of CSPα and ANCL mutant, we currently focus our interest in the characterisation of the CSP aggregates in human brains from ANCL patients and other neurodegenerative diseases. 1. Title: Increased pro-nerve growth factor induces RhoA activation in PC12 cells similar to Alzheimer's disease

Authors: J. SUSTARICH[1], S. SUCHDEVA[1], M. SYCHEVA[2], *R. B. JEGANATHAN[2], G. THANGIAH[1];
[1]Chem., Auburn Univ. Montgomery, Montgomery, AL; [2]Dept. of Nutr., Auburn Univ., Auburn, AL

Abstract: Recently we have shown that the expression of pro-nerve growth factor (proNGF) was significantly increased and NGF level was decreased in Alzheimer's disease (AD) hippocampal samples. NGF regulates cell survival and differentiation by binding TrkA and $p75^{NTR}$ receptors. ProNGF is the precursor form of NGF, binds to $p75^{NTR}$ receptor and induces cell apoptosis. Here, we show that the PC12 cells stimulated with proNGF significantly enhanced the expression of $p75^{NTR}$ receptor. The proNGF stimulation also increased the activation of RhoA

kinase and JNK apoptotic pathway. Interestingly, the activation of RhoA kinase and phosphorylation of JNK was also found to be increased in post-mortem human AD hippocampus compared to control, which might be due to increased expression of proNGF and $p75^{NTR}$ receptor. The addition of RhoA kinase inhibitor Y27632 not only blocked the RhoA kinase activity but also reduced the expression of $p75^{NTR}$ receptor induced by proNGF in PC12 cells. RhoA kinase inhibitor Y27632 also inhibited the proNGF induced neuronal death by abrogating the activation of JNK. These results suggest that overexpression of proNGF in AD enhances activation of RhoA thereby leading to neuronal cell death. Supported by Alabama Agricultural Experiment Station funding to RJ and Faculty Grant-in-aid to GT.

Title: Examination of dose-dependency on the effects of life-long voluntary exercise intervention on behavior in a mouse model of cerebral amyloid angiopathy

Authors: *L. S. ROBISON[1], D. L. POPESCU[1], S. I. BEIGELMAN[1], S. A. AMREIN[1], A. E. KUZMINA[1], D. A. LITUMA[1], W. LIU[1], S. M. FITZGERALD[1], S. SUBZWARI[1], F. XU[2], J. DAVIS[2], W. E. VAN NOSTRAND[2], J. K. ROBINSON[1];
[1]Psychology, [2]Neurosurg., Stony Brook Univ., Stony Brook, NY

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder for which pharmacological treatment has proven largely ineffective, resulting in interest in alternatives for prevention and treatment, particularly cardiovascular exercise. Cerebral amyloid angiopathy (CAA) is a neurological condition in which fibrillar amyloid is deposited around the cerebral vasculature. CAA is an important component of AD, predicting early cognitive deficits. The TgSwDI mouse is a well-characterized model of CAA, and due to the vascular nature of the pathology, is an ideal model to examine the effects of exercise on CAA symptomology. Therefore, we are investigating the dose-dependent effects of exercise on C57 WT and TgSwDI mice (n=10/group) split into four groups at 3-4 months of age: Sedentary, 1h, 3h, or 12h daily access to running wheel. Mice are run five days per week for 10 months, with behavioral testing

occurring prior to exercise, at the mid-point of exercise, and at the end of exercise treatment. An interesting qualitative difference in exercise groups emerged. While number of rotations (exercise volume) was greater in the 12h group, 1h and 3h mice took fewer breaks, producing increased training intensity. TgSwDI mice showed comparable rates of running to WT controls though consumed more food and weighed more than WT mice. Running dose-dependently reduced body weight in both genotypes despite increasing food intake. TgSwDI mice were also less active in the open field (OF) and radial arm maze (RAM). Interestingly, there was an inverse dose response (intensity versus volume) of exercise on activity levels in the OF and RAM, with 1h mice being most active, and this was consistent across genotypes. TgSwDI mice exhibited marginally anxiogenic behavior in the OF and light-dark box test (LDB). Running dose-dependently reduced anxiety-like behavior in several settings. TgSwDI mice were not impaired on object displacement or novel object recognition tasks and tasks involving social behavior. TgSwDI mice were marginally impaired on the rotarod, and exercise normalized this deficit. These findings suggest that the benefits of exercise may be dependent on exercise intensity and behavior measured, and that TgSwDI mice may be particularly sensitive to some of the beneficial effects of cardiovascular exercise.

Affairs Med. Ctr., Columbia, SC; [5]Anat. and Neurobio., Central South Univ. Xiangya Sch. of Med., Changsha, China

Abstract: Alzheimer's disease (AD) is characterized by CNS hypometabolism, neuropathological symptoms (β-amyloid plaques and neurofibrillary tangles) and dementia. A recent study on mid-aged humans suggests that insulin resistance is associated with regional cerebral hypometabolism (Willette et al., 2015) and a growing body of literature links Alzheimer's disease (AD) to diabetes and insulin resistance, although the mechanisms involved are unclear. Recently, Calon et al. (2014) reported that the 3xTg mouse model of AD exhibits peripheral glucose intolerance and prior data suggest that this model exhibits CNS hypometabolism (Nicholson et al., 2010). Since the primary source of CNS insulin is from the periphery, we tested the hypothesis that alterations in peripheral insulin can translate into altered CNS insulin signaling in 3xTg mice. Further, since the translocation of both glucose transporter 3 and 4 (GLUT3 and GLUT4) into the plasma membrane can be stimulated by insulin (Grillo et al., 2009; Uemura and Greenlee, 2006) we proposed that GLUT translocation could be altered. This could contribute to the hippocampal hypometabolism seen in 3xTg mice. We examined both the MAPK/ERK and PI3K/AKT insulin signaling pathways using immunoblotting in the hippocampus of 3xTg mice at a time point when neuropathology is observed (20-24 months). We then used immunohistochemistry (IHC) to assess whether this change could occur in a cell type or regionally specific manner. Additionally, we used immunoblotting to examine hippocampal GLUT3 and GLUT4 translocation by assessing GLUT levels in crude plasma membrane and total cell fractions. In aged 3xTg mice pAKT levels ($n = 7$ wild type, 8 3xTg; $p < 0.0001$) but not activated MAPK ($n = 8, 8$), are significantly decreased relative to age matched controls and IHC reveals that this change occurs throughout the hippocampus; astrocytes, pyramidal neurons and inhibitory neurons exhibited decreased pAKT immunoreactivity ($n = 4, 4$). Further, the level of GLUT3, but not GLUT4, was significantly decreased in the crude plasma membrane fraction of 3xTg mice ($n = 14, 14$; $p < 0.0001$); total GLUT levels were not altered. These data suggest that insulin signaling via the PI3K/AKT pathway can be altered in aged 3xTg mice and is associated with a decrease in GLUT3 translocation. This decrease in GLUT3 translocation could cause decreased glucose uptake in the CNS thereby contributing to AD-related hypometabolism and may explain why intranasal insulin administration can affect cognitive function and AD-related CNS hypometabolism.

Title: Human neural organoids: Predictive and personalized medicine models of brain diseases

Authors: *R. ANAND[1,3], S. B. MCKAY[2,3];
[1]Dept Pharmacol, [2]Dept Biol. Chem. and Pharmacol., Ohio State Univ., Columbus, OH;
[3]NEURXSTEM, Columbus, OH

Abstract: We engineered neural organoids (containing the retina, cortex, midbrain, hindbrain, brain stem and spinal cord) from normal as well as Alzheimer's disease (APP gene duplication) and tuberous sclerosis (TSC2Arg1743Gln) patient skin cells. Methods: We used transcriptomics, immunohistochemistry, and 3D whole brain imaging. Results: Transcriptomic results remarkably show comprehensive and accurate correlation of the dysregulated expression of hundreds of genes previously correlated with the clinical symptoms and/or pathologies of both of these diseases. For Alzheimer's disease these include genes for lipid homeostasis, inflammation, metal ion homeostasis, water homeostasis and longevity. For tuberous sclerosis these include genes for tumor formation, autism, blood pressure regulation, Zn++ ion homeostasis, Pb++ ion toxicity, round worm infections, and cholesterol metabolism among others. Discussion: Our results suggest that synchronous dysregulation of the spatial-temporal coordination of these genes cause these diseases. These genes possibly define disease-specific functional "homunculi" within the structure of the human genome.

Title: Hippocampal neuron loss and hippocampal sclerosis in the population

Authors: *S. R. HOKKANEN[1], S. HUNTER[1], T. S. MINETT[1], H. A. D. KEAGE[2], F. E. MATTHEWS[3], T. M. POLVIKOSKI[4], C. BRAYNE[1];
[1]Univ. of Cambridge, Inst. of Publ. Hlth., Cambridge, United Kingdom; [2]Univ. of South Australia, Cognitive Neurosci. Lab. Sch. of Psychology, Social Work and Social Policy, Adelaide, Australia; [3]Newcastle University, Inst. for Hlth. and Society, Newcastle upon Tyne, United Kingdom; [4]Newcastle University, Inst. of Neurosci., Newcastle upon Tyne, United Kingdom

Abstract: *Introduction*: Hippocampal neuron loss is a common neuropathological finding in the aging brain. Old-age hippocampal sclerosis (HS) is a dementing disorder, characterised by severe neuron loss and gliosis in hippocampal CA1. However, there are currently no objective HS criteria, and diagnoses vary considerably. HS aetiology is unclear, although it has been associated with both ischemia and TAR-DNA-binding protein-43 (TDP-43)- related neurodegeneration.
Methods: Hippocampal sections (6-9µm thick) from 691 brains donated for the population-based cohorts Cambridge City over-75s Cohort or MRC Cognitive Function and Ageing Study were evaluated. A semi-quantitative protocol capturing severity and extent of hippocampal neuron loss independent of the underlying cause was developed using hematoxylin-eosin stained slides. Vascular pathology was noted. HS was first evaluated independently from the protocol, and then described by observed neuron loss patterns. 624/ 691 cases had pTDP-43 staining. TDP-43 solid neuronal inclusions and neurites were assessed semi-quantitatively by hippocampal area and entorhinal cortex layer. All scorings were inter-rater evaluated.
Results: Focal CA1 neuron loss bordering CA2 was significantly associated with vascular aetiology (χ^2=8.2, p=0.004), whereas neuron loss in the subicular CA1 end presented significantly more frequently with TDP-43 inclusions (z=4.21, p<0.001). 34 HS cases exhibited maximal five pyramidal neurons in each of over half CA1 fields-of-view at x200 magnification, and were not associated with vascular lesions. All HS cases presented with hippocampal TDP-43

pathology.
Conclusion: We propose a protocol to describe hippocampal neuron loss patterns, and show that there are distinct neuron loss patterns associated with different etiologies within the hippocampal CA1 in the elderly population. We suggest easily applicable objective semi-quantitative neuropathological criteria defining old-age HS.

Title: Mechanisms linking depression and dementia in a genetic rat model of depression

Authors: *P. LIM, S. L. WERT, E. TUNC-OZCAN, E. E. REDEI;
Psychiatry and Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: As the population ages, age related diseases such as dementia including Alzheimer's Disease (AD) will have an increasingly significant burden on the sufferers, their family and the society. Dementia, specifically AD, has been found to be associated with depression. Mid-life depression is a risk factor for late-life dementia, but the mechanism(s) linking depression and dementia are not known. Both AD and depression show greater prevalence in women. To investigate the molecular mechanisms common to some forms of depression and dementia, a genetic rat model of depression was used. The Wistar-Kyoto (WKY) rat strain has been established as an animal model for adult and adolescent depression due to their behavioral, hormonal and sleep characteristics. Selective breeding of WKYs resulted in two inbred strains. The more immobile WKY (WMI) rats consistently display depression-like behavior in the forced swim test compared to the control less immobile (WLI) strain. We tested young, 5-7 month old, and "middle-aged" 11-13 months old female WLIs and WMIs in hippocampus dependent contextual fear conditioning (CFC). The young females did not differ in their memory functions between the two strains. In contrast, the aged female WMIs showed fear memory deficits compared to their same age WLI controls. The enclosed figure shows the freezing duration during the second day of the CFC. Please note that normalizing day 2 freeze duration to day 1 eliminated the differences in freeze duration between the young and aged females, but retained

the significant difference between aged WLIs and WMIs. Hippocampal expression of genes known to be associated with dementia such as Presenelin-1, Presenelin-2, and Insulin-like growth factor 2, parallel these differences in fear memory. Hippocampal expression of memory loss- related genes could be used to further identify depression-related cause(s) of dementia. Understanding the underlying processes by which depression predisposes to later life memory loss may lead to prevention and perhaps treatment.

Title: EFhd2, a novel amyloid protein linked to neurodegeneration

Authors: *I. E. VEGA;
Translational Sciene and Mol. Med., Michigan State Univ. Clin. and Translational Sci. Inst., Grand Rapids, MI

Abstract: EFhd2 is a novel amyloid and calcium binding protein that has been associated with different neurological disorders. EFhd2 is highly expressed in neurons compared to other cell types of the central nervous system. The physiological function of this novel protein is still unclear, but it has been shown *in vitro* that may play an important role in synapse formation. EFhd2 co- localized with neurite markers such as tau, MAP2, synapsin and PSD95, suggesting that its neuronal function could be associated with vesicle transport and synapse homeostasis. Knockdown of EFhd2 increased synpasin 1a/b puncta labeling in neurites, suggesting that modulation of EFhd2 affects the development of functional synapses, but it had no effect on converting them to mature synapses as determined by the co-localization of synapsin and PSD95. Previous work showed altered expression of EFhd2 in Alzheimer's disease (AD), Parkinson's disease, Huntington's disease, Amyotrophic Lateral Sclerosis, and schizophrenia, indicating that *Efhd2* gene expression could be modulated in response to neuropathological processes. Importantly, we showed that EFhd2 self-oligomerize and co-purify with filamentous tau proteins extracted from AD brain. However, the specific role that EFhd2 plays in the pathophysiology of neurological disorders is still poorly understood. Recent studies demonstrated that EFhd2 has structural characteristics similar to amyloid proteins found in neurological disorders. In order to dissect the molecular requirements that mediate EFhd2 oligomerization, we used a cell model system to question the role of phosphorylation, calcium binding and its coiled-coil domain in oligomerization. Additionally, we tested the effect that induced EFhd2 oligomerization has on cell survival. The understanding of EFhd2's oligomerization could lead to decipher molecular mechanisms that become activated in response to neuronal stress and degeneration.

Title: Endothelin-1 induces formation of cofilin rods in hippocampal neurons via endothelin receptor type B and oxidative stress

Authors: *S. TAM[1], W. LAU[1], P. YEUNG[2], S. CHUNG[2], A. LAW[1];
[1]Psychiatry, [2]Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Endothelin-1 (ET-1), which is a potent vasoconstrictor and neuromodulator, is shown to be over-expressed in the temporal lobe and white matter of post-mortem brains of patients who suffered from Alzheimer's disease (AD). In AD mouse models, ET-1 is also over-expressed in brain and may contribute to beta-amyloid (Aβ)-induced oxidative stress via binding to its receptors. On the other hand, oxidative stress induces cofilin to undergo dimerization and formation of rod-shaped aggregates, which contribute to loss of synapse and neuronal degeneration. In addition, an increase in cofilin rods can be seen in Aβ-treated *ex vivo* hippocampal slices or primary hippocampal neurons. Here, we hypothesized that the ET-1, of which level is increased in AD brain, may mediate cofilin rod formation via oxidative stress pathway in primary hippocampal neurons of mice.
Primary hippocampal neurons were isolated from C57BL/6N mouse on embryonic day 16 and cultured. In addition, these primary neurons expressed both ET receptor type A (ETAR) and type B (ETBR) on 14 day *in vitro* (DIV). On 14 DIV, neurons were treated with 100nM ET-1 with or without pretreatment of ETAR antagonist (BQ123) or ETBR antagonist (BQ788) for 24 hours. The involvement of oxidative stress in ET-1-induced rod formation was tested by co-treating neurons with ET-1 and N-acetylcysteine (NAC), which is known to block oxidative stress. Cofilin rods were visualized by immunostaining using anti-total cofilin antibody. The ET-1-induced oxidative stress was examined by CellRox reagent.
After 24h treatment with ET-1, there was a significantly higher percentage of neurons with cofilin rods, which was abolished by the co-treatment of NAC, suggesting ET-1 induces rod formation via oxidative stress pathway. In addition, ET-1-induced rod formation was also prevented by the pretreatment of BQ788, but not by BQ123, indicating the activation of ETBR pathway mediates the rod formation. Taken together, the over-expression of ET-1 in AD condition may induce oxidative stress-mediated cofilin rod formation.

Abstract: Progressive Supranuclear Palsy (PSP) and Corticobasal Degeneration (CBD) are sporadic parkinsonian disorders with Tau pathology that share many molecular and clinical features. Patients with these disorders experience relentless neurodegeneration and typically succumb within 5 years of diagnosis. There are currently no disease modifying therapies for PSP or CBD, representing a significant unmet medical need.
In this study, we performed comprehensive microRNA profiling in brain samples from PSP (n=10) and CBD (n=10) independent human patients. As control groups, we used brain samples from patients with no neurodegenerative disease (n=10). We also included samples from patients with Diffuse Lewy Body Disease (DLBD) that lack Tau involvement (n=10). From each subject, the frontal cortex and cerebellum were isolated (total 80 samples) and profiled for microRNA expression using the Human Nanostring microRNA assays version 2. Data were normalized by positive controls and total microRNA signal, background adjusted, and batch adjusted using *ComBat* (R library *sva*). microRNAs with log2 expression > 2 in less than 10% of samples were removed from analysis (low expression). 461 sufficiently expressed microRNAs passed this cut-off and were used in subsequent differential expression analyses.
Many microRNAs were differentially expressed in PSP, CBD, and DLBD patients compared to controls. Expression changes in the frontal cortex were much more pronounced compared to the cerebellum. In the cortex, we found 54 microRNAs commonly deregulated at a false discovery rate (FDR) < 20% in both PSP and CBD samples compared to normal controls. Most of the significant microRNAs, including many brain-specific transcripts, were downregulated indicating potential cell loss. A similar pattern of down regulation was observed in the cortex of DLBD samples compared to normal controls. Many of the differentially expressed microRNAs identified in this study have been implicated in pathogenesis of other neurodegenerative diseases and may represent common drivers of neurodegenerative disorders warranting further investigations.

Title: Impaired wnt signaling in the prefrontal cortex of alzheimer's disease patients

Authors: *J. FOLKE[1], B. PAKKENBERG[1], T. BRUDEK[2];
[1]Res. Lab. For Stereology and Neurosci., Bispebjerg-Frederiksberg Hosp., Kobenhavn NV, Denmark; [2]Res. Lab. For Stereology and Neurosci., Bispebjerg-Frederiksberg Hosp., Copenhagen, Denmark

Abstract: Objective: To investigate the transcriptional and translational link between the Wnt signaling and Alzheimer's disease (AD) pathology in the prefrontal cortex.
Background: AD is a progressive neurodegenerative brain disorder and is the leading cause of dementia in the elderly population. AD is accompanied by three main pathological changes: diffuse loss of neurons, intracellular protein deposits termed neurofibrillary tangles and extracellular protein deposits termed neuritic plaques. The Wnt singaling pathway comprises an evolutionary conserved family of proteins important during embryonic neural patterning and the regulation of cell proliferation, polarity and fate determination. The canonical Wnt signaling negatively regulates the protein glycogen synthase kinase-3 beta (GSK-3β) activity. It has been suggested that increased GSK-3β activity is linked to both "genetic" and "sporadic" forms of AD, suggesting a crucial role of GSK-3β in AD pathogenesis. However, little is known about the specific properties of GSK-3β in AD.
Methods: Using microarray analyses, gene expression profiles were investigated in post-mortem brain tissue from patients (*n*=30) with AD and age-matched controls (*n*=30) in three interconnected areas of the prefrontal lobe structures. Furthermore, the significant findings in the gene expression were validated using RT-qPCR and Western Blotting.
Results: Our data indicate that in AD several genes related to the Wnt pathway are aberrant on both transcriptional and post-/translational levels. Noteworthy, we observed a switch in the dynamics of the two main components of the pathway, the transcriptional activator, β-catenin, and the regulatory GSK-3β kinase in the orbitofrontal cortex and medial frontal gyrus, whereas the superior frontal gyrus showed only modest alterations. Furthermore, we found that the aberrancy was correlated to the disease progression following post-mortem Braak Stage evaluation.
Conclusions: Our study is the first to comprehensively evaluate the Wnt signaling pathway in the prefrontal cortex of AD brains. At the transcriptional level, several Wnt signaling related genes in AD patients were found to be altered compared to healthy controls. Furthermore, we found that the two main components in the Wnt signaling pathway were altered either in activity or on protein level, and was in most cases correlated to the disease progression. Overall our findings suggest that increased GSK-3β activity is associated with AD pathogenesis and could potentially act as a therapeutic target.

Title: Chronic short sleep fuels embers of Alzheimer's in locus coeruleus neurons

Authors: *S. C. VEASEY, Y. ZHU, P. FENIK, G. ZHAN, Z. ZHAO;
Ctr. for Sleep and Circadian Neurobio., Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Chronic short sleep (CSS) is pervasive in modern societies; yet recent studies raise the possibility that sleep loss might exacerbate Alzheimer's disease (AD). AD animal model studies demonstrating increased plaque burden and greater neurobehavioral impairment have all been performed using transgenic amyloid precursor protein (APP) models where APP is massively upregulated. We have shown that CSS in the adult mouse results in mitochondrial metabolic stress and degeneration of locus coeruleus neurons (LCn). Intriguingly, LCn are highly susceptible to early deposition of tau aggregates and degeneration and may contribute to the spread of tau. We hypothesized that CSS increases LCn APP processing to Aβ, that in turn disturbs sirtuin 3 deacetylase activity and increases acetylation of tau within the LCn that over time could spread. Adult amyloid precursor protein knock-in mice with the Swedish mutation ($APP_{KI}NL$) and wild type (WT) controls were randomized to CSS or rested conditions for 4wk and then allowed to recover for 4wk. Rested APP_{KI} mice relative to WT, showed reduced LCn counts (25%). Both genotypes showed comparable LCn loss upon CSS (25%). $APP_{KI}NL$ exposed to CSS showed greater mitochondrial lysine acetylation and reduced SirT3 levels. Additionally APP mRNA increased significantly in both WT and $APP_{KI}NL$ exposed to CSS and amyloid beta in LC micropunches showed increased oligomerization. Importantly both WT and $APP_{KI}NL$ mice exposed to CSS showed impaired spatial object recognition. Collectively, these findings support that CSS markedly alters APP levels and modifications within LCn, changes that persist beyond sleep loss and that CSS has important molecular and behavioral effects in not only the $APP_{KI}NL$ mouse but WT, as well. Remarkably, changes in mitochondrial homeostasis, amyloid processing and LC degeneration happen in WT mice, suggesting a key role for sleep loss in sporadic AD.

Title: Deficiency of membrane-anchored CX3CL1 lead to reduced cell-surface expression of CX3CR1 and elevates tau pathology in a model of systemic inflammation.

Authors: N. MAPHIS[1], G. XU[3], O. N. KOKIKO-COCHRAN[4], S. JUNG[5], J. CANNON[1], R. RANSOHOFF[6], B. T. LAMB[3], *K. BHASKAR[2];

Abstract: One of the primary means of neuron-microglia communication occurs via secretion of a neuronally derived chemokine, fractalkine (FKN) or CX3CL1, which binds to its cognate receptor (CX3CR1) on microglia and in turn regulates microglial function. FKN communicates with CX3CR1 either as a membrane-anchored ligand or as a soluble molecule following constitutive cleavage by proteases. Our previous studies have suggested that the CX3CR1 deficiency in microglia lead to accelerated tau pathology and cognitive impairment in an hTau mouse model of tauopathy. We also observed elevated tau pathology within the brains of non-transgenic mice when they received reactive microglia derived from hTau*Cx3cr1*$^{-/-}$ donor mice. However, it is still unclear whether the soluble versus membrane-anchored form of FKN is responsible for the negative regulation of microglial activation. Here we utilized a recently characterized transgenic mouse model (FKN$^{\Delta 105}$/mFKN$^{-/-}$ mice) which expresses only obligatory soluble FKN (FKN$^{\Delta 105}$) in the mouse FKN knockout background (mFKN$^{-/-}$) and studied the effects of inflammation via LPS-induced tau phosphorylation. First, the basal level of phosphorylated tau (pTau) on the AT8 (S202) site was higher in mFKN$^{-/-}$ and FKN$^{\Delta 105}$/mFKN$^{-/-}$ mice compared to non-transgenic and mFKN$^{+/-}$ mice. Second, the level of pTau on the AT180 (T231) site was lower in mFKN$^{+/-}$ mice compared to non-transgenic mice. Interestingly, LPS administration did not induce any alterations in the pTau levels except there was a decreased

trend in both $mFKN^{+/-}$ and $mFKN^{-/-}$ mice at both the AT8 and AT180 sites. Third, mononuclear cells isolated from the $FKN^{\Delta 105}/mFKN^{-/-}$ mice showed a significant reduction in the expression of CX3CR1 compared to $mFKN^{-/-}$ mice. Finally, $FKN^{\Delta 105}/mFKN^{-/-}$ mice showed significant behavioral impairments in the Elevated Plus Maze and Novel Object Recognition behavioral tasks. Together, these results suggest that exclusive expression of the soluble form of FKN by neurons renders microglia unable to suppress neuroinflammation because of the reduced CX3CR1 expression on the cell surface and results in elevated tau hyperphosphorylation.

Title: The biophysical determinants of prion neuroinvasion

Authors: ***C. SIGURDSON**[1,3], J. LAWRENCE[2], C. BETT[2], T. KURT[2], C. ORRU[4], P. AGUILAR-CALVO[2], C. WU[2], B. CAUGHEY[5];

Abstract: Pathologic beta-sheet rich protein aggregates accumulate in several devastating neurodegenerative diseases, including Alzheimer’s, Parkinson’s, and prion disease. Yet only prion protein aggregates have the unique ability to spread from extraneural sites into the interstitial spaces of the brain, causing fatal neurodegenerative disease. Interestingly, rare prion subtypes replicate extraneurally without spreading into the brain, leading to persistent subclinical carriers, and the factors that underlie the transfer of prion aggregates into the brain are unclear. Using prion strains having the same sequence but differing in structure, we identify a subset with a limited capacity for neuroinvasion in vivo. These prion aggregates rarely invade the CNS following intraperitoneal or intra-tongue inoculation, yet accumulate in extraneural organs, leading to lifelong subclinical carriers of infectious prions. Intriguingly, these poorly neuroinvasive prions are fibrillar, which are uncommon structures in prion disease, as most prions form oligomers. In vitro, however, these poorly invasive prions are endocytosed and can

spread from the axon terminal to the neuronal cell body. We found that reducing the prion aggregate size markedly impacts the neuroinvasive ability of fibrillar prions, suggesting that size plays an important role in prion neuroinvasion. Additionally, we have found that the intravenous route is surprisingly efficient for fibrillar prion entry into the CNS, which may help explain how human to human transmission of variant-Creutzfeldt Jakob disease prions occurred following blood transfusion. Taken together, these results indicate that aggregate size and route of exposure are major determinants that impact the ability of a prion to neuroinvade and may help explain how prions, which are largely oligomeric, spread so effectively as infectious pathogens.

Title: Neurodegeneration-like pathological and behavioral changes in an AAV9-mediated p25 overexpression mouse model

Authors: ***Y. HU**, X. ZHOU, J. HUANG, S. PAN, M. XU, R. HE, Z. JI;
Dept. of Neurol., Nanfang Hosp., Guangzhou, China

Abstract: Background: The transgenic mice models overexpressing human p25 contribute greatly to the in-vivo neurotoxic mechanism of p25 in neurodegenerative diseases. However, it is time-consuming to manipulate existing transgenic mice models. Objective: Here, we aim to establish a novel mouse model of neurodegeneration by overexpressing p25 mediated by recombinant adeno-associated virus serotype 9 (rAAV9). Methods: AAV9-GFP-p25 encoding GFP-fused p25 driven by synapsin promoter, and the control, AAV9-GFP, were delivered in mice by tail-vein injection. Assessments of p25 expression, neurodegenerative pathology, and behavioral changes were performed. Results: GFP expression was detected by in-vivo imaging as early as one week after virus injection. Notably, widespread expression of p25 was obviously

found in cortex, hippocampus and cerebellum in AAV9-GFP-p25 mice. Moreover, decreased hippocampus volumes in AAV9-GFP-p25 mice were detected by 7T MRI examination about one month after injection. Further, these AAV9-GFP-p25 mice exhibited progressive memory impairment from three-month to six-month after virus injection. At last, hyper-phosphorylated tau, neurofibrillary tangles, activated astrocytes and microglia cells were elevated in these p25 mice at about six months after virus delivery. However, amyloid-β (Aβ) plaque, overt neuronal loss and apoptosis in the hippocampus and cortex were not significantly induced by AAV9-mediated p25 overexpression. Conclusion: The AAV9-mediated p25 overexpression mouse model, which is a practical model exhibiting neurodegeneration-like pathological and behavioral changes, provides an easier and time-saving method to explore the functions of p25 in vivo, as well as an alternative tool for development of drugs against neurotoxic of p25.

Title: RCAN1 overexpression and mitochondrial dysfunction

Authors: *H. WONG, J. LEVENGA, C. ARDIZZONE, C. HOEFFER;
Inst. for Behavioral Genet., Univ. of Colorado Boulder, Boulder, CO

Abstract: Patients with Down syndrome (DS) develop symptoms consistent with early onset Alzheimer’s disease (AD), suggesting that factors involved in DS may also play a role in AD onset. DS is caused by trisomy of all or part of chromosome 21, resulting in overexpression of

genes within this region. One such gene is *Regulator of calcineurin 1* (*RCAN1*). RCAN1 is a potent regulator of the calcium/calmodulin-dependent phosphatase calcineurin and is required for long-lasting memory and synaptic plasticity. Overexpression of RCAN1 has been observed in brain tissue from not only DS patients but also AD patients and with normal aging. We recently found that brain-specific overexpression of a human RCAN1 isoform in mice promotes early age-dependent memory and synaptic plasticity deficits, tau pathology, and dysregulation of dynamin-related protein 1 (DRP1) activity associated with mitochondrial dysfunction and oxidative stress, reproducing key AD features. We are currently investigating how RCAN1 overexpression may alter calcineurin signaling to promote these phenotypes. In addition, we are investigating how increased RCAN1 levels may contribute to AD-related pathology in DS using the *Dp(16)1Yey/+ (Dp16)* mouse model of DS. These studies should provide insight into the molecular basis of AD progression in DS and the general population and whether RCAN1 is a therapeutic target for treatment.

Title: CRISPR-Cas9-mediated knock-in of TREM2 R47H significantly modifies Alzheimer's disease pathology & neuroinflammation *In vivo*

Authors: *P. J.-W. CHENG-HATHAWAY[1], E. REED[1], T. R. JAY[1], S. BEMILLER[2], S. PUNTAMBEKAR[2], J. C. KARLO[1], G. XU[2], R. M. RANSOHOFF[3], G. E. LANDRETH[1], B. T. LAMB[2];
[1]Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH; [2]Neurosciences, Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Neuroimmunology, Biogen, Boston, MA

Abstract: Variants in the gene encoding the Triggering Receptor Expressed on Myeloid Cells 2 (TREM2) confer a greatly elevated risk for development of late onset Alzheimer’s disease (AD). The R47H missense mutation linked to AD risk was proposed to be a loss of function mutation. Recently, Jay et al., (2015) found that homozygous TREM2 knockout in the APPPS1 AD mouse

model resulted in significant attenuation of AD-like pathology and neuroinflammation at 4 months of age. Flow cytometry and bone marrow chimera studies suggested that plaque associated myeloid cells were infiltrating monocytes and that the survival and association of these cells with plaques was dependent on TREM2. Moreover, gene expression studies demonstrated that the loss of TREM2 resulted in a phenotypic shift to expression of anti-inflammatory genes. These data suggest that TREM2 loss of function ameliorates inflammatory processes driving AD pathology, a conclusion that is inconsistent with the postulated loss of function of the R47H TREM2 variant. To further examine the role of the R47H allele in AD pathogenesis, CRISPR/Cas9 genome editing technology was utilized to generate a *Trem2*$^{R47H/+}$ knock-in mouse and crossed to the APPPS1 mouse model. Immunohistochemical and biochemical assays were utilized to assess AD pathology and neuroinflammation in this novel model. Strikingly, *Trem2*$^{R47H/+}$; APPPS1 mice exhibited a decrease in amyloid plaques compared to *Trem2*$^{+/+}$; APPPS1 mice at 4 months as assessed by immunohistochemistry. Levels of amyloid precursor protein (APP) and the C-terminal fragment and amyloid beta generated by APP cleavage were significantly reduced. Finally, the number of plaque associated myeloid cells was found to be significantly decreased in the *Trem2*$^{R47H/+}$; APPPS1 mice. These preliminary results suggest that the TREM2 R47H mutation may confer both a gain- and loss-of-function mutation conferring significant differences in amyloid processing and neuroinflammation. Further experiments are needed to understand how the R47H TREM2 variant impacts myeloid cell function and will ultimately provide new insights into disease mechanisms and potential therapeutic targets for AD.

Title: Contactins function as ligands for amyloid precursor proteins in regulating neuronal migration

Authors: J. M. RAMAKER[1], T. L. SWANSON[1], *P. F. COPENHAVER[2];
[1]Cell & Developmental Biol., [2]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Although Amyloid Precursor Protein (APP) is the source of amyloid fragments that accumulate in Alzheimer's disease (AD), APP may also regulate neurogenesis and differentiation in the developing nervous system, albeit via mechanisms that are still controversial. Studies in cell culture suggested that APP can interact with the heterotrimeric G protein Goα and function as an unconventional G protein-coupled receptor, but compensatory interactions by other related proteins have hindered an analysis of this process in the mammalian brain. Using Manduca (hawkmoth) and Drosophila (fruit fly) as simpler models, we have shown that the sole insect ortholog of APP (APPL) directly binds Goα in the leading processes and synaptic terminals of developing neurons, and that endogenous APPL-Goα interactions are regulated by Goα activation. In cultured embryos, we found that stimulating APPL-Goα signaling restricts the polarized outgrowth and migration of developing neurons, consistent with other evidence that APP family proteins function as neuronal guidance receptors. Recent studies have shown that GPI-linked Contactins can interact with APP, potentially acting as binding partners or co-receptors. We have now shown that Manduca Contactin (MsContactin) is selectively expressed by glial cells that ensheath migratory neurons (expressing APPL), and that Contactin-APPL signaling regulates neuronal-glial adhesive interactions. Short-term treatment with Contactin-Fc fusion proteins labeled the migratory neurons in an APPL-dependent manner, while more prolonged treatment inhibited their migration and outgrowth, an effect that was blocked by knocking down APPL expression or preventing Goα activation. Conversely, APPL fusion proteins labeled the ensheathing glial cells, an interaction that was MsContactin-dependent. These results support the model that Contactins function as authentic ligands for APP family proteins in the developing nervous system, whereby Contactin-induced activation of APP-Goα signaling regulates neuronal growth and motility. Conversely, abnormal stimulation of this pathway might cause the aberrant activation of Goα and its downstream effectors, resulting in neurite retraction, synaptic loss, and neurodegeneration. In support of this model, APP-Goα interactions were reduced in brains from AD patients compared to healthy controls. We are currently investigating how this signaling pathway is altered in the aging brain, with the goal of understanding how the misregulation of APP-Goα signaling might contribute to the progressive neurodegeneration that typifies AD. Title: The mitochondria-targeted antioxidant MitoQ affects memory retention and neuropathology in aged 3xTgAD mice

Authors: *M. L. YOUNG, J. L. FRANKLIN;
Univ. of Georgia, Athens, GA

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder. Despite extensive effort, there remains no effective therapy beyond symptomatic treatments. Considerable evidence suggests neuropathologies occurring well before the appearance of amyloid plaques and neurofibrillary tangles may have a role in disease progression. As oxidative stress is an early occurrence in neurodegeneration, we focus on this pathology as a potential mediator of AD. Dysfunctional mitochondria are a likely source of reactive species that contribute to oxidative stress. To further understand oxidative stress derived from mitochondria in the etiology of AD, we took advantage of a novel mitochondria-targeted antioxidant, mitoquinone mesylate (MitoQ). We've previously published data showing that MitoQ treatment in young 3xTg-AD mice, prior to pathology development, prevents oxidative stress, memory loss and several other AD-like pathologies present in this animal model. To determine whether this same antioxidant treatment would be effective during later disease progression we chose two time points to study. Mice began treatment at 7 and 12 months old and received MitoQ (100μM) continuously in drinking water for 5 months. At both age points, several AD-like disease hallmarks are present. Following treatment, mice underwent behavioral assessment and brain tissue was harvested for biochemical assays. Morris Water Maze training, a measure of spatial memory retention, showed that mice treated with MitoQ in each group learn spatial cues an average of 3 days before littermate controls. Interestingly, memory retention varied among age groups. In the younger age group, MitoQ treated animals and littermate controls retain memory equally in a measure of short- term memory retention. However, littermate controls did not retain spatial memory in long-term memory task. In our oldest group, mice treated with MitoQ retain spatial memory better than littermate controls in both short and long-term memory retention task. Sensorimotor deficiencies and escape motivation from the water maze were evaluated and did not prove to be significantly different between treatment groups or age groups. Supporting our behavioral data, MitoQ altered several AD-like pathologies in these mice. Synaptophysin, a marker for synapse loss, was significantly increased in MitoQ treated animals while nitrotyrosine

and reactive astrocytes were significantly reduced. Caspase-3 activity, implicated in tau pathology, and hyperphosphorylated tau were both significantly reduced with treatment. However Aβ 1-42 load remained the same in both treatment groups.

Title: Progranulin insufficiency drives biphasic social dominance abnormalities associated with altered neuronal morphology in the amygdala and prelimbic cortex

Authors: *E. D. ROBERSON, A. J. FILIANO, B. A. WARMUS, A. M. HALL, A. E. ARRANT;
Neurol & Neurobio, UAB, Birmingham, AL

Abstract: Loss-of-function mutations in progranulin (*GRN*) are a major autosomal dominant cause of frontotemporal dementia (FTD), a neurodegenerative disorder in which social behavior is disrupted. As disease causing mutations are all loss-of-function mutations, progranulin haploinsufficiency is thought to cause FTD in patients with *GRN* mutations. Therefore, treatments that boost progranulin levels may be an effective strategy to prevent or treat FTD due to *GRN* mutations. Progranulin-insufficient mice ($Grn^{+/-}$) model the progranulin haploinsufficiency of FTD patients with *GRN* mutations and develop abnormal social behavior beginning around 6 months of age, making them a potentially useful model for preclinical testing. We have previously reported that $Grn^{+/-}$ mice develop increased social dominance in the tube test at 6 months of age. To assess the usefulness of this abnormal behavior for preclinical testing, we investigated how the tube test phenotype of $Grn^{+/-}$ mice changes with age,

determined its robustness under several testing conditions, and performed a proof-of-principle study for progranulin-boosting therapies by overexpressing progranulin in the brain with an AAV vector. We also explored cellular mechanisms associated with these tube test dominance abnormalities. We observed biphasic social dominance abnormalities in *Grn*$^{+/-}$ mice: at 6-8 months, *Grn*$^{+/-}$ mice were more dominant than wild-type littermates, while after 9 months of age, *Grn*$^{+/-}$ mice were less dominant. The dominant phenotype of 6-8 month-old *Grn*$^{+/-}$ mice diminished with repeated testing, while the low dominance phenotype of older *Grn*$^{+/-}$ mice was robust over many testing sessions. In a proof-of-principle study for progranulin-boosting therapies, we found that overexpressing progranulin with an AAV-progranulin vector reversed the low dominance phenotype of older *Grn*$^{+/-}$ mice. In studies of the underlying mechanisms of the biphasic tube test abnormalities of *Grn*$^{+/-}$ mice, we found associations of abnormal cellular signaling and neuronal morphology in the amygdala and prelimbic cortex with tube test behavior. At 6-9 months of age, when *Grn*$^{+/-}$ mice are dominant, we observed evidence of potentially elevated mTORC2 signaling in the amygdala, as well as enhanced dendritic arbors in the basomedial amygdala. At 9-16 months of age, when *Grn*$^{+/-}$ mice are submissive, we observed impaired basal dendritic arbors in the prelimbic cortex, a region which drives social dominance in the tube test. These data demonstrate that tube test abnormalities in *Grn*$^{+/-}$ mice are a useful preclinical model, and are associated with dysfunction in brain regions that also degenerate in FTD.

Title: AAV-progranulin improves pathology in Grn$^{-/-}$ mice, an animal model of CLN11-neuronal ceroid lipofuscinosis (NCL)

Authors: *A. E. ARRANT, V. ONYILO, D. UNGER, E. D. ROBERSON;
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Progranulin (*GRN*) is a secreted glycoprotein that modulates inflammation and is critical for normal lysosomal function. Loss-of-function *GRN* mutations are a major autosomal dominant cause of Frontotemporal Dementia (FTD), and individuals homozygous for loss-of-function *GRN* mutations develop the lysosomal storage disorder Neuronal Ceroid Lipofuscinosis (NCL). NCL is a devastating, early onset neurodegenerative disorder with multiple genetic subtypes that causes retinal degeneration and seizures. NCL due to *GRN* mutations has been designated as CLN11-NCL. *Grn*$^{-/-}$ mice develop retinal degeneration, thalamic hyperexcitability, and NCL-like pathology, thus providing an animal model of NCL due to progranulin deficiency. *Grn*$^{-/-}$ mice exhibit the characteristic NCL lesion, accumulation of autofluorescent lipofuscin granules, as well as astrogliosis and microgliosis throughout the brain. We hypothesized that restoring progranulin to *Grn*$^{-/-}$ mice might improve this NCL-like pathology. To test this hypothesis, we injected an AAV2/1 vector expressing mouse progranulin (AAV-*Grn*) into the medial prefrontal cortex (mPFC) of 10–12-month-old wild-type and *Grn*$^{-/-}$ mice. At this age, *Grn*$^{-/-}$ mice exhibit robust NCL-like pathology. Additional wild-type and *Grn*$^{-/-}$ mice were injected with AAV-GFP as a control, and uninjected *Grn*$^{-/-}$ mice were run to provide a baseline measure of pathology in the absence of AAV. All mice were euthanized 8–10 weeks after injection, and brains were processed for immunohistochemistry. AAV-*Grn* strongly overexpressed progranulin in wild-type and *Grn*$^{-/-}$ mice, such that AAV-*Grn*-treated *Grn*$^{-/-}$ mice had higher progranulin levels in the mPFC than AAV-GFP-treated wild-type mice. In support of our hypothesis, we observed significant reductions in lipofuscinosis as well as in microgliosis (CD68 immunoreactivity, Iba1+ cell morphology), but no change in astrogliosis (GFAP immunoreactivity) in regions distant from the injection site (motor cortex, CA3 of hippocampus, and ventral posterior thalamus). At the injection site in the mPFC of *Grn*$^{-/-}$ mice, we observed an increase in microgliosis with AAV-*Grn* (CD68 immunoreactivity), as well as immune activation (MHCII immunoreactivity). This indicates a local inflammatory reaction that could be driven by a non-self reaction to progranulin or cleavage of progranulin into pro-inflammatory granulin fragments. As this negative side effect is unlikely to occur in CLN11-NCL patients, who are not completely progranulin-deficient, these data support the use of progranulin-boosting therapies for CLN11-NCL.

Title: Progranulin and cathepsin D: A potential mechanism for neurodegeneration

Authors: *C. B. VALDEZ;
Neurol., Northwestern Univ. Ken and Ruth Davee Dept. of Neurol., Chicago, IL

Abstract: Frontotemporal Dementia (FTD) encompasses a group of neurodegenerative disorders characterized by cognitive and behavioral impairments as a result of progressive degeneration of frontal and temporal lobes. A mutation in the gene encoding progranulin (PGRN) accounts for up to 25 percent of familial FTD and results in decreased progranulin expression. Progranulin is normally expressed in neurons and microglia within the CNS but the function of progranulin and the mechanism by which its decrease leads to disease is still unknown. While progranulin has been implicated in a wide array of biological functions including inflammation and neurite outgrowth, recent literature has shown that complete loss of progranulin due to a homozygous PGRN mutation leads to neuronal ceroid lipofuscinosis (NCL), a group of neurodegenerative lysosomal storage disorders. The discovery that patients with homozygous PGRN mutations present with a lysosomal storage disorder suggests that the pathogenesis caused by progranulin deficiency could be dose-dependent and that PGRN mutations that lead to FTD may cause lysosomal dysfunction. Our current research has demonstrated that a decreased level of progranulin does significantly impair lysosomal proteolysis. We hypothesize that progranulin, or individual granulins, can alter the expression or activity of lysosomal enzymes. A preliminary screen to determine the effect of progranulin expression on lysosomal enzymes demonstrated that cathepsin D was particularly affected by progranulin expression. Furthermore, we demonstrated that progranulin interacts with cathepsin D and can increase its activity *in vitro*. Taken together, these experiments suggest that progranulin, or individual granulins, may act as an activator of cathepsin D. This progranulin-cathepsin D interaction may provide a potential mechanism by which progranulin haploinsufficiency leads to lysosomal dysfunction and contribute to our understanding of the pathogenesis that leads to neurodegeneration in FTD patients with PGRN mutations.

Title: TDP-43 pathology in the hippocampus of centenarians

Authors: *T. IWASE[1], M. YOSHIDA[2], Y. HASHIZUME[3];
[1]Nagoya City Koseiin Med. Welfare Ctr., Nagoya, Japan; [2]Inst. for Med. Sci. of Aging, Aichi Med. Univ., Nagakute, Aichi, Japan; [3]Inst. for Neuropathology, Fukushimura Hosp., Toyohashi, Aichi, Japan

Abstract: Transactivation response element DNA-binding protein 43 kDa (TDP-43) is a major component of the inclusions in frontotemporal lobar degeneration and sporadic amyotrophic lateral sclerosis. TDP-43-positive inclusions are also detected in cases of Alzheimer's disease, Lewy body disease, and argyrophilic grain disease. Concomitant mixed pathologies related to these diseases exist in aging brain, and the incidence of TDP-43 pathology in cognitively unimpaired subjects varies greatly (3% to 40%). Therefore age-related TDP-43 deposition is not clear. We previously studied TDP-43-positive inclusions in the hippocampus of centenarians using non-phospho specific TDP-43 antibody and found a high prevalence of TDP-43 positivity. In this study, we reevaluated incidence and extent of TDP-43-positive structures in centenarians using anti-phosphorylated TDP-43 antibody. The autopsied brains from 30 centenarians were studied. TDP-43-positive 6 cases in the previous study were included. In all cases, the pathologies of the most commonly seen in the aging brain were confirmed with Gallyas-Braak silver staining, and immunostainings for amyloid-β, phosphorylated tau (AT8) and α-synuclein. We performed phosphorylated TDP-43 immunostaining of the brain sections from the region including hippocampus, parahippocampal gyrus and adjacent temporal neocortex. We found TDP-43-positive neuronal cytoplasmic inclusions in 10 cases. Among the 10 cases, 4 cases were complicated with high Alzheimer's disease neuropathologic change. Lewy body pathology (limbic type) was found in 1 case. Argyrophilic grains were found in 3 cases (2 Saito stage II, 1 stage III). 2 cases had tangle-predominant dementia pathology. Only 1 case was solely with TDP-43-positive structures. TDP-43 depositions involved hippocampus and entorhinal cortex, but did not extend to the temporal neocortex. Our findings indicate a high prevalence of TDP-43-positive structures with limited distribution in centenarians. Age-related TDP-43 pathology in specific brain areas is supposed to exist, however, the assessment is difficult because of the co-existence of mixed pathologies associated with TDP-43 deposition in centenarians.

Title: Discovery of potential autoantibody biomarkers for the detection of Alzheimer's disease

Authors: *J.-P. JEON[1], S.-M. SHIM[2], S.-M. YUN[3], J. SONG[2];
[1]Dept. of Brain Dis., Korea Natl. Inst. of Hlth., Osongsaengmyung-2-ro, Osong-eup, Chungju, Korea, Republic of; [3]Dept. of Brain Dis., [2]Korea Natl. Inst. of Hlth., Chungju, Korea, Republic of

Abstract: Autoantibody is known to be associated with autoimmune and neurodegenerative diseases as well as cancers. Anti-neuronal autoantibodies have been detected in neurodegenerative disease serum but their significance remains to be further investigated. In order to discover diagnostic biomarkers of Alzheimer's disease (AD), we analyzed serum autoantibody profiles from AD patients (n = 5) and cognitively normal control subjects (n = 5) using the HuProt human proteome microarray. The AD group exhibited more numbers of autoantibodies (98.0 ± 39.9 per person) than the normal control group (66.0 ± 39.6 per person). Among 434 autoantibodies detected in all subjects, 66.5% of autoantibodies (n=289) represented the occurrence number of one out of 10 subjects while 1.2% of autoantibodies (n=5) occurred in all 10 subjects. Functional analysis revealed that 47 AD-abundant autoantibodies were annotated to antigen proteins enriched in non-membrane-bounded organelle and cytoskeleton and ErbB signaling pathway. After validating proteome chip results using ELISA, five candidate AD-associated autoantibodies were subjected to subsequent ELISA-based validation in age- and sex-matched three different groups including AD (n=44), amnestic mild cognitive impairment (n=44), and cognitively normal subjects (n=44). In particular, the autoantibody XXX IgG levels were significantly higher in AD patients than cognitively normal control (p=0.02). Moreover, anti-XXX IgG levels were significantly correlated with mini-mental state examination (MMSE) scores (r_s=-0.204, p=0.019). The present study supports the presence of AD-associated autoantibodies can be used as potential biomarkers for diagnosis of AD.

Abstract: Protein misfolding is a key pathological event in many neurodegenerative diseases like prion diseases, synucleinopathies and tauopathies that are collectively termed protein misfolding disorders (PMD). Prions serve as a prototypic model to study protein aggregation mechanisms and therapeutic development. Several attempts to develop anti-prion therapeutics have been impeded due to the lack of screening models that replicate a broad array of prion strains and the lack of a sensitive high-throughput biological system with reasonably short processing times. In addition to this, the differing outcomes of already tested compounds in different prion strains and species hindered the advancement of high-throughput screening. Therefore, a sensitive model encompassing prion replication and neurotoxicity would be indispensable to the pursuit of therapeutics for PMD. In this study, we present an ultrasensitive screening system coupled to an *ex-vivo* prion organotypic slice culture model to further accelerate progress towards rationale-based high-throughput therapeutic strategies. We developed a hybrid, organotypic slice culture assay coupled to RT-QuIC assay (OSCAR) that permits rapid, sensitive, specific and quantitative detection of prions from slice cultures, making it amenable to high-throughput screening. Additionally, the anti-prion activity of compounds can be resolved based on the power and kinetics of seeding activity. We used the OSCAR model to characterize the time-dependent augmentation of prion seeding activity. Furthermore, we determined that the prions generated in slice cultures can be efficiently passed to the second generation of slice cultures. Collectively, our results suggest that OSCAR is a robust model of prion diseases that offers increased versatility and a promising platform for understanding prion

proteinopathies as well as advancing anti-prion therapeutics (ES19267, ISU Wildlife Initiative, VDL fund).

Abstract: Prion diseases are caused by the misfolding of the cellular prion protein (PrP^{C}) into a pathogenic β-sheet rich isoform (PrP^{Sc}) that accumulates mainly in the brain. Prions can misfold into a wide variety of PrP^{Sc} conformations, known as strains, that correlate to diverse biochemical properties and disease phenotypes, including differences in incubation times, clinical signs, histopathological lesion profiles, and PrP^{Sc} deposition patterns in the brain within the same host genotype. PrP^{C} is post-translationally modified during biosynthesis by the addition of zero to two N-linked glycans and a glycophosphatidylinositol (GPI) anchor that may increase the conformational spectrum of PrP^{Sc}. Previous studies have shown that passage of GPI-anchored prion oligomers into mice expressing GPI-anchorless PrP^{C} switches the prion morphology from diffuse aggregates to dense, fibrillar plaques, yet it is unclear whether the original prion conformation is maintained within the anchorless PrP^{Sc} fibrils. Here we use mice expressing GPI-anchored or GPI-anchorless PrP^{C} 1) to investigate how post-translational modifications impact the aggregated protein structure and disease phenotype in mice infected with four prion strains and 2) to identify the properties of the original GPI-anchored prions that are maintained within the GPI-anchorless fibril. We found that the four GPI-anchorless prion strains seemed to converge into a similar strain, as mice showed equivalent incubation periods and morphologically-identical vasotropic fibrillar plaques in the brain. However, remarkable

biochemical differences reminiscent of their respective original GPI-anchored strains were also identified among anchorless prions. Upon passage of one anchorless strain into mice expressing GPI-anchored PrP^{C}, a novel strain emerged with unique structural and phenotypic properties, revealing that the GPI-anchorless state can be a source of novel PrP^{Sc} conformations. The remaining three strains emerged from the anchorless state nearly identical to their original anchored strains suggesting that only the quaternary structure had changed in the anchorless state. Together, our findings establish that variations in post-translational modifications that occur in vivo (i) explain one source for the emergence of new protein aggregate conformations, and (ii) may only affect the quaternary structure yet profoundly alter the pathogenesis of prion diseases.

Title: A structure-based approach to identifying novel modulators of the Nrf2 transcription pathway

Authors: *T. CARRENO VELAZQUEZ[1], P. BESWICK[2], B. WAHAB[2], J. ATACK[2]; [1]Life Sci., Sussex Drug Discovery Centre, Univ. of Sussex, Brighton, United Kingdom; [2]Sussex Drug Discovery Ctr., Univ. of Sussex, Brighton, United Kingdom

Abstract: Oxidative stress results when the antioxidant response is not sufficient to balance the production of reactive oxygen species (ROS). Fortunately, the cell contains antioxidant defence pathways that are essential for cell survival. However, dysfunction and up-regulation of the oxidative stress pathways have been implicated in the pathogenesis of many neurodegenerative diseases, including, for example, Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis. The nuclear factor (erythroid-derived 2)-like 2 (Nrf2) protein is an important transcription factor that ordinarily is sequestered in an inactive form within the cytoplasm by association the Kelch-like erythroid cell-derived protein with CNC homology-associated protein (Keap1) protein. However, when it senses oxidative stress, Nrf2 dissociates from Keap1 and translocates to the nucleus to activate the transcription of antioxidant enzymes such as the phase II detoxifying enzymes glutathione S-transferase (GST), quinone reductase (QR), heme oxygenase-1 (HO-1) and NAD(P)H quinone oxidoreductase 1 (NQO1). Modulation of the Nrf2

pathway is therefore an attractive cellular pathway for drug discovery. In order to identify a novel Nrf2 activator that disrupts the Nrf2-Keap1 protein-protein interaction, we performed a virtual screen based upon the known structure of the protein interface and evaluated compounds in a DiscoveRx nuclear complementation assay that measures the translocation of Nrf2 from the cytoplasm to the nucleus. In this assay, sulforaphane was used as a positive control and had an EC_{50} of 400 ± 55 nM. In silico screening of a library of over 3 million compounds identified a number of virtual screening "hits" of which 122 were purchased and evaluated further. Of these compounds, five produced an activation of 15%, 20%, 25%, 40% and 100% relative to the sulforaphane control (which was defined as 100% activity). However, the use of a ROS-Glo assay showed that three of these five compounds were activating the pathway non-specifically by themselves producing free radicals rather than disrupting the protein-protein interaction. The remaining two compounds are currently being characterised further.

Title: Effects of macular carotenoid supplementation on brain-derived neurotrophic factor and pro-inflammatory cytokines

Authors: *N. T. STRINGHAM[1], P. V. HOLMES[1], J. M. STRINGHAM[2];
[1]Neurosci., [2]Physiol. and Pharmacol., Univ. of Georgia, Athens, GA

Abstract: Purpose: Oxidative and inflammatory processes play a major role in stress-induced neural atrophy. There is a wide body of literature linking oxidative and inflammatory stress with a reduction in both neurotrophic factors and psychological stress resilience. We investigated the potential for the dietary carotenoids lutein, zeaxanthin, and mesozeaxanthin (the "macular carotenoids" [MC]), which have high antioxidant / anti-inflammatory capacity, to increase brain-derived neurotrophic factor (BDNF) and reduce concentrations of the pro-inflammatory cytokines TNF-α, IL-6, and IL-1β. Methods: 59 young (18-25 yrs.), healthy subjects participated in a 6-month, double-blind, placebo-controlled trial to evaluate the effects of MC supplementation serum BDNF, TNF-α, IL-6, and IL-1β. Serum antioxidant potential (AOP) and

the retinal concentration of MCs (termed macular pigment optical density [MPOD]), were also measured. Blood was obtained via fasting blood draws. All parameters were assessed at baseline and 6 months. Subjects were randomly assigned to one of three groups: placebo, 13 mg, or 27 mg / day total MCs. BDNF and the cytokines were assessed via ELISA, and MPOD via customized heterochromatic flicker photometry. Results: BDNF, MPOD, and AOP all increased significantly versus placebo in both treatment groups over the 6 month study period ($p < 0,05$ for all). By contrast, IL1-β decreased significantly versus placebo in both treatment groups ($p = 0.0036$ and $p = 0.006$, respectively). In terms of changes over the course of the study, significant relationships were determined for BDNF and IL1-β ($r = -0.47$; $p < 0.001$), and for BDNF and TNF-α ($r = -0.41$; $p = 0.0014$). No significant changes in any parameter were found for the placebo group. Conclusions: 6 months of daily supplementation with at least 13 mg of MCs significantly reduces serum IL1-β, and significantly increases serum BDNF, MPOD, and AOP. Although increases in AOP and MPOD were not directly related to decreases in IL-1β and BDNF, it is reasonable to suggest that the effects on IL-1β and BDNF are due to the increase in systemic and perhaps local (neural) antioxidant / anti-inflammatory capacity in our treatment groups. The significant relationships between the change in BDNF and both IL-1β and TNF-α over the course of the study suggest that regular consumption of MCs can interrupt the inflammatory pathway that leads to reduction of BDNF.

Title: The effects of cellular senescence through the regulation of ubiquitin proteasome system in cholinergic neuron

Authors: *J. KIM, J. JANG, S. KANG, H. SEO;
Hanyang Univ., Ansan, Korea, Republic of

Abstract: Cellular senescence with progressive decline of its function implies the biological aging of an organism. Previous studies showed the dysfunction of protein degradation in aging process. In this study, we determined the effects of cellular senescence through the regulation of ubiquitin proteasome system in cholinergic neuron. We found that the chymotrypsin-like activity of ubiquitin proteasome system was down-regulated in several senescence conditions. However, ubiquitin-dependent proteasome activity was up-regulated in senescence conditions. When parkin, E3 ligase, over-expressed in cholinergic neuron, it increased the activities of ubiquitin proteasome system. We also detected the effects of parkin on cell viability and the expression of aging factors including hypoxia-inducible factor 1-alpha (HIF1-alpha). These results indicate that cellular senescence environment induces dysfunctional protein degradation and that the down-regulated cellular activities under senescence condition can be improved by the regulation of ubiquitin proteasome system, suggesting potential future therapeutic approach for senescence related diseases.

Title: Telomere length dynamics and telomerase activity in the aging murine brain

Authors: Q. AIN[1], A. KRETZ[1], D. PENNDORF[1], M. FISCHER[2], T. BONDEVA[3], O. WITTE[1], *C. W. SCHMEER[1];
[1]Hans Berger Dept. of Neurol., Jena, Germany; [2]Dept. of Intrnl. Med. II, Jena, Germany; [3]Dept. of Intrnl. Med. III, Jena, Germany

Abstract: Telomeres are repetitive nucleotide sequences that maintain chromosome stability and cell replicative capacity. Critical telomere shortening by repeated cell division triggers cellular senescence in replicative tissue and organs, and is considered a strong paradigm to explain aging in general. However, a contribution of telomere dysfunction, or shortening to the mechanism of physiological brain aging is still uninvestigated. The post-replicative state of the mature brain appears to be nominal, since neurons can re-induce unscheduled cell cycle (CC) activity under stress conditions, and glia populations preserve a life-long replicative capability. Therefore, in

this study, we addressed telomere length dynamics in the murine brain during physiological aging and determined the effect of increasing life-time on the catalytic activity of TERT, an enzyme which elongates telomeres in DNA strands, and directly influences age-related gene transcription, e.g. by interaction with NF-κB. Relative telomere length (RTL) as a function of age was assessed in cortical neural cells by Flow-FISH in a CC-dependent manner. TERT activity was analyzed in cortical tissue extracts by a qPCR-based TRAP assay. Levels of NF-κB expression were determined by real time qPCR in corresponding tissue.
Results from our study show that RTL remains stable in cells belonging to G_0/G_1 phase of the CC, which are most likely neurons. In contrast, we detected a significant age-dependent reduction in RTL by ~54% for a portion of brain cell populations in G_2 phase. Moreover, we found an increase in the S/G_2 phase population at the expense of the G_0/G_1 fraction, indicating a shift in CC activity. The identity of these cells still has to be specified, however, is likely to include neurons with instable DNA or CC reactivation, and dividing glia populations. TERT activity remained stable upon increasing age, which might point to alternative telomerase functions within the mature brain. In support of this and the feed-forward interaction between TERT and the RelA subunit of NF-κB, we found a significant age-related up-regulation of RelA mRNA, whereas c-Rel expression was down-regulated. In summary, our data provide evidence for unexpected age-related telomere dynamics in the postmitotic environment of the brain. Considering CC- and telomere-related pathomechanisms might contribute to a better understanding of physiological brain aging and age-related CNS disorders.

Title: The role of brain-derived neurotrophic factor in Capsosiphon fulvescens proteins-induced cognitive enhancement

Authors: *J. OH;
Inst. of Fisheries Sci., Busan, Korea, Republic of

Abstract: Reactive oxygen species (ROS) causes functional declines in many organs of the body including the brain, and antioxidants can reduce these ROS-induced neuronal damage with age. Extracts form *Capsosiphon fulvescens* (*C. fulvescens*) contain various antioxidants including protein, polysaccharide, etc. In this study, effects of crude proteins of *C. fulvescens* (Cf-CPs) on brain-derived neurotrophic factor (BDNF) and calcium-dependent protein kinases were investigated. Following extraction with 0.1 M sodium acetate (pH 6) and methanol precipitation, Cf-CPs were freeze-dried and saline soluble proteins were used. Rats were given 14 daily oral administration of saline or Cf-CPs (100 and 200 mg//kg) and then sacrificed at different time points (30 and 90 min) after the final administration. Oral administration of Cf-CPs significantly upregulated expression of mature and truncated BDNF in the rat hippocampus at 90 min post administration. At the same time point, phosphorylation of calcium/calmodulin-dependent protein kinase II was significantly increased in a dose-dependent manner. These finding suggest that Cf-CPs regulate activation of calcium-dependent protein kinase associated with BDNF in the rat hippocampus and could play an important role in learning and memory with age.

Title: Antioxidant regulator nrf2 increases with age, while molecular chaperone HSPA8 decreases, in CSF from healthy subjects: associations with oxidative stress

Authors: *D. A. LOEFFLER[1], A. C. KLAVER[2], M. P. COFFEY[1], J. O. AASLY[3], P. A. LEWITT[4,5];
[2]Neurol., [1]Beaumont Hlth., Royal Oak, MI; [3]St. Olav's Hosp., Trondheim, Norway; [4]Henry Ford West Bloomfield Hosp., West Bloomfield, MI; [5]Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: Age-associated declines in antioxidant defense and protein homeostasis mechanisms ("proteostasis") are thought to contribute to age-related neurodegenerative disorders. Decreased brain antioxidant activity results in oxidative stress, which can activate a key proteostasis process, chaperone-mediated autophagy (CMA). The literature contains conflicting reports for age-related changes in experimental animals for nuclear factor erythroid 2-related factor 2 (nrf2),

a “master regulator” of the antioxidant response, and heat shock 70-kDa protein 8 (HSPA8), a molecular chaperone involved in multiple proteostasis mechanisms including CMA. The objective of this study was to explore age-related changes in these proteins, and their associations with oxidative stress and anti-oxidant biomarkers, in human cerebrospinal fluid (CSF). We examined correlations between age and CSF nrf2, HSPA8, 8-hydroxy-2’-deoxyguanosine (8-OHdG), 8-isoprostane (8-ISO), and total antioxidant capacity (TAC) in CSF samples from 34 healthy subjects ages 20-75. Age was positively associated with nrf2 (Spearman rho = 0.47; p = .005) and negatively associated with HSPA8 (rho = -0.47; p = .005). An age-related increase in oxidative stress was suggested by a positive association between age and 8-OHdG (rho = 0.61; p = .0001). 8-OHdG was moderately positively associated with nrf2 (rho = 0.32; p = .06) and strongly negatively associated with HSPA8 (rho = -0.58; p = .0004). These findings suggest that during healthy aging, CSF levels of nrf2 may increase while HSPA8 levels may decrease. An age-related increase in oxidative stress may contribute to these alterations. Further studies are indicated to determine if the age-related changes in CSF nrf2 and HSPA8 reflect similar changes in the brain.

Title: Resveratrol effect on the Sirtuins regulation during aging process

Authors: M. F. FERRO-ABELLA[1], R. RAMIREZ-Y AYALA[1], J. C. MORALES[2], E. M. BRAMBILA[1], G. FLORES[3], L. M. PEREZ-PEÑA[4], *P. Abstract: The aging process is a biological phenomenon that concerns all population sectors, the individual productive life decrease and his physical, emotional and cognitive functions are affected by aging. It has been noted that the uptake of resveratrol mimics some caloric restriction characteristics, process in which un member of Sirtuin family, the SIRT1 protein, is involved. In the aging rat experimental model, it is still unclear the effect that the chronic administration of resveratrol has on the SIRT family member's expression. The objective of this study was to assess the effect of resveratrol chronic administration (10 mg/kg) on cognitive performance and to clarify any change of the level of expression in the members of SIRT family 7 members level expression. On this Long-term evaluation, resveratrol shows an important decrease in nitrites and lipid peroxidation products' production showing its antioxidant property. It was observed that the cytoarchitecture of the regions CA1 and CA2 region in hippocampus in rats treated with resveratrol keep their integrity with the passing pf time and the behavioral test shows cognitive performance improvements on rats with chronic administration of resveratrol during 8 months. Regarding the transcription regulation. The administration of resveratrol for 2 months promotes changes in the regulation of SIRT1 and after 8 months of vitamin E administration the regulation of SIRT3 is positive. Nevertheless, significant changes weren´t found in other Sirtuin member during the resveratrol administration. This shows that the chronic administration of resveratrol is a determining factor in the reduction of oxidative stress and conservation of the hippocampus integrity in rats, as well as their cognitive performance.

Title: Neuromuscular excitability and synaptic transmission in *Drosophila* Superoxide Dismutase (Sod) mutant larvae

Authors: ***A. UEDA**, C.-F. WU;
Univ. of Iowa, Iowa City, IA

Abstract: It has been established that reactive oxygen species (ROS) modulate the function of a variety of ion channels. However, identifying and analyzing the consequences of ion channel

redox regulation in membrane excitability and synaptic transmission await further exploration. The Sod gene in Drosophila encodes the cytoplasmic Cu/Zn superoxide dismutase (Cu/Zn Sod), which is an essential component in a major antioxidant defense pathway for scavenging ROS generated during aerobic respiration and other metabolic processes. Drosophila Sod mutant flies show increased sensitivity to ROS generating agents, such as paraquat, and greatly decreased lifespan. We found that defects in both axonal excitability and synaptic transmission could be detected in the larval neuromuscular preparation of Sod mutants. Upon high frequency nerve stimulation, Sod motor axons displayed supernumerary action potentials, resulting in greatly enhanced synaptic transmission, composed of superimposing excitatory junctional potentials (EJPs). Furthermore, spontaneous miniature EJPs (mEJPs) in Sod larvae were significantly smaller compared to WT, even though nerve-evoked EJPs appear normal, indicating that the number of synaptic vesicles released upon arrival of individual nerve action potentials can be increased by Sod mutations. This suggests an increased quantal content, a potential homeostatic mechanism for sustaining transmission efficacy (EJP size maintenance). Our results demonstrated that defects in *Sod* enzymatic function can cause nerve excitability and synaptic transmission defects even at an early developmental stage, even though the Sod mutant fly can undergo pupation and its lethality phase occurs in adulthood. This finding suggests a possibility of defining early predictive physiological indicators for late-onset Sod-related neurodegenerative disorders.

Title: Nature-inspired new hybrids to counteract oxidative stress in neurodegeneration

Authors: M. M. SERAFINI[1], L. POLONI[1], M. RONFANI[1], M. GALASSO[1], *M. RACCHI[2], M. BARTOLINI[3], M. ROSINI[3], C. LANNI[1];
[1]Dept. of Drug Sci. - Univ. of Pavia, Pavia, Italy; [2]Univ. Pavia, Pavia 27100, Italy; [3]Dept Pharm. and Biotech. - Univ. of Bologna, Bologna, Italy

Abstract: Background: Oxidative stress is a common feature of different neurodegenerative disorders. The identification of new drugs acting on oxidative stress pathways is an open field of research because of their potential application in different pathologies. Natural products offer great chemical diversity and have already proven to be a rich source of therapeutics. Polyphenols

are widely diffused in nature. They have been shown to modulate several pathways, including oxidative injuries. Diallyl sulfides are garlic-derived organosulfur compounds carrying allyl mercaptan moieties. They counteract oxidative stress through antioxidant phase II enzymes expression. In our previous paper, we combined these molecular fragments in new chemical entities to produce hybrids with Aβ anti-aggregant and anti-oxidant activity (Simoni et al. 2015) which have been the basis for the synthesis of different new derivatives. These compounds have been tested in human neuroblastoma SH-SY5Y cells for their ability to counteract oxidative stress and to exert a neuroprotective effect.
Objective: In order to investigate the structure-activity relationship (SAR) our goal has been to test the anti-oxidant ability of the new derivatives and to investigate the pathways involved in this activity.
Methodology: To determine the potential interest of new nature-inspired molecules as antioxidants, we investigated their protective effects against H_2O_2-induced oxidative damage. The scavenging effect on reactive oxygen species (ROS) was evaluated in human neuroblastoma SH-SY5Y cells by using the fluorescent probe dichlorofluorescein diacetate (DCFH-DA) as a specific marker for the quantitative intracellular formation of ROS. Furthermore, the expression of proteins involved in the anti-oxidant phase II response has been investigated by RT-PCR and western blot.
Conclusions: The new nature-inspired molecules protect against H_2O_2-induced oxidative damage with different potencies, as assessed by DCFH-DA experiments. The most promising compounds were also tested for their mechanism of action, demonstrating their involvement in the anti-oxidant phase II response. In particular, a modulation of Nrf-2 and its targets has been observed.

Title: Sexual Dimorphism of the Hippocampal Transcriptome

Authors: ***N. M. PORTER**[1], L. D. BREWER[1], M. RAUHUT[2], K.-C. CHEN[1], O. THIBAULT[1], P. W. LANDFIELD[1], E. M. BLALOCK[1];
[1]Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY; [2]Dickinson Col., Carlisle, PA

Abstract: Many traits in mammals are sexually dimorphic including the sensitivity of brain cells to neurotransmitters or noxious stimuli/toxins. Further, sexual dimorphism is recognized to contribute to age-related differences in cognitive function, neurodegenerative disease pathology, disease outcomes and responses to therapy or drug treatment. However, very little is known regarding the underlying genomic basis of the sexual dimorphism of the brain. Here we investigated the difference in the hippocampal transcriptome of male and female rats to identify genes and genomic networks that may contribute to the dimorphism of hippocampal-dependent processes such as learning and memory. Twelve-month old, middle-aged male or female F344 rats were gonadectomized in order to study the sexual dimorphism of the transcriptome in isolation from the actions of circulating sex hormones. Other similar groups of gonadectomized male and female rats were treated with low, physiological levels of estradiol for six weeks to separately assess the action of this hormone on gene expression. Affymetrix microarrays were used to identify hippocampal genes that differed significantly between male and female rats. Those genes were then subjected to a DAVID analysis to identify the major categories and gene pathways that differed by sex. Our analyses revealed that 183 (of ~2000 tested) genes differed significantly by sex with a false discovery rate of 0.3. Of these 183 genes, 102 exhibited significantly higher expression in females compared to males. Among the genes with higher expression in females were genes that play a role in lipid and cholesterol metabolism and vascular function. In addition, several neuromodulators, neurotransmitter receptors and synaptic proteins important in plasticity were identified. Surprisingly, very few genes were altered in male or female rats by treatment with estradiol. Taken together, it appears possible that dimorphic gene expression may account for important sex differences in hippocampal-dependent functions.

Title: The enhanced oxidative damage of sequestosome/p62 promoter in type 2 diabetic rats with age

Authors: *S. AHN, J. JEONG, J. IM, S. PARK;
Dept. of Neurol., Soonchunhyang Univ. Bucheon Hosp., Bucheon, Korea, Republic of

Abstract: Background - Sequestosome/p62 (p62) is frequently detected in the tau inclusions in Alzheimer disease (AD). We reported that the mRNA and protein levels of p62 decreased robustly with age in Otsuka Long-Evans Tokushima Fatty (OLETF) rats. However, the underlying mechanisms remain unknown. The objective of this study is to examine the association of oxidative damage of p62 promoter with the decrease of p62 transcription.
Materials and Methods - Diabetic OLETF rat and their corresponding non-diabetic controls, Long-Evans Tokushima Otsuka rats were utilized in this study. Rats were sacrificed at 32 or 60 weeks. Genomic DNA was isolated from brain tissue and purified. The formamidopyrimidine glycosylase (fpg) cleavage reaction was performed using genomic DNA. With the specific primers of p62 promoter real time polymerase chain reaction was employed. Then the levels of damaged DNA within the rat p62 promoter were quantified.
Results - The extent of oxidative damage to the p62 promoter containing a CpG island (>60%) was found increased in the brain of OLETF rats. Further, the oxidative modification was enhanced in an age-dependent manner.
Conclusions - These findings suggest that oxidative damage to the p62 promoter is the underlying mechanism of the decreased expression of p62 in diabetic rats. And the age-dependent increased oxidative damage may contribute to the age-associated neurodegenerative diseases in the model.
Acknowledgments - This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (HI14C1943).

Title: Identifying regulators of synaptic stability during normal healthy ageing in non human primates

Authors: *L. C. GRAHAM[1], I. S. AMORIM[1], T. H. GILLINGWATER[1], M. J. NALDRETT[2], S. G. KOHAMA[3], G. PENNETTA[1], P. A. SKEHEL[1], H. F. URBANSKI[3], T. M. WISHART[1]; [1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Donald Danforth Plant Sci. Ctr., St. Louis, MO; [3]Oregon Natl. Primate Res. Ctr., Beaverton, OR

Abstract: Humans, like many other mammals, are susceptible to age-related cognitive decline in the absence of neurodegenerative disease[1, 2, 3, 4]. The hippocampus and its complex projections appear to be the most vulnerable during normal healthy ageing[1, 2, 3] whereas other brain regions, such as the occipital cortex, are almost completely spared[4, 5, 6, 7]. In what appears to be the first study utilizing label-free proteomics on synaptic isolates from the non-human primate (NHP) brain, we have tracked regional synaptic protein expression profiles in the rhesus macaque during normal healthy ageing. Synaptosomes from 'spared' (occipital cortex) and 'vulnerable' (hippocampus) brain regions identified differential regulation (>20%) of over 200 proteins throughout the ageing timecourse. Further examination of these candidates *in silico* highlighted mitochondrial function and calcium binding differ between the 'spared' and 'vulnerable' regions - processes which have been widely described as contributors to neuronal vulnerability. By applying stringent filtering parameters to the proteomic and *in silico* data, we have identified several novel regulators of synaptic stability which have the propensity to promote morphological alterations *in vivo*. Experimental manipulation of such candidates at the Drosophila larval neuromuscular junction demonstrates robust phenotypes ($p<0.0001$). The data described illustrate how modern bottom-up proteomic methodologies may be utilized to identify potential candidates capable of modulating regional synaptic and neuronal stability. This study may be more relevant than equivalent rodent based studies for the identification of biomarkers in human ageing due to our unique phylogenetic relationship with NHP species.

Title: Peptide Hormone amylin Reduces oxidative stress through improved mitochondrial dynamics

Authors: *A. S. PALIOBEIS[1], J. GRIZZANTI[2], S. PATRICK[2], G. CASADESUS[3,2];
[1]Biol. Sci., [2]Sch. of Biomed. Sci., [3]Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstract: Oxidative stress has been shown to be an early predictor and key pathological feature of neurodegenerative diseases including Alzheimer's disease (AD). Previous work in our laboratory has demonstrated that administration of the peptide hormone amylin can reduce levels of oxidative stress in a transgenic mouse model of AD (APP/PS1) as well as Neuroscreen-1 cultures (neuronal cell model). Although it is apparent that amylin has antioxidant activity, its mechanism of action remains unclear. Because mitochondria are the main producers of reactive oxygen species (ROS) that account for oxidative stress in a cell, they have been a target of our investigation. Specifically, we determined whether amylin treatment regulates mitochondrial associated proteins and mobility deficits in the APP/PS1 AD mouse model. Our data show that amylin treatment regulates mitochondrial dynamics-associated proteins as well as proteins associated with mitochondrial biogenesis. Taken together, our data suggest that some of the effects of amylin on oxidative stress regulation may stem from improving mitochondrial function.

Title: WNIN/Ob obese rat as an appropriate animal model to study the neurobiology of premature aging

Authors: *S. GHOSH, J. K. SINHA, M. RAGHUNATH;
NATIONAL INSTITUTE OF NUTRITION, HYDERABAD, India

Abstract: Purpose: Proportion of aged individuals is on the rise globally and so is the burden of non-communicable diseases like obesity. Wistar of National Institute of Nutrition obese (WNIN/Ob) rat is a novel strain developed at NIN, Hyderabad, India. These rats have significantly reduced average lifespan of 15-18 months in contrast to 36 months in normal WNIN rats. Elucidation of various molecular and biochemical characteristics in these rats would help to establish it as an appropriate model to study the neurobiology of ageing and obesity. Methods: Different growth characteristics were studied and the lifespan analysis was performed using OASIS software. The neuronal and glial changes were studied using Nissl staining and immunohistochemistry. Levels of oxidative stress, antioxidant enzyme activity and extent DNA damage were studied in various brain parts. Results: The brain weights were significantly decreased and there was a 60% decrease in the total lifespan in the WNIN/Ob obese rats as compared to the lean littermates as well as WNIN normal rats. Various neuronal and glial changes were observed that are seen in the ageing brain. In addition, oxidative stress levels and extent of DNA damage were observed to be significantly high in the brain of young WNIN/Ob obese rats as compared to age-matched rats and it was as high as comparable to what observed in 15 months old WNIN normal rats. The levels of antioxidants enzyme activity were also significantly low in the WNIN/Ob obese rats. Conclusion: Onset of various degenerative features like increased oxidative stress, astrogliosis, DNA damage and decreased antioxidant levels in different brain regions of WNIN/Ob obese rats at a much younger age is a plausible cause of reduced longevity observed in this novel obese rat model. This model may be used to study the connecting link between obesity and ageing.

Title: Cyclophilin D associated brain mitochondrial F1FO ATP synthase dysfunction in aging mice

Authors: *E. GAUBA, L. GUO, H. DU;
Dept. of Mol. & Cell Biol., Univ. of Texas At Dallas, Richardson, TX

Abstract: Mitochondrial dysfunction is a pronounced brain pathology closely associated with declined cognitive function accompanying brain aging. Among the recognized aging-related mitochondrial abnormalities, F1FO ATP synthase dysfunction has been proposed to be a critical mitochondrial defect. However, the molecular mechanisms causing the dysfunction of this key mitochondrial enzyme in aging brains still remains unresolved. Cyclophilin D (CypD), a mitochondrial peptidylprolyl isomerase is the key regulator of mitochondrial permeability transition pore (mPTP). Recent studies suggest that F1FO ATP synthase subunit Oligomycin Sensitivity Conferring Protein (OSCP) is a binding partner of CypD. The interaction of CypD with OSCP affects the integrity of F1FO ATP synthase, thus leading to lowered oxidative phosphorylation (OXPHOS) efficiency and sensitized mPTP formation. In view of our previous findings of increased CypD expression in aging animals as well as in aging human subjects, the objective of this study is to determine whether CypD modulates F1FO ATP synthase deregulation in aging brain. By immunoblotting we have found that increased CypD expression, enhanced CypD/OSCP interaction and selective loss of OSCP are prominent brain mitochondrial changes in aging mice. Additionally, further mitochondrial functional assays showed that brain mitochondria from the aging mice demonstrated decreased F1FO ATP synthase catalytic activity and defected F1FO complex coupling, along with lowered OXPHOS capacity and sensitized mPTP formation. To determine the impacts of CypD, we employed CypD deficient mice and found such aging-related F1FO ATP synthase deregulation was largely mitigated by the depletion of CypD. Therefore, the simplest interpretation of this study is that CypD promotes F1FO ATP synthase dysfunction and the resultant mitochondrial deficits in aging brains. Increased CypD expression, enhanced CypD/ OSCP interaction and loss of OSCP may constitute primary mitochondrial defects in aging brains; and the aging-related brain mitochondrial F1FO ATP synthase dysfunction could be at least partly protected by the inhibition of CypD.

Sydney, Sydney, Australia; [5]The Florey Inst. of Neurosci. and Mental Hlth., [6]iolite Software, Sch. of Earth Sci., The Univ. of Melbourne, Melbourne, Australia; [7]Nencki Inst. of Exptl. Biol., Warsaw, Poland; [8]Australian Res. Council, Ctr. of Excellence for Integrative Brain Function, Melbourne, Australia

Abstract: Objective: Biometals are essential for normal brain function and metal dysregulation is implicated in a number of disease states. However, the distribution of metal ions in normal brain tissue has not been well characterized in primates. Here we employed laser ablation – inductively coupled plasma – mass spectrometry (LA-ICP-MS) to map the tissue distribution of manganese (^{55}Mn), iron (^{56}Fe), copper (^{63}Cu), and zinc (^{66}Zn), across the cerebral cortex of the adult common marmoset (*Callithrix jacchus*) at multiple spatial resolutions.
Methods: Brain tissue from 4 adult marmosets was obtained from other experiments in our laboratory or from archived specimens (preserved in 4% PFA, cryoprotected, and used fresh or frozen at -80º C). In one case, the cortical hemisphere caudal to the lateral sulcus was flat mounted, including V1 and most extrastriate visual areas. Remaining cerebral hemispheres were sectioned at 40 µm in the coronal or sagittal planes and mounted uncoverslippped on glass slides for LA-ICP-MS (laser spot size of 50, 60, or 100 µm). Adjacent series were stained for histological markers including Nissl, myelin, cytochrome oxidase (CO), and calbindin. LA-ICP-MS output was aligned to histological data, with special focus on the primary visual, auditory,

and somatosensory cortical areas. Australian NHMRC guidelines encourage the use of scavenged tissue for research, and all specimens were obtained from studies approved by the Monash Animal Research Ethics Committee.
Results: In comparison to white matter, grey matter showed higher concentrations for all the metal ions investigated. In coronal and sagittal sections the change in ^{55}Mn and ^{56}Fe concentrations demarcated known anatomical boundaries of the primary sensory areas. Regions with dense CO staining were associated with high ^{55}Mn and ^{56}Fe concentrations. In the flat mounted preparation, high ^{55}Mn and ^{56}Fe concentrations were evident in early visual areas, but individual CO blobs or stripes could not be resolved.
Conclusions: The marmoset brain is an ideal target for mapping the complete distribution of redox metals, as the small, yet highly differentiated brain allows for identification of regions of interest for further study of traumatic and age-related changes in metal concentrations.

Title: The role of IL-1 signaling in behavior and neurodegeneration after soman-induced convulsions

Authors: *T. M. FERRARA-BOWENS, J. K. CHANDLER, J. F. IRWIN, K. LAITIPAYA, D. D. PALMER, E. A. JOHNSON;
Pharmacol., USAMRICD, Gunpowder, MD

Abstract: Chemical warfare nerve agent (CWNA) exposure initiates convulsive activity resulting in status epilepticus (SE), which leads to severe neuropathology and behavioral impairment in rodents. While treatments are available to ameliorate SE, the therapeutic window for control is relatively short, with no approved treatments available to address the neurodegenerative process. Following exposure, brain damage resulting from SE activates microglia and astrocytes to upregulate pro-inflammatory cytokines including IL-1α, IL-1β, IL-6, and TNFα. This creates a positive feedback loop to exacerbate neurodegeneration and to damage potentially healthy neuronal tissue. A soman (GD) model was developed using wild-type and IL-1 signaling knockout (KO) mouse strains (i.e., IL-1R1 and IL-1Ra) to validate IL-1 signaling as

a viable neuroprotective target. Behavioral studies were conducted with the Open Field, Zero Maze, and Barnes Maze to assess mobility, anxiety, and cognitive function. In a separate study, anakinra, the human recombinant IL-1Ra, was used to treat GD-exposed WT mice. Results showed that the absence of IL-1R1 improves neuropathology over time and attenuates anxious behavior, whereas the absence of IL-1Ra worsens brain damage and does not improve anxiety. Hyperactivity does not improve with the absence of IL-1R1 or IL-1Ra, nor does it prevent spatial learning and memory, but the absence of IL-1Ra worsens damage in the CA2/3 region of the hippocampus, which may account for the slowed learning and memory in these mice over time. Finally, anakinra is neuroprotective 24 hours after convulsion onset. These results show that therapeutically targeting the IL-1 signaling pathway is necessary to attenuate brain damage, and therefore, research into neuroprotective strategies is important to improve brain pathology and potentially improve behavioral outcomes. Title: Pathophysiological role of TRPM2 in a mouse model of chronic cerebral hypoperfusion

Authors: J. MIYANOHARA[1], *H. SHIRAKAWA[1], K. NAGAYASU[1], T. NAKAGAWA[1,2], S. KANEKO[1];
[1]Grad Sch. Pharm Sci, Kyoto Univ., Kyoto, Japan; [2]Kyoto Univ. Hosp., Kyoto, Japan

Abstract: Vascular dementia (VaD) is one of the most common forms of cognitive disorder, responsible for more than 20% of cases of dementia. It has been recognized that cognitive impairment in VaD is highly associated with inflammation in both animal and human, suggesting that regulation of inflammatory response is potential target for cognitive decline in VaD. Transient receptor potential melastatin 2 (TRPM2), a Ca^{2+}-permeable nonselective cation channel, is functionally expressed in the brain and immune cells, implying that TRPM2 could be involved in inflammation during chronic cerebral hypoperfusion. In this study, wild-type (WT) and TRPM2-knockout (KO) mice were subjected to bilateral common carotid artery stenosis (BCAS) using microcoil with 0.18 mm diameter. At 28 days after BCAS, cognitive impairment and white matter injury were significantly attenuated in TRPM2-KO mice compared with WT mice. Immunohistochemical analysis revealed that the accumulation of Iba1-positive microglia/macrophages in corpus callosum was reduced in TRPM2-KO mice, whereas no change was observed in the number of GFAP-positive astrocytes and Gr1-positive neutrophils. In addition, we found that accumulation of microglia/macrophages in corpus callosum area and the cognitive impairment observed in vehicle-treated BCAS mice were reduced in mice treated with minocycline, an inhibitor of microglia/macrophage activation at a dose of 50 mg/kg per day for 28 days after the BCAS surgery. These results indicate that TRPM2 is involved in chronic cerebral hypoperfusion-induced cognitive impairment and white matter injury by regulating microglia/macrophages activation.

Title: Upregulation of microglial toll-like receptor 4 induced by prothrombin kringle-2 contributes to neurotoxicity in the hippocampus *In vivo*

Authors: S. KIM[1,2], H. JANG[1,2], U. JUNG[5], *S. KIM[1,2,3,4];
[1]Sch. of Life Sci. & Biotech., [2]BK21 plus KNU Creative BioResearch Group, [3]Inst. of Life Sci. & Biotech., [4]Brain Sci. and Engin. Inst., Kyungpook Natl. Univ., Daegu, Korea, Republic of; [5]Dept. of Food Sci. and Nutr., Pukyong Natl. Univ., Busan, Korea, Republic of

Abstract: We have recently reported that overexpression of prothrombin kringle-2 (pKr-2), which is a domain of prothrombin that is generated by active thrombin, induces microglial activation in the substantia nigra (SN) of mouse brains, resulting in neurodegeneration in the nigrostriatal dopaminergic system. In addition, we found that patients with Parkinson's disease (PD) showed a significant increase in pKr-2 expression in the SN compared with age-matched controls, suggesting that there might be a correlation between pKr-2 expression and parkinsonism in patients. However, it is still unknown whether there is any correlation between pKr-2 and neurotoxicity in the hippocampus of adult brains, even though there was a report showing that the level of active thrombin was significantly increased in the hippocampus of patients with Alzheimer's disease (AD), suggesting that pKr-2 might be also increased in the lesioned hippocampus. Here, we report that the levels of pKr-2 and toll-like receptor 4 (TLR4) are upregulated in the hippocampus of patients with AD, and intra-hippocampal injection of pKr-2 induces a significant increase in microglial TLR4 expression, resulting in microglial activation and neurotoxicity in the hippocampus of mouse brains. Moreover, pKr-2-induced neurotoxic events were significantly diminished in TLR4-deficient mice compared with normal mice. Therefore, our results suggest that pKr-2 may be a pathogenic factor in neurodegenerative diseases such as PD and AD, and that the inhibition of pKr-2-induced microglial TLR4 may be protective against neurodegeneration in the adult brains. **Acknowledgements:** This research was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (2014R1A1A2056508 and 2014R1A1A4A01007858), and also by grants from the Korea Healthcare Technology R&D Project, Ministry of Health & Welfare (HI15C1928).

Title: Lack of Galectin-3 alters microglial phenotype and affects Alzheimer's Disease Progression in 5xFAD the mouse model .

Authors: *A. BOZA-SERRANO;
Lund Univ., Lund, Sweden

Abstract: Background: Alzheimer's Disease (AD) is the most prevalent type of dementia. The two main pathological hallmarks most commonly used to describe the pathology are the extracellular protein aggregates of amyloid beta (Aβ), called senile plaques, and the formation of intracellular neurofibrillary tangles. Previous studies have shown that Aβ can activate microglial cells, inducing an inflammatory response believed to contribute to the neurodegenerative process in AD. Galectin-3 (gal3) is involved in microglial activation and inflammation. Therefore, we have investigated whether gal3 if the lack of gal3 is able to protect against disease progression in the 5xFAD mouse model of AD.
Results: Challenging microglial cells with Aβ induced a significant increase in the levels of pro-inflammatory mediators including the inducible Nitric Oxide Synthase (iNOS) and pro-inflammatory cytokines. Reducing the Gal3 levels or activity led us to a significant reduction of the observed inflammatory response induced by Aβ fibrils. Using an AD mouse model (5xFAD) we studied if the lack of gal3 is able to reduce the pathology *in vivo*. A significant reduction in Aβ40 was observed at 6 and 18 months in the soluble fraction from 5xFAD-Gal3 KO compare to the WT. The insoluble fraction showed a significant reduction in the Aβ40 and Aβ42 levels at 6 months in the 5xFAD-Gal3 KO mice compared to WT. A reduction of Amyloid Precursor Protein (APP) and APP cleavage products were found at 6 and 18 months, in 5xFAD-Gal3 KO mice. Immunohistochemistry confirmed a reduction in amyloid plaque deposition in the CA1 region of hippocampus in the 5xFAD-Gal3 KO at 6 months. Finally, in human AD brain sections, we were able to confirm the presence of Gal3 positive cells in association with senile plaques, corroborating our animal data.
Conclusions: We demonstrated that Gal3 is related with disease progression in the 5xFAD mouse model. A deficiency in Gal3 reduced the pro-inflammatory response, the amyloid plaque burden, the APP processing, in addition to altering the amyloid-beta CSF levels in this AD mouse model. Notably, Gal3 levels were up-regulated in correlation with the progression of the disease, and only microglial cells close to amyloid plaques showed Gal3 immunoreactivity. In summary, our findings suggest that Gal3 is a key molecule in AD pathogenesis and could be a potential therapeutic target in AD.

Title: Mechanistic and structural studies of the double-hit maternal immune activation model: How microglia and neurons are involved in the progression of schizophrenia

Authors: *C. HUI, J. SAVAGE, M.-E. TREMBLAY;
Univ. Laval, Canada, QC, Canada

Abstract: Schizophrenia is a mental disorder affecting 0.4% of the population, with disease onset occurring in late adolescence or early adulthood. Patients have difficulty with working memory, attention, executive functions, and social interactions. There is emerging evidence from human studies that inflammation experienced prenatally is linked with increased risk for the development of neuropsychiatric disorders including schizophrenia. Moreover, changes of brain volume and increased inflammatory status are observed in schizophrenia patients. Polyinosinic:polycytidylic acid (Poly I:C), a toll-like receptor 3 agonist, is commonly used to mimic viral maternal immune activation in pregnant mice as a preclinical model of schizophrenia. Our recent work revealed that mice receiving a double-hit of Poly I:C, once prenatally at embryonic day (E)9.5 or E12.5 and once at postnatal day (P)30, show several behavioral deficits, including increased repetitive marble burying activity, enhanced anxiety in elevated plus maze, and reduced social interaction in the 3-chamber social novelty test.
To explain how the double-immune challenge leads to behavioral deficits, frontal cortex, hippocampus and cerebellum were harvested from animals 24-48 hours after the behavioral tests. Inflammatory status and expression of schizophrenia-related genes/proteins were investigated by qRT-PCR and western blot. Microglial and neuronal morphologies, cellular damage, microglial remodeling of neuronal circuits, and other modes of microglia-synapse interactions were assessed by confocal and electron microscopy. To determine the physiological activities of microglia in the brain, two-photon imaging was performed in live heterozygous CX3CR1-GFP mice after double Poly I:C challenge. By matching these biochemical and physiological results with previous behavioral findings, we hope to demonstrate how microglial-neuronal interactions are critically involved in the progression of schizophrenia and suggest novel therapeutic avenues for prevention and treatment.

Title: Corticosterone primes the inflammatory response to Gulf War Illness associated agent exposures in the brain but not the periphery

Authors: *A. R. LOCKER[1], K. A. KELLY[1], L. T. MICHALOVICZ[1], J. A. VRANA[1], Z. M. BARNES[2], M. FLETCHER[3], D. B. MILLER[1], J. P. O'CALLAGHAN[1];
[1]Mol. Neurotoxicology, CDC/NIOSH, Morgantown, WV; [2]Dept. of Med., Univ. of Miami, Miami, FL; [3]Inst. for Neuro Immune Med., Nova Southeastern Univ., Fort Lauderdale, FL

Abstract: Following the 1991 Persian Gulf War, 250,000 soldiers returned with symptoms of Gulf War Illness (GWI), a complex disorder with characteristics similar to chronic, persistent sickness behavior - a condition associated with neuroinflammation. Troops were exposed to a variety of conditions in theater, including physiological stressors (e.g., high temperatures, exercise, physical threat) and organophosphate (OP) acetylcholinesterase inhibitors (AChEI) in the form of insecticides (e.g. chlorpyrifos) or the nerve agent, sarin. Previously, we have shown that exposure to the AChEIs, chlorpyrifos-oxon (CPO) and diisopropyl fluorophosphate (DFP, a sarin surrogate), produces neuroinflammation, an effect that is augmented by pretreatment with the stress hormone, corticosterone (CORT) - a stress mimic. Here, we investigated the peripheral effects of exposure to CORT and DFP to determine if systemic inflammatory effects would align with the previously observed neuroinflammatory effects. We assessed peripheral inflammation by measuring cytokine levels in the liver and serum. We also investigated whether AChE activity predicted inflammation in the brain or periphery. Adult male C57BL/6J mice were exposed to CORT (either 200mg/L or 400mg/L) in their drinking water, followed by exposure to a single i.p. dose of DFP (4.0mg/kg). Unlike our previous results in the brain, exposure to DFP alone or with CORT did not result in the increased expression of inflammatory markers in the serum or liver. Interestingly, brain and blood AChE inhibition was not predictive of the neuroinflammation seen in mice exposed to CORT and DFP. In fact, CORT modestly ameliorated the AChE inhibiting effects of DFP, suggesting that neuroinflammation is not the result of AChE inhibition. This paradigm models veteran exposure in theater, but mice exposed to this initial paradigm followed by multiple waves of CORT and an inflammatory challenge with lipopolysaccharide (LPS - a bacterial mimic) more closely models the circumstances surrounding GWI. Exposure to this paradigm revealed that inflammation was increased in both

brain and blood. Unlike the brain, there was no difference in the levels of blood cytokines between mice exposed to CORT or CORT and DFP prior to the LPS challenge. Our results suggest that the persistent sickness behavior symptoms of GWI are a result of neuroinflammation, not peripheral inflammation, induced by a key combination of exposures (e.g., CORT and DFP). Moreover, the identification of blood markers for GWI may not be indicative of the neuropathobiology of the illness. Future treatments of GWI should focus on ameliorating neuroinflammation, a major contributor to GWI.

Title: Central effects of chronic methylphenidate treatment in control and hyperactive rats: neuroinflammation and blood-brain barrier

Authors: *V. COELHO-SANTOS[1,2,3], F. L. CARDOSO[1,2,3], R. A. LEITÃO[1,2,3], C. FONTES-RIBEIRO[1,2,3], A. P. SILVA[1,2,3];

Abstract: Methylphenidate (MPH) is the most commonly prescribed drug for the treatment of attention deficit hyperactivity disorder (ADHD). Despite the widespread use of this psychostimulant, the cellular impact of its use is still largely unknown. Thus, the aim of the present study was to clarify the effect of MPH on cortical immune surveillance and blood-brain

barrier (BBB) properties in both physiological and ADHD conditions. For that, we used a rat model of ADHD, the Spontaneously Hypertensive (SHR) rats, as well as Wistar Kyoto (WKY) as inbred comparator strain. Also, to mimic a clinical dosing regimen in ADHD, rats were administered for Monday to Friday with vehicle or MPH (1.5 or 5 mg/kg/day, per os) during 4 weeks (P28-P55).
We concluded that 1.5 mg/kg/day of MPH downregulated both glial fibrillary acidic protein (GFAP; astrocytic marker) and ionized calcium-binding adapter molecule 1 (IBA1; microglia marker) in hyperactive rats. On the contrary, in WKY rats, both MPH doses increased GFAP levels, led to perivascular astrogliosis, and microgliosis. Neuroinflammatory events are known to perturb the BBB integrity, which is a multicellular vascular structure that separates the brain from the peripheral blood circulation maintaining an environment that allows neural cells to function properly. Thus, BBB dysfunction can lead to immune cell infiltration and brain injury. Herein, we observed that 5 mg/kg/day MPH increased BBB permeability in both WKY and SHR animals; however, more prominent in WKY rats. This effect can be explained by the downregulation of the tight junction protein, claudin-5, and disruption of the cerebrovascular basal lamina protein, collagen-IV. Noteworthy, WKY animals also showed an increase in the expression of caveolin-1, which is a structural protein required for caveolar transcytosis, and both vascular cell and intercellular adhesion molecules (VCAM-1 and ICAM-1), important proteins to promote adhesion and transmigration of peripheral cells into the brain. As a consequence of BBB alterations, CD169+macrophages were significantly identified in the brain parenchyma.
Overall, we demonstrated that chronic exposure to MPH under physiological conditions promotes neuroinflammatory events and brain vascular alterations. Interestingly, in the ADHD animal model, MPH at the lower dose had an anti-inflammatory. Our conclusions highlight the importance of an appropriate MPH dose regimen for ADHD, and the negative impact of MPH misuse.

Title: Recurrent coccidiodal meningitis treated with intrathecal administration of liposomal Amphotericin B

Authors: *B. FIANI, A. NGUYEN, D. NACIONALES, A. SODHI, G. FISCHBERG;
Desert Regional Med. Ctr. - ICON, Palm Springs, CA

Abstract: Background: Coccidiodal meningitis is a fungal infection that effects the meninges of the brain and is common to the southwestern United States and northwestern Mexico. Fluconazole is the accepted medical therapy, along with, amphotericin B.[1] Previous literature supports the use of intrathecal or IV liposomal amphotericin B in animal studies, but the importance of its usage in humans is evidenced by this case.[4] **Case Presentation:** A 44 year old Hispanic male presented with a past medical history significant for Coccidiodal meningitis in 10/2014 with recurrence. On physical exam, he was GCS 9 (M4 V1 E4), non-verbal, and did not cooperate with commands or physical exam, including testing Kernigs or Brudzinski sign. He symmetrically withdrew in all 4 extremities to painful stimuli. CT head showed diffuse ventriculomegaly. Enlargement of all ventricles. Hydrocephalus. No etiology identified. An EVD was placed for diagnostic and therapeutic purposes. CSF studies showed: 1,122 RBC, 186 WBC (21% neutrophils, 76% lymphocytes), 9.7 Coccidi IgG, 1:32 Coccidods Ab Qn, glucose 45 (serum glucose 99), protein 2,152. The patient was treated with intrathecal administration of liposomal amphotericin B thirteen times throughout the course of stay, 1.5 mg followed by 2 mL of sterile saline each time. Patient was also increased from fluconazole 400 mg to fluconazole 800 mg IV. Serial CSF studies were drawn before each administration of amphotericin B. Patient's labs and clinical picture improved from treatment. **Discussion:** The importance of this case comes from its applicability to show the effectiveness of intrathecal liposomal amphotericin B as a treatment method. CSF studies that were routinely collected trended in a promising direction toward improvement. In this patient, the use of intrathecal liposomal amphotericin B decreased CSF protein and CSF WBC including lymphocyte percentage. **Conclusion:** The above is a case of Coccidiodal meningitis in the setting of severe altered mental status and new-onset seizure. This patient shows the results of treatment with intrathecal administration of liposomal amphotericin B which supports prior animal studies and is breakthrough evidence in humans.

Title: Pharamcologically inhibiting soluble tumor necrosis factor α signaling mitigates autonomic dysreflexia and improves cardiovascular function after a complete high thoracic spinal cord injury

Authors: *E. MIRONETS[1], S. HOU[1], J. R. BETHEA[2], P. OSEI-OWUSU[3], V. J. TOM[1]; [1]Neurosci., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Biol., [3]Pharmacol. and Physiol., Drexel Univ., Philadelphia, PA

Abstract: A consequence of severe, high-level spinal cord injury (SCI) is autonomic dysreflexia (AD), a life-threatening syndrome characterized by extreme, sudden bouts of hypertension triggered by sensory stimuli caudal to the injury. AD develops partly due to aberrant plasticity of sensory circuits caudal to the injury that lead to hyperactivation of sympathetic preganglionic neurons and hypertension. Since the pro-inflammatory, "master regulator" cytokine soluble tumor necrosis factor α (sTNFα) has been correlated with hyperexcitability, we hypothesize it plays a crucial role in this plasticity. We found that 4 weeks after a complete T3 transection (Tx) in adult rats, which virtually always results in AD, TNFα levels in lumbar cord are significantly higher than in naïve tissue, indicative of chronic inflammation in tissue caudal to a SCI. To test whether sTNFα is key for AD development, after T3 Tx, animals continuously received XPro1595, a biologic that inhibits sTNFα signaling, or saline intrathecally to spinal cord caudal to the SCI for 4 weeks. Notably, these rats had radiotelemeters implanted into the descending aorta at least 1 week prior to Tx to allow us to measure blood pressure (BP) and heart rate (HR) in the same rats at multiple time points. At 2, 3 and 4 weeks post-Tx, we assessed BP and HR before, during, and after colorectal distension (CRD) to trigger AD. Both groups of rats had similar basal BP. CRD induced sharp spikes in BP in saline rats that persisted long after CRD was alleviated. XPro1595 rats had significantly smaller and shorter hypertensive episodes during and after CRD. We also determined the number of spontaneous AD events that occurred over a 24-hour period at 2, 3, or 4 weeks. XPro1595 rats had significantly fewer spontaneously occuring events at all 3 testing points than saline animals. These data show that inhibiting sTNFα in caudal spinal cord dramatically diminished AD. This may be due to significantly less sprouting of $CGRP^+$ nociceptive afferents in dorsal horn and lamina X observed in the XPro1595 rats. To determine if inhibiting spinal sTNFα signaling improves peripheral vasculature function after SCI, we harvested mesenteric artery 4 weeks after Tx for ex vivo analysis. Vessels from saline-treated T3Tx rats had increased reactivity to vasopressors K^+ and phenylephrine compared to those from both naïve and XPro1595-treated T3Tx rats. Importantly, vessels from XPro1595 rats reacted similarly to naïve vessels. These data indicate that spinal sTNFα after SCI plays a critical role in plasticity leading to AD and altered peripheral vasculature, elucidating a potential target to diminish AD and improve cardiovascular health after SCI.

Title: Intrauterine inflammation leads to sex-dependent alterations in CNS inflammatory responses, and sex-independent changes in behavior

Authors: *R. A. MAKINSON[1], S. MCKEE[2], N. GRISSOM[1], B. GEORGE[2], M. MARINI[2], A. RAYASAM[3], Z. FABRY[3], T. REYES[1];

Abstract: Early life is a critical period in brain development, and adverse events during this time can have lasting effects on brain function and behavior. A common event that can disrupt normal brain development is exposure to inflammation *in utero*. In models using systemic maternal immune activation, a number of adverse effects on the brain and behavior have been documented. Chorioamnionitis, or the infection of the fetal membranes, occurs in approximately 10-15% of term births and is the focus of the current studies. Specifically, the goal is to investigate the extent to which intrauterine inflammation adversely affects the brain and behavior in male and female offspring. To model IUI, we utilize an injection of lipopolysaccharide (LPS), a bacterial mimic that induces an innate inflammatory response, directly into the uterus at embryonic day 15 in mice. We show that IUI significantly alters a number of parameters associated with proper brain development, behavior and immune activation. Specifically, IUI exposure decreased myelin basic protein (MBP) mRNA and protein, as assessed by immunohistochemistry and qPCR. Sex differences in assessed end points were also found. Specifically, the central nervous system's immune response to an acute LPS injection in adult males was potentiated, an effect absent in the female offspring. Males exposed to IUI exhibited a greater increase in interleukin-1beta, tumor necrosis factor alpha, C-X-C motif ligand 10 and suppressor of cytokine signaling 3. IUI also significantly increased the total number of microglia in both males and females. Lastly, current studies are underway to test whether IUI alters cognitive performance in the 5 choice serial reaction time task, which assesses executive function (e.g., attention and impulse control). These results indicate that IUI negatively impacts neurological development in a sex-dependent matter, and these effects persist into adulthood.

Abstract: Neuroinflammation is associated with neurodegenerative diseases, including multiple sclerosis (MS), Parkinson's disease (PD), Alzheimer's disease (AD), Huntington's disease (HD), and traumatic brain injury (TBI). Activation of the mitochondrial translocator protein (TSPO) in neuronal tissue is linked with neuroinflammation, thus TSPO ligands can be applied to image the progression of neuroniflammation *in vivo* using PET imaging. ^{18}F-FEPPA is second-generation TSPO ligand with improved BBB penetration, selectivity and suitable metabolic profile, with hydrophilic metabolites, which are less likely to penetrate the blood brain barrier. ^{18}F-FEPPA has been used in clinical PET imaging of neuroinflammation e.g. in PD, AD and schizophrenia. Dynamic PET imaging of neuroinflammation in rodent models is challenging due to several factors. TSPO upregulation is uniform in most many neurodegenerative diseases with neuroinflammation. This limits the use of reference tissue models, as no valid reference tissue is available. Traditional techniques for blood sampling to generate full arterial input function (AIF) are not feasible due to limited blood volume of rodents. Significant blood loss may also bias tracer pharmacokinetics. Furthermore, multiple blood sampling can be conducted only as a terminal procedure preventing longitudinal studies within individual. With arteriovenous shunt and coincidence counter blood input function can be obtained during dynamic PET scan without blood loss. Correction for plasma activity and parent fraction can be achieved from minimal blood volume samples collected from the shunt during the scan. This nonsurgical novel approach requires only minimal blood sampling allowing longitudinal PET studies with AIF in rats. Lipopolysaccharide (LPS) is a known potent immunostimulant, which can be used to induce acute local neuroinflammation after intracranial stereotactic infusion. In this study dynamic PET imaging of ^{18}F-FEPPA was performed after unilateral infusion of LPS to rat striatum. Dynamic 90 min PET scan was performed and blood activity was measured simultaneously from the shunt using coincidence counter. After imaging brains were collected for additional autoradiography and histological analysis. As a summary, applying this novel methodology to generate AIF

simultaneously with pre-clinical PET imaging provides more translational and reliable approach to monitor progression of inflammation applicable for several neurodegenerative rodent models.

Title: Intercellular adhesion molecule-5 (ICAM-5) facilitates a unique and dynamic relationship between CD4+ t cells and hippocampal neurons during HIV-associated neurocognitive disorder (HAND)

Authors: ***A. J. TRZECIAK**[1], J. HAMMOND[2], S.-M. LU[2], H. GELBARD[3];

Abstract: Neuroinflammation is often an unwanted side effect of many inflammatory disorders and peripheral infections. In the case of HIV-1 infection, circulating T cells are known to infiltrate the brain and cause neuronal damage and gliosis. In an effort to more closely examine some of these interactions, an *in vitro* rodent hippocampal model of HIV-associated neurocognitive disorder (HAND) was created using a well-known inflammatory mediator of HIV-1 infection known as platelet-activating factor (PAF), in addition to CD4+ T cells isolated from rodent splenocytes with a cocktail of anti-CD3ε, anti-CD28, rIL-2, then supplemented with additional IL-2 and co-cultured with DIV18 neurons. We specifically focused on the expression of a homing molecule in telencephalic neurons called intercellular adhesion molecule-5 (ICAM-5) and its unique ability to both recruit and suppress T cell function via interactions with its cognate receptor, leukocyte function antigen type 1 (LFA-1). We used the carbamyl congener of PAF (cPAF) because it is resistant to degradation by tissue acetylhydrolases. We found that over a 2log difference in cPAF concentration (100nM-10μM), there was no effect on neuronal viability, but subsequent co-culture with CD4+ T cells in increasing numbers demonstrated an inverse relationship between the transmembrane and soluble forms of ICAM-5. These findings indicate that neurons express intracellular ICAM-5 during PAF-induced toxicity, but switch to a secreted form of the molecule when CD4+ T cells are added at higher ratios, suggesting that

soluble ICAM-5 may be an "SOS" signal from neurons during HIV-1 infection of the CNS with increased CD4+ T cell trafficking into the CNS. The translational relevance of these findings is underscored by previous data from our lab that demonstrate a striking increase of soluble ICAM-5 seropositivity in serum from patients with HIV-1 infection, suggesting potential alterations in blood-brain barrier integrity and/or lymphocyte trafficking from the CNS to the periphery with bound soluble ICAM-5. We are extending these studies to assess whether there are additional effects of this type of signaling on adaptive immune cell populations including Tregs. Support: MH64570

Title: Inflammasome activation exhibits sex difference and estrogen receptor beta agonist treatment reduces its activation and protects the brain from ischemic damage

Authors: *N. D'ADESKY[1], M. SCHATZ[2], M. A. PEREZ-PINZON[2], H. BRAMLETT[2], J. DE RIVERO VACCARI[2], A. P. RAVAL[2];
[1]Neurol., [2]Univ. of Miami, Miami, FL

Abstract: Cerebral ischemia is known to activate the innate immune response, and the inflammasome is a key component of the innate immune response. The inflammasome is comprised of caspase-1, the adaptor protein apoptosis associated speck-like protein containing a CARD (ASC), and a pattern recognition receptor such as a NOD-like receptor. Prior literature suggested that the inflammasome proteins are regulated by sex steroids. In a published study, we reported that the silencing of estrogen receptor subtype beta (ER-β) attenuated 17β-estradiol mediated decreases in caspase-1, ASC and interleukin-1β (IL-1β). Based on this information, the goal of the current study was to investigate whether inflammasome proteins alter with age and/or sex in the hippocampus and if these differences could contribute to increases in damage due to cerebral ischemia. We hypothesize that inflammasome activation is significantly higher in the hippocampus of reproductively senescent (RS) females as compared to their young counterparts and age-matched males. We also hypothesize that periodic pretreatment of ER-β agonist will reduce both inflammasome activation and cerebral ischemic damage in RS female rats. We

tested our hypothesis by investigating inflammasome protein levels in the hippocampus of young (6-7 month old) and reproductively senescent (11-13 month old) female Sprague-Dawley rats and age matched males. To test the efficacy of ER-β agonist on reducing inflammasome proteins and ischemic brain damage, ER-β agonist (1 mg/kg; every 48 h for 21 days) or vehicle (DMSO) treated RS females were sacrificed for collection of brain tissue or exposed to global cerebral ischemia. Results of western blot analysis demonstrated a significant increase in the inflammasome proteins caspase-1 ($p < 0.05$) and ASC ($p < 0.01$) in the hippocampus of RS females as compared to RS matched male rats. In the RS female periodic ER-β agonist pretreated group, we observed a significant decrease of the inflammasome proteins caspase-1 ($p<0.05$), ASC ($p<0.05$) and IL-1β ($p<0.05$) as compared to vehicle treated RS females. Furthermore, histological analysis of the hippocampus 15 days after global cerebral ischemia demonstrated a significantly higher number of live neurons ($p< 0.05$) in the ER-β agonist group as compared to vehicle treated RS female rats. Our findings suggest the role of sex hormones in the regulation of the inflammasomes in the hippocampus and that activation of ER-β could be useful in the prevention of post-ischemic inflammasome activation and reduction in ischemic brain damage.

Title: Nuclear imaging of neuroinflammation in rodent models of neurodegenerative diseases

Authors: T. HUHTALA[1], J. RYTKÖNEN[1], P. POUTIAINEN[2,3], L. TOLPPANEN[1], A.-M. ZAINANA[1], T. PARKKARI[1], O. KONTKANEN[1], P. J. SWEENEY[1], *A. J. NURMI[1]; [1]Charles River Discovery, Kuopio, Finland; [2]Univ. of Eastern Finland, Kuopio, Finland; [3]Kuopio Univ. Hosp., Kuopio, Finland

Abstract: Neuroinflammation is associated with progression of various neurodegenerative diseases. Activation of the mitochondrial translocator protein (TSPO) is linked to neuroinflammation and TSPO ligands can be used for *in vivo* PET or SPECT imaging. ^{18}F-FEPPA is a second-generation TSPO ligand with improved penetration, selectivity and suitable metabolic profile. For *in vivo* SPECT/CT imaging of neuroinflammation, ^{123}I-CLINDE has been used as a TSPO radioligand. In the current studies, we utilized these ligands to assess the extent of neuroinflammation after lipopolysaccharide (LPS) infusion, following induction of multiple

sclerosis (MS) and neuropathic pain. LPS, a known potent immunostimulant, was used to induce acute local neuroinflammation. Dynamic PET imaging of ^{18}F-FEPPA after a unilateral infusion of LPS into the rat striatum was performed and blood activity was measured simultaneously from the shunt using a coincidence counter to generate the arterial input function (AIF) for kinetic modeling. To model MS, C57Bl/6 mice were given cuprizone (0.3% w/w) in their diet for 6 weeks. After SPECT/CT (^{123}I-CLINDE) and PET/CT (FDG) imaging had been performed, brains were dissected for autoradiography analysis and densities of cannabinoid receptor 1 (CB1) in treated and control animals were compared. A significant increase in accumulation of ^{123}I-CLINDE ($P < 0.05$) was observed in all studied brain regions, and a significant decrease in brain metabolism was revealed in several brain regions of cuprizone-treated animals compared to parameters measured in control mice. In addition, CB1 receptor density in the globus pallidus was significantly lower in cuprizone-treated mice than in control animals. Neuritis model was used to study perineural inflammation in rats. Induction was done using modified Complete Freund's adjuvant in Oxygel band wrapped around sciatic nerve. Animals exhibited neuropathic pain as well as five-fold accumulation of FDG on day 7, and 1.6-fold accumulation of CLINDE on day 4 post-induction was observed in the operated left hind leg. Persistent increase in metabolic activity was seen on day 7 and 21 post induction using FDG-PET imaging. As a summary, pre-clinical nuclear imaging provides more translational approach to monitor progression of inflammation and is applicable in several rodent models with neuroinflammation. In these studies, SPECT/CT imaging with ^{123}I-CLINDE was shown to effectively detect neuroinflammation. In addition, metabolic alterations associated with neuroinflammation were also quantified by using FDG/PET. Results highlight multiple options to study neuroinflammation in animal models.

Title: Ketogenic diet-mediated K_{ATP} channels activation ameliorates neuroinflammation by intervening ketone body

Authors: H. OH[1], M. LEE[2], S.-C. MA[1], I.-H. CHO[1], *D. KIM[1];
[1]Barrow Neurolog. Institute, St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ; [2]Col. of Korean Medicine, Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Ketogenic diet (KD) is a proven therapy for patients with medically refractory epilepsy. There is also emerging data supporting its use beyond epilepsy in various neurological disorders (NDs). The metabolic shift towards fatty acid oxidation following the KD administration results in the eminent production of ketone bodies [KBs; β - hydroxybutyrate (BHB) and acetoacetate (ACA)] as a hallmark of metabolic change. While there is growing evidence suggesting that both the KD and KBs appear sufficient as disease-modifying actions in diverse NDs, the underlying mechanisms of this beneficial effect have yet to be elucidated. Our recent observation has provided that KBs negate neuroinflammation in glial cells and its effect may be relevant in control of ATP-sensitive potassium (K_{ATP}) channels (*SFN 2015, #121.14).* In the present study, we explored the functional relevance of K_{ATP} channels on the anti-inflammatory effect of either the KD or KBs under glial activation induced by lipopolysaccharide (LPS; an endotoxin) or rotenone (a mitochondrial respiratory complex 1 inhibitor) using immunohistochemistry, western blotting, mRNA expression, and CRISP shRNA. C57BL/6J mice were fed either the KD or a standard diet (SD) from postnatal 6 wks until 8 wks, and then LPS (3 mg/kg, intraperitoneally) was administrated to evoke glial cells activation. The KD significantly attenuated upregulation of tumor necrosis factor-α, interleukin-1 β (IL-1β) and IL-6 mRNA in hippocampi at 4 h after LPS injection. Morphological changes of microglia (Iba1 protein) and astrocyte (GFAP) by LPS were normalized with the KD. Hippocampal lysates collected from the KD-fed mice exhibited an increase in the inwardly rectifying K^+ channel subunit Kir6.2, a critical component of K_{ATP} channels, as compared to SD-fed mice. Under either LPS - or rotenone - induced glial cells activation, BHB had a strong reduction in the release of pro-inflammatory mediators and its action was linearly correlated with the downregulation of LPS-mediated M1 expression for pro-inflammatory cytokines or upregulation of IL4-induced M2 expression for anti-inflammatory cytokines. As expected, Kir6.2 immunoreactivity was significantly enhanced in both microglia and astrocyte exposed to BHB. The anti-inflammatory effects were counteracted by pharmacological blockers or shRNA of K_{ATP} channels. Collectively, our data indicate that both the KD and BHB protect against neuroinflammation. Furthermore, the underlying protective activity of both the KD and KBs influences either by enhancing anti-inflammatory properties and/or increasing K_{ATP} channels activation.

Title: MiRNA-22 regulates chronic inflammatory pain by positively targeting Mtf1

Authors: *Z. PAN[1], L.-Y. HAO[2], G.-F. LI[2], M.-L. SUN[2], L.-J. ZHU[2], Y.-D. LI[2], H.-L. DING[2], J.-L. CAO[2];

Abstract: Increasing evidence has shown that miRNA negatively regulating expression of pain-related gene contributes to chronic pain, however, it remains unknown whether miRNA could positively gene expression in the modulation of chronic pain. Here, we found that complete Freund's adjuvant (CFA)-induced chronic inflammation pain significantly induced the increase of miRNA-22 expression in mice spinal neurons. Furthermore, Mtf1, a possible positive target of miRNA-22, was increased in the spinal cord of CFA mice. Knockdown of spinal miRNA-22 markedly attenuated pain behavior induced by CFA. Concurrently, the increased expression of spinal Mtf1 was reversed by miRNA-22 knockdown. In contrast, overexpression of spinal miRNA-22 in naive mice increased the expression of spinal Mtf1, and induced the production of pain-like behaviors, which could be inhibited by knockdown of spinal Mtf1 with siRNA. Collectively, we conclude that miRNA-22 regulates chronic inflammatory pain by positively targeting Mtf1.

Title: VCAM1 is a mediator of age-related brain inflammation and decreased neurogenesis caused by an aged systemic milieu

Authors: *H. YOUSEF[1], C. CZUPALLA[2], J. ZANDSTRA[1], A. BURKE[1], H. HADEIBA[3], E. BUTCHER[2,4], T. WYSS-CORAY[1,4];
[1]Neurol., [2]Pathology, Stanford Univ., Palo Alto, CA; [3]Immunol. and Vascular Biol., Palo Alto Veterans Inst. for Res., Palo Alto, CA; [4]VA Palo Alto Hlth. Care Syst., Palo Alto, CA

Abstract: Studies from our lab and others have recently shown that brain function - specifically neurogenesis, synaptic plasticity and cognitive function in the hippocampus, a key center for learning and memory- is inhibited in young mice connected to aged mice through heterochronic parabiosis or aged plasma intravenous injections. While the identity of systemic inhibitory factors from aged plasma are beginning to be elucidated, the question of how and if these factors cross the blood brain barrier (BBB) and act directly on brain tissue to inhibit neurogenesis, or whether they act through their direct contact with brain endothelial cells (BECs) of the vasculature remain unanswered. BECs upregulate expression of vascular adhesion molecules as a result of increased systemic inflammatory signaling resulting from multiple diseases that afflict the CNS. We discovered that BEC-specific VCAM1 increases in the hippocampus during normal aging. Exposure of young BECs to an aged systemic environment induces BEC activation and upregulation of VCAM1 both in vitro and in vivo. Specifically, systemic injections of aged human blood into young immunodeficient (NSG) mice- acutely over 4 days or spread over 3 weeks- increased BEC-specific VCAM1 expression, increased brain inflammation as assessed by microglial activation, and inhibited hippocampal neurogenesis. Blocking VCAM1 signaling systemically with a neutralizing monoclonal antibody rescued neurogenesis and prevented aged plasma induced microglial activation. This study suggests that preventing BEC-immune cell crosstalk through VCAM1 may be a therapeutic target for ameliorating aged blood induced decline in brain function.

Title: A novel small-molecule agonist of PPAR-γ potentiates an anti-inflammatory phenotype in glia and endothelial cells

Authors: ***G. SONG**[1], Y. NAM[1], M. JO[1], J. KOO[2], S. PARK[2], K. SUK[1];
[1]Brain Sci. and Engin. Institute, Dept. of Pharmacology,, Kyungpook Natl. Univ., Taegu-City, Korea, Republic of; [2]Dept. of Chem., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Neuroinflammation is a key process for many neurodegenerative diseases. Activated microglia and astrocytes play an essential role in neuroinflammation by producing nitric oxide (NO), inflammatory cytokines, chemokines, and neurotoxins. Therefore, targeting glia-mediated neuroinflammation using small-molecules is a potential therapeutic strategy. In this study, we performed a phenotypic screen using microglia cell-based assay to identify a hit compound (SNU-BP), which inhibits lipopolysaccharide (LPS)-induced NO production in microglia. SNU-BP inhibited pro-inflammatory cytokines and inducible nitric oxide synthase in LPS-stimulated microglia and astrocytes, and potentiated interleukin-4-induced arginase-1 expression. PPAR-γ was identified as a molecular target of SNU-BP. The PPAR response element reporter assay revealed that SNU-BP specifically activated PPAR-γ, but not PPAR-δ or -α, confirming that PPAR-γ is the target protein of SNU-BP. The anti-inflammatory effect of SNU-BP was attenuated by genetic and pharmacological inhibition of PPAR-γ. In addition, SNU-BP has anti-inflammatory effects in endothelial cells as well, by inhibiting LPS-induced MCP-1 and VCAM

expression. Finally, SNU-BP exhibited an anti-inflammatory effect in the LPS-injected mouse brain, demonstrating a therapeutic potential for neuroinflammatory diseases.

Title: Skin overexpression of neurturin increases antigen presenting cells recruitment to the skin and dorsal root ganglia and provides resistance to C. albicans infection

Authors: ***M. E. RITTER JONES**[1], C.-Y. LUI[2], C. YAO[5,6], B. M. DAVIS[2], D. H. KAPLAN[3,4], K. M. ALBERS[2];
[1]Anesthesiol., [2]Neurobio., [3]Dermatol., [4]Immunol., Univ. of Pittsburgh, Pittsburgh, PA; [5]Dept. of Dermatol., [6]Ctr. for Immunol., Univ. of Minnesota, Minneapolis, MN

Abstract: Tissue inflammation and nerve injury can lead to chronic neurogenic inflammation and pain. Neurogenic inflammation involves cytokine release from nerve endings, both locally (at site of injury) and centrally, which induces vasodilation and further activation of the immune system. Changes in neurotrophic growth factors, which are known to increase sensory neuron activity, also occur in response to injury and inflammatory challenge. However, the exact role of these factors in modulating the inflammatory milieu at the site of injury remains to be elucidated. In recent studies, we determined that the growth factor neurturin (Nrtn) may regulate immune cell infiltration. In mice that overexpress Nrtn (Nrtn-OE) in the skin, an increased density of major histocompatibility complex II positive (MHC II+) antigen presenting cells (APCs) was observed in both the dorsal root ganglia (DRG) and skin when compared to wild type (WT) mice. We then tested if this Nrtn-induced increase in APCs altered the response to an inflammatory challenge elicited by a *Candida albicans* (CA) cutaneous infection. At 3 days post infection, the infected skin and DRG were isolated and analyzed by immunohistochemistry to detect MHC II+ cells. Colony forming assays (CFUs) were also done to assess the clearance of CA from infected skin. CFU assays showed significantly fewer colonies in Nrtn-OE skin

indicating enhanced CA clearance. Immunohistochemistry demonstrated that, in both the skin and DRG, there were a greater number of MHC II+ cells in NrtnOE mice. In the DRG, MHC II+ labeled cells appeared preferentially adjacent to neuronal cell bodies. The increase in Nrtn and APCs was associated with faster clearance of *C. albicans* and suggests a new role for Nrtn as a modulator of inflammatory cell infiltration and the innate immune system response.

Title: Unfolded protein response and iron metabolism interplay in the CNS

Authors: *S. HEALY, J. MCMAHON, U. FITZGERALD;
Multiple Sclerosis Res. Group, Galway Neurosci. Centre, NUI Galway, Galway, Ireland

Abstract: The unfolded protein response (UPR), a ‘check-and-balance’ program activated upon disturbed homeostasis in the endoplasmic reticulum (i.e. ER stress), has been linked with iron homeostasis. Given that aberrant iron metabolism and increased expression of markers of the UPR have been independently reported in multiple sclerosis, Alzheimer’s disease and Parkinson’s disease, we believe that the crosstalk between UPR signaling/iron homeostasis might participate in neurodegeneration and that clarifying this relationship in the CNS will provide further clues into disease pathogenesis.
For the first time, using our novel *ex vivo* slice brain slice culture model of iron mismanagement, we demonstrate that 5 μg/ml tunicamycin exposure, which activates the UPR, ameliorates the toxic 1.6-fold iron accumulation produced by one μM ferrocene exposure ($P < 0.05$) suggesting a protective mechanism. Given that their interplay is reciprocal, the effect of iron dyshomeostais and UPR activation on each other was investigated both independently and together in our slice culture system.
By activating the UPR with tunicamycin, we investigated whether the CNS activation

recapitulates the iron dyshomeostasis (i.e. effects on hepcidin, ferroportin and ferritin-H expression) reported in UPR-activated hepatocytes. Building on this preliminary profile, we have also assessed changes in the transcripts of 14 key iron homeostasis molecules in our UPR-activated brain slices and also a subset of these molecules at the cellular level using immunohistochemistry and confocal microscopy.
Using real-time PCR, we have also identified and comprehensively characterized the effects of iron on the transmembrane sensors, ATF6 and PERK, the resident UPR chaperones, BiP and calreticulin, and also the proteins, CHOP and XBP1. These findings were confirmed at a cellular level where activated nuclear ATF6 was observed in the cell nuclei in iron-loaded slice cultures. In summary, we have comprehensively characterised the iron-UPR interplay in the brain and believe this research provides groundwork for understanding the role this relationship plays in neurodegenerative disease.

Title: Using a novel hybrid enzyme to identify the mechanisms of paracrine and autocrine effects of the inducible COX-2 and mPGES-1-produced prostaglandin E_2 on mouse hippocampal neurons

Authors: *Q. LING, H. AKASAKA, E. MURDOCH, K.-H. RUAN;
Univ. of Houston, Houston, TX

Abstract: Nonsteroidal anti-inflammatory drugs (NSAIDs) are specific inhibitors of cyclooxygenase (COX)-1 and COX-2, which mediate metabolism of arachidonic acid (AA). Their effects in heart and vascular diseases have been well established, but how they regulate neuronal inflammation and neurodegeneration is still not clear. In order to address this question, we have investigated both paracrine and autocrine effects of the NSAIDs-targeted AA-metabolites, prostaglandin E_2 (PGE_2), prostacyclin (PGI_2) and thromboxane A_2 (TXA_2) on

mouse hippocampal neurons. First, to study the paracrine effects, HT22 cells, the hippocampal neuronal cell line, were co-cultured with the HEK293 cells over expressing our created hybrid enzymes (COX-2-10aa-mPGES-1, COX-1-10aa-PGIS, and COX-1-TXAS) to specifically direct the AA metabolites to PGE_2, PGI_2 or TXA_2, respectively. The PGE_2 produced by COX-2-10aa-mPGES-1 and secreted from the HEK293 cell exerted cell damage on HT22 cells, compared to that of the HEK293 cells secreted PGI_2 and TXA_2. These data demonstrated that PGE_2 mediated neuronal inflammation could be through paracrine mechanism. Next, to test the autocrine effect of the PGE_2, we transfected HT22 cells with the cDNA of the hybrid enzymes and redirected their cellular AA metabolites to the corresponding prostanoids. When challenged by amyloid beta peptide (residues 25-35), the PGE_2 produced by COX-2-10aa-mPGES-1 and released by the neuron cells caused self-damages and death, similar to that of the paracrine effects. These data indicated that autocrine effect of the inflammatory PGE_2 on the neuronal cells. The study has provided novel evidences that neuronal inflammation and degeneration could be exerted by the inflammatory PGE_2 produced by the neuron cell self and the surrounding microglia cells through both autocrine and paracrine effects. Additionally, we incubated HT22 cells with analogues of PGE_2, which also induced cellular damages, leading to cell death. These effects were blocked by specific EP1 antagonist SC-19220. The identified EP1 involved in mediating the PGE_2 singling on the neuronal inflammation could be a potential target for the anti-neuronal inflammation and degeneration. As a support, we are going to investigate the genes that are involved in the EP1-mediated neuronal inflammation and degeneration within the neuron cells.

Title: Hmgb1 and il-1β heterocomplexes in brain increase neuroimmune responses

Authors: *L. G. COLEMAN, JR[1], F. T. CREWS, 27599[2], J. ZOU[2];
[1]Univ. of North Carolina at Chapel Hill, Durham, NC; [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Introduction: Innate immune responses involve release of classical innate immune molecules such as HMGB1 and IL-1β. The brain is rich in these molecules and neuroimmune

activation has been implicated in many disease states. Microglia are the primary mediator of neuroimmunity and release HMGB1 in response to ethanol. HMGB1 is also known to act as a chaperone for certain cytokines, enhancing their action at their receptors. **Methods**: *In Vivo:* Adult C57/BL6 mice were treated with ethanol (6g/kg, i.g.). Brain, plasma and lung were collected and analyzed at 6, 12, 18, 24, and 48 hours after ethanol. *In Vitro:* BV2 microglia were exposed to ethanol for 6-24 hours. Lysates and media were analyzed for HMGB1 protein. Hippocampal-entorrhinal brain slice culture (HEC) was used to assess the immune actions of HMGB1/IL-1β heterocomplexes. Recombinant HMGB1 and recombinant IL-1β were at 4C for 24 hours to form HMGB1/IL-1β complexes for functional experiments. **Results**: *In Vivo:* We found that HMGB1 and IL-1β were stored in the brain and lung in heterodimeric complexes in addition to free forms. Acute high dose ethanol resulted in a transient increases in HMGB1 in the brain (95% increase at 1 h), plasma (119% increase at 12 h), and lung (171% at 6 hours). Western blot and co-immunoprecipitation revealed that HMGB1 and IL-1β were stored in the brain together as a heterocomplex. *In Vitro*: HMGB1/IL-1β heterocomplex were also found in BV2 microglia. However, they were not present in SH-SY5Y neurons. Acute ethanol (100mM for 24 hours) increased the amount of HMGB1/IL-1β heterocomplexes in BV2 microglia (4-fold). HMGB1/IL-1β heterocomplexes were hyper-inflammatory in HEC brain slice culture. HMGB1 (17mM) alone did not induce iNOS. IL-1β alone (600pM and 6nM) increased iNOS by 712% and 2981% respectively. HMGB1/IL-1 complexes increased iNOS expression by 1.7- 2-fold above IL-1β alone (1452% and 4941% at 600pM and 6nM). IL-1β induced its own gene induction to 2367% and 11,621% of control (600pM and 6nM respectively). HMGB1/IL-1β complexes increased IL-1β gene induction by 1.7 to 3.5 fold above IL-1β alone (8379% and 19,916% above control, 600pM and 6nM IL-1β respectively). IL-1 receptor antagonist reduced the HMGB1/ILβ induction of iNOS by 64% while returning TNFα and IL-1β to control levels.**Conclusions**: HMGB1 and IL-1β are stored together as a heterocomplex in the brain in addition to their free forms. HMGB1/IL-1β complexes are more potent than IL-1β alone and act via enhancement of IL-1β signaling. Ethanol increases HMGB1/IL-1β heterocomplexes in microglia. Induction of neuro-HMGB1/IL-1β heterocomplex formation may be involved in the neuroimmune activation associated with alcoholism.

Abstract: Stroke is known to induce a proinflammatory response leading to increased cell death and exacerbated secondary injury in the brain. We have shown that interleukin-33 (IL-33) administration is protective against ischemic insult by decreasing neuroinflammation and by shifting the microglial polarization towards M2 phase in the brains of Balb/cOlaHsd mice subjected to permanent middle cerebral artery occlusion (pMCAo).
The role of small, non-coding RNAs in regulation of gene expression in stroke is still emerging. We found out, that IL-33 treatment diminishes stroke-induced increase in Scm-like with four mbt domains 2 (Sfmbt2) cluster miRNA (referred to as Sfmbt2 miRNA) levels in the ipsilateral hemisphere of the brain 3 days after pMCAo. We carried out this study to investigate the influence of this particular miRNA on neuronal survival and microglial functions. Sfmbt2 miRNA levels were increased in mouse primary cortical neurons after glutamate treatment and in Neuro-2a exposed to 2 h oxygen-glucose deprivation and 24 h reperfusion (OGD/R), while microglial BV2 cells exposed to lipopolysaccharide (LPS) exhibited decreased levels of this miRNA. To study the gain-of-function of Sfmbt2 miRNA on neuronal survival and microglial properties, we stably transduced N2a and BV2 cells with lentiviral vector and thus drove Sfmbt2 miRNA overexpression. N2a viability following OGD/R exposure was measured by MTT assay. BV2 cells were treated with LPS, after which cytokine levels in the conditioned media were measured by the cytometric bead array, phagocytic activity by phagocytosis assay, nitric oxide (NO) production by the Griess colorimetric assay and protein levels quantified by Western blot. Sfmbt2 miRNA and inflammation-related gene expression levels were measured by qRT-PCR. The results show that overexpression of Sfmbt2 miRNA reduces N2a viability after OGD/R as compared to the cells expressing the control vector. After LPS exposure, production of proinflammatory cytokines by BV2 cells stably transduced with lenti-Sfmbt2 miRNA was decreased, as well as expression levels of proinflammatory factors, such as matrix metalloproteinase 9 (MMP-9) and tumor necrosis factor alpha (TNFα). Phagocytic capacity of Sfmbt2 miRNA transduced BV2 cells was decreased and these cells exhibited increased NO release. Protein levels of triggering receptor expressed on myeloid cells 2 (TREM2) were decreased in Sfmbt2 miRNA overexpressing BV2 cells compared to cells expressing the control vector. Our results suggest that in ischemic stroke Sfmbt2 miRNA may exhibit cell-specific actions resulting in decreased neuronal survival and dampened microglial phagocytic activity.

Abstract: Recently, methamphetamine (MA) use in adolescent has increased persistently and their exposure to MA at earlier ages compared to adults can cause more severe damage in the brain. It is necessary to evaluate the cellular and molecular mechanisms associated with brain damage induced by MA depending on the age. The present study was aimed to investigate the differentially expressed genes (DEGs) and their functions in the hippocampus of cynomolgus macaques, *Macaca fascicularis*, according to age after the administration of MA. Cynomolgus monkeys were divided as follows: Control, 6-12 months (age1, A1), 3-4 (A2) and 7-9 (A3)

years, and more than 11 years (A4). After the administration of MA in cynomolgus monkeys on an age-dependent dose (2 mg/kg, intramuscular injection in A1, A2, A3 and A4), transcriptome profiling in the hippocampus was performed using RNA-seq technology. The functions and networks of analyzed DEGs were classified using GO analysis tool (DAVID) and IPA software. Some genes were validated with real-time RT-PCR (RT-qPCR). In MA-treated animals, the correlation of DEGs between M1 and M4 was higher than other groups, showing the possibility that biological mechanisms in the hippocampus of M1 and M4 are similarly affected by METH. Based on the GO analysis using the DEGs, transmission of nerve impulse (GO:0019226) and synaptic transmission (GO:0007268) were significantly ranked within top three of GO biological process (BP) terms in all age monkeys exposed to MA compared to the control. As a result of RT-qPCR, expression patterns of FEZF1, GPR1N1, DLX1 and KCNIP2 mRNAs associated with neuron differentiation were similar to the results from RNA-seq. Our results suggest not only molecular mechanisms related to the DEGs in the impaired hippocampus but also a clue for developing MA addiction marker according to ages.

Title: Inflammasome expression in the central nervous system.

Authors: *S. ADAMCZAK[1], J. KRESAK[2], M. RAHMAN[3];
[1]Univ. of Florida, Dept of Neurosurg., Gainesville, FL; [2]Dept. of Pathology, [3]Dept. of Neurosurg., Univ. of Florida, Gainesville, FL

Abstract: The innate immune system is the body's first line of defense against danger, either from pathogens or damaged host tissue. The central nervous system (CNS), once believed to be a victim of chemical warfare between pathogens and professional immune cells, is now recognized as an active player in the innate immune defense against not only infection, but also injured tissue and malignancy. However, the role of the innate immune system, specifically the inflammasome, in primary brain tumors is unknown. Here, we used immunohistochemistry to measure the expression levels of inflammasome proteins in 25 human glioma samples (both high

and low-grade.) We found that inflammasome proteins ASC, caspase-1, Pannexin- 1, and NALP-1 are expressed in human gliomas. The expression pattern is highly variable, suggesting important molecular differences among both high and low-grade gliomas. This is the first characterization of inflammasome proteins in human glioma samples, and the high expression levels suggest an important role for the inflammasome in primary CNS tumor biology. Further elucidating the role of inflammasome proteins in tumorgenesis may help direct treatment.

Title: Inflammation decreases AMPA-mediated calcium permeability in striatal D2 but not D1 spiny projection neurons through L-type voltage-gated calcium channels

Authors: *C. WINLAND[1], N. WELSH[1], S. VICINI[2], K. MAGUIRE-ZEISS[1];
[1]Neurosci., [2]Pharmacol., Georgetown Univ., Washington, DC

Abstract: Neuroinflammation coincides with the progression of striatal neurodegenerative diseases. It is well established that activated microglia release proinflammatory molecules. In addition to perpetuating the innate immune response, these proinflammatory cytokines can also regulate synaptic plasticity through alterations of AMPA receptors (AMPARs). AMPARs are glutamatergic ion channels that can be calcium permeable or impermeable. The preferential trafficking of calcium-permeable versus impermeable AMPARs alter $[Ca^{2+}]_i$ which can have numerous consequences. Furthermore, voltage-gated calcium channels can be activated by small depolarizations, as in the case of AMPAR activation, and are also affected in proinflammatory conditions. Therefore, the present study sought to determine if a proinflammatory environment could alter AMPA-mediated $[Ca^{2+}]_i$ in dopamine-2 and dopamine-1 expressing spiny projection neurons (D2 and D1 SPNs). Lipopolysaccharide (LPS) was used as a model neuroinflammation. Acute striatal slices were incubated with LPS or vehicle for 2 hours prior to biochemical or imaging experiments. Microglial activation was confirmed by morphofunctional analyses. AMPA-mediated $[Ca^{2+}]_i$ was elicited with an AMPA cocktail containing AMPA, CPP, and

cyclothiazide with or without TTX and voltage-gated calcium channel blockers. Calcium imaging was conducted in slices prepared from Adora2a-GCaMP6 or D1-GCaMP6 transgenic mice. The percent of responding cells in both Adora2a-GCaMP6 and D1-GCaMP6 slices did not differ between the vehicle and LPS condition suggesting that LPS treatment did not result in direct toxicity. We found that LPS treated slices from Adora2a-GCaMP6 mice resulted in an increase of $[Ca^{2+}]_i$ without voltage-gated calcium channel blockade. In contrast, there were no changes in AMPA mediated $[Ca^{2+}]_i$ due to LPS treatment in D1-GCaMP6 slices without voltage-gated calcium channel blockade. Interestingly, when a nonspecific (i.e., cadmium) calcium channel blocker was included in the AMPA cocktail, we observed a decrease of AMPA-mediated $[Ca^{2+}]_i$ in D2 SPNs but not in D1 SPNs following exposure to LPS. Similarly, when a specific L-type voltage-gated calcium channel blocker (i.e., Isradapine) was included in the AMPA cocktail, we observed a decrease of AMPA-mediated $[Ca^{2+}]_i$ in D2 but not in D1 SPNs in the LPS condition. The findings of this study suggest that D2 SPNs may be more susceptible to proinflammatory conditions when compared to D1 SPNs and that this susceptibility is mediated in part by L-type voltage-gated calcium channels.

Title: Intracerebroventricular (icv) injections of endotoxin (ET) reduces hippocampal neurogenesis

Authors: L. BITAR[1], F. CHAMAA[1], B. SAFIEH-GARABEDIAN[2], E. AL-CHAER[1], N. SAADE[1], *W. ABOU-KHEIR[1];
[1]American Univ. of Beirut, Beirut, Lebanon; [2]Qatar Univ., Doha, Qatar

Abstract: Background: Constant formation of functional neurons from neural stem and progenitor cells in postnatal stages has been observed in two main neurogenic brain regions; the subgranular zone (SGZ) in the dentate gyrus (DG) of the hippocampus and the subventricular zone (SVZ) in the lateral ventricles. Adult neurogenesis, however, is prone to alterations by different physiological, pathological and pharmacological stimuli. One flaunting stimulus is neural inflammation which has been implicated in neurodegenerative disorders. Subsequently,

attempts to reverse inflammation using anti-inflammatory agents may serve as a possible intervention. Our aim was to demonstrate that inflammation, induced by *icv* injection of Endotoxin (ET) altered the behavior as well as the neurogenic niche of adult rats by decreasing neurogenesis.
Methods: Adult Sprague-Dawley male rats (250-300g) received stereotaxic *icv* injections of ET (6 µg in 1.5 µl) or sterile saline as described previously (Safieh-Garabedian et al., Neuropharmacology, 2011,60:496-504). Rats then received 3 injections (66mg/Kg/injection; *ip*) of 5'-bromo-2'-deoxyuridine (BrdU) and were perfused at different time intervals (Days 1, 2, 3, 6, and 9). The non-steroidal anti-inflammatory drug piroxicam® was given as daily injections to rats perfused at day 3. Behavioral pain tests were performed and BrdU positive cells were counted in the DG of the hippocampus.
Results: ET injection resulted in a significant decrease ($p < 0.0002$) of adult neurogenesis in rats at day 2 (439.75±81.16) and day 3 (479.875±94.69) when compared to sham (966.16±49.60). This was followed by an overshoot at day 6 (1124.80±161.18) then recovered the basal levels at day 9 (997±87.23). These alterations were accompanied by thermal hyperalgesia that peaked at day 3 (500%). Daily treatment with Piroxicam® (12.5 mg/kg; ip) was able to alleviate the ET effects on neurogenesis and reduce hyperalgesia.
Conclusions: The current study sheds light on the negative impact, reflected on neurogenesis in the hippocampal formation, of discrete neuro-inflammation which is a hallmark of neurodegenerative disorders. Thus, understanding the adverse effects of neuro-inflammation on neurogenesis opens a new window for the treatment and management of neuro-inflammatory disorders.

Title: Transcriptional profiling of circulating leukocytes in persons with chronic spinal cord injury

Authors: P. HERMAN[1], A. STEIN[2], K. GIBBS[1], *O. BLOOM[1,2];
[1]Hofstra Northwell Sch. of Med., Feinstein Inst. For Med. Res., Manhasset, NY; [2]Physical Med. and Rehabil., Hofstra Northwell Sch. of Med., Manhasset, NY

Abstract: Introduction: It is increasingly clear that persons living with traumatic spinal cord injury (SCI) have altered immune system responses, which include hallmarks of inflammation, immunosuppression, and autoimmunity (Schwab et al 2014). It has been proposed that these altered immune system responses may deleteriously impact functional recovery and promote infections, accelerated atherogenesis and other medical complications of living with SCI (Schwab et al 2014). Here, we investigated the hypothesis that the transcriptional profile of circulating leukocytes isolated from persons with chronic SCI would be altered as compared to uninjured persons.
Methods: This prospective, IRB-approved, observational study of adults with chronic (≥1 year from initial injury) SCI was performed in an academic medical center. RNA was isolated from whole blood from a PAXgene tube, using standard methods and the manufacturer's protocol (Qiagen QIAcube, Venlo, The Netherlands). RNA was amplified using Illumina RNA Total Prep Amplification Kit (Life Technologies, Carlsbad, CA) and analyzed on the Illumina Human HT-12v4 chip. Data was quantile normalized using Illumina's Genome Studio software and then analyzed for differential gene expression using Partek Genomics Suite (St. Louis, MO).
Results: Uninjured (N=26) and SCI (N=31) participants included 7 and 6 females, respectively. Participants in both groups were of similar ages (mean±sem, range): (48.3±2.3, 23-66 and 55.0±2.8, 21-80 years, $P<0.06$). Participants with chronic SCI were injured for 15.7±2.3 years (mean±sem). The most common etiologies of SCI were Fall (32%), Sports (32%), MVA (23%), and Other (13%). Spinal cord injuries occurred mostly above the level of T5 (74%) and 52% were neurologically complete (AIS A). We determined that there were 1693 genes that were differentially expressed (DE) in persons with SCI, with a false discovery rate (FDR) equal to 0.05. Gene set enrichment analysis was performed using the Enrichr platform (Chen et al 2013). Within the Kyoto Encyclopedia of Genes and Genomes (KEGG), WikiPathways, and Panther databases, DE genes were enriched in categories and pathways related to immune system function and metabolic signaling. Ongoing and future analyses will examine correlations between DE genes with level and severity of injury, as well as gender.

Title: IL1 and TNF signaling pathway inhibition reduces morbidity, mortality, neurodegeneration and convulsion incidence in mice following exposure to soman

Authors: *E. A. JOHNSON, J. F. IRWIN, K. LAITIPAYA, J. K. CHANDLER, D. D. PALMER, T. M. FERRARA-BOWENS, M. WEGNER, C. L. HONNOLD;
Pharmacol., US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Exposure to organophosphorus compounds such as soman (GD) can initiate status epilepticus (SE) that can lead to progressive brain damage and behavioral impairment. GD, a potent acetylcholinesterase inhibitor and chemical warfare nerve agent, causes prolonged SE activity and cell death in the hippocampus, thalamus and piriform cortex. Current treatments can ameliorate GD-induced SE, though treatment effectiveness diminishes rapidly following exposure. Therefore, neuroprotective strategies that can be used at later time points are needed to reduce neurodegeneration and improve cognitive outcomes. One strategy involves modulation of the neuroinflammatory response, a prominent feature in GD-induced brain injury. We have previously shown that loss of TNF and IL-1 signaling can confer moderate neuroprotection after SE, though the absence of both has a synergistic effect. This study focused on inhibition of IL-1 and TNF signaling as a viable neuroprotective and anti-convulsant strategy and to reduce morbidity and mortality after GD-induced SE. Using a IL-1 receptor 1 (IL-1R1)/TNF receptor 1A (TNFR1A) double knockout (KO) mouse and background strain mice treated with inhibitors for IL-1 and TNF signaling, changes in neuropathology, mortality, seizure onset and other relevant physiological responses were compared to untreated wild type, IL-1R1 KO and TNFR1A KO mice. These results suggest that inhibition of multiple pathways is superior to treating individual inflammatory pathways to improve acute outcomes following GD-induced SE. Further studies will investigate the chronic neuroprotective and behavioral outcomes of these treatments. Title: Nmda receptor-gated and L-type Ca^{2+} channels critically contribute to cxcl12-induced neurotoxicity.

Authors: ***M. KAUL**[1,2], K. MEDDERS[1,3], P. SANCHEZ-PAVON[1], D. OJEDA-JUAREZ[1], R. MAUNG[1], A. B. SANCHEZ[1];
[1]Infect & Infl Dis Ctr., Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [2]Dept. of Psychiatry, Univ. of California San Diego, San Diego, San Diego, CA; [3]UC San Diego Hlth., San Diego, CA

Abstract: The chemokine receptor CXCR4 (CD184) and its natural ligand CXCL12 contribute to many physiological processes besides cell migration, including decisions about cell death and survival in the central nervous system. Previously, we observed that CXCL12 can cause toxicity in cerebrocortical neurons in mixed neuronal-glial cell cultures via a pathway that required CXCR4 and the stress-associated mitogen activated protein kinase p38 (p38 MAPK). In the present study we show that blockade of NMDA type glutamate receptor-gated ion channels and L-type Ca2+ channels both prevent CXCR4-mediated toxicity of CXCL12 in cerebrocortical neurons. We also found that in cerebrocortical cells active/phosphorylated p38 MAPK is

primarily located in neurons, and CXCL12 increased the level of active of p38 MAPK. While blocking L-type Ca2+ channels with Nimodipine kept the active kinase at baseline levels, phospho-p38 MAPK was strongly reduced by blocking NMDA receptors with MK-801. Altogether, our findings linked CXCL12 induced neuronal death to regulation of cellular Ca2+ flux which is not only controlled by NMDA receptors but also by L-type Ca2+ channels upstream of p38 MAPK activation.

Title: Rapid F-actin reorganization occurs in neurons during cytotoxic edema both *In vitro* and *In vivo*

Authors: ***B. CALABRESE**[1,2], H. ZHANG[2], J. T. AUNG[2], A. Y. SHIH[3], S. HALPAIN[2]; [1]Div. Biol, Sec Neurobiol, [2]UC San Diego, La Jolla, CA; [3]Med. Univ. of South Carolina, Charleston, SC

Abstract: Acute brain injury during stroke disrupts neural circuits, resulting in impaired cognitive and motor functions. Such injuries induce cytotoxic edema (pathological cell swelling), which is the primary mode of acute neuronal cell death in early post-ischemic stages. Cytotoxic edema is triggered by hyperactivation of voltage-gated ion channels or glutamate receptors. The capacity of neurons to cope with cellular edema is critical for cell survival; however little is known about the subcellular and molecular changes regulating this process. We find that a substantial reorganization of filamentous actin (F-actin) occurs during cytotoxic edema, both *in vitro* and *in vivo*. This reorganization is visualized using either fluorescently labeled phalloidin to detect F-actin directly, or by immunostaining for the actin binding protein drebrin. Following a localized photothrombotic stroke in mouse cortex, F-actin is lost from dendritic spines of pyramidal neurons and accumulates aberrantly within the soma and proximal dendrites. A similar redistribution of F-actin occurs in cultured hippocampal neurons within 15-120 min following oxygen-glucose deprivation and is blocked by NMDA receptor antagonists. Incubation of cultured neurons with either NMDA or the sodium channel activator veratridine induces this

F-actin reorganization within 4-5 min in 40-60% of neurons, with longer NMDA exposures recruiting larger fractions of neurons up to >95%. However, if NMDA receptor hyperactivation is limited to 5-10 min, neurons spontaneously recover their normal F-actin distribution within 1-2 hours and do not undergo cell death, suggesting that these actin changes may be pro-survival. Significant cell swelling accompanies the accumulation of F-actin within the somatodendritic domain, and the two phenomena share a similar time course and pharmacological profile, including a dependence on specific chloride ion influx pathways. Other forms of cellular stress do not trigger the same neuronal F-actin changes. We therefore postulate that the "actinification" of the somatodendritic compartment is specifically connected to cytotoxic edema, helping to preserve the neuron's structural integrity until ionic and osmotic homeostasis can be restored, and thereby limiting necrotic cell death.

Title: The role of miR-34 in ischemia-induced neuronal death

Authors: *J.-Y. HWANG, F. PONTARELLI, B. L. COURT VAZQUEZ, R. ZUKIN;
Dept Neurosci, Albert Einstein Col. Med., Bronx, NY

Abstract: Transient global ischemia arising as a consequence of cardiac arrest in humans causes selective, delayed death of hippocampal CA1 pyramidal neurons and cognitive impairment. Effective treatments to ameliorate the neurodegeneration and cognitive dysfunction associated with global ischemia are an unmet need. Emerging evidence points to a widespread role for microRNAs (miRNAs) as key modulators of target gene expression in neurons. Accordingly, dysregulation of miRNAs are implicated in the pathophysiology of neurodegenerative disease and neurological disorders. Our findings, derived *via* miRNA-seq, indicate that a subset of microRNAs is altered in postischemic CA1 including miR-34b/c. Dysregulation of miR-34 has been implicated in pathophysiology of neurological disorder such as Parkinson's disease and epilepsy. However, a role for miR-34 in the pathogenesis of global ischemia is, as yet, unclear. Here we show ischemia induces p53-dependent activation of miR-34b/c and downregulation of

its target genes, which together promote neuronal death in selectively vulnerable hippocampal neurons. These findings have great potential for our understanding of how global ischemia induces neuronal death and identify a novel therapeutic target for amelioration of the neurodegeneration and cognitive deficits associated with ischemic stroke.

Title: Mosaic multiscale computer modeling of ischemic stroke

Authors: *A. SEIDENSTEIN[1], W. W. LYTTON[2], R. A. MCDOUGAL[3], M. L. HINES[3]; [1]CBE, New York University- Tandon Sch. of Engin., Brooklyn, NY; [2]Physiol. and Pharmacol., SUNY-Downstate Med. Ctr., Brooklyn, NY; [3]Neurosci., Yale Univ., New Haven, CT

Abstract: Ischemic stroke produces oxygen and glucose deprivation in brain cells, leading to cell dysfunction and death. We employ computer modeling to provide a platform to stimulate cell death, ion dysregulation, and edema due to ischemia. In doing so, we create tools to understand damage across temporal and spatial scales and to suggest where there is potential for neuroprotection.

On a cellular level, molecular cascades produce damage that can lead to apoptosis, necrosis or necroptosis. Damage spreads due to a combination of bulk flow of glutamate, reactive oxygen species, and other agents over the tissue scale of centimeters, while at the same time triggering rapid hyperactivity more remotely via synaptic connections. Temporally, we are interested in aberrant spiking activity over milliseconds up to the progression of ischemia extending over a period of hours. We provide our simulation with locations of blood vessels providing a field of oxygen concentration. Disruption at one location produces a central area of cell damage to provide the ischemic core -- the central area where cells are deprived of oxygen and glucose. Toxic agents extending from this core then set up the penumbra, where cells can potentially be saved or protected. In order to cover this vast range of scales, we have developed a mosaic

multiscale model in the NEURON simulator. The notion of a mosaic highlights the contrasting aspects of the model: some components represented in great detail, down to molecular levels, and others that are only represented at the highest level. Into this mosaic we place electrophysiology and intracellular chemophysiology in the context of broad diffusion in the extracellular space.
The development of the mosaic multiscale model thus far includes multiple scales. We explore how tissue-scale ischemic effects produce cellular level changes such as programmed cell death via caspase cascades . Intracellular ischemic cascades also involve calcium induced calcium release. Extracellular space (ECS) simulation provides the ability to test the correlations between edema, astrocyte function, and neuronal outcome.

Title: Mutation and phosphorylation of the apoptosis signal-regulating kinase 1 (ASK1) in oxidative stress signaling

Authors: *A. D. PEGGINS[1], A. PALUBINSKY[2], J. FEDERSPIEL[3], D. LIEBLER[3], B. MCLAUGHLIN[2];
[1]Neurosci. and Pharmacol., Meharry Med. College/Vanderbilt Univ., Nashville, TN; [2]Neurol., [3]Biochem., Vanderbilt Univ., Nashville, TN

Abstract: Apoptosis signal regulating kinase 1 (ASK1) is a mitogen-activated protein kinase (MAPK) kinase kinase (MAP3K) that acts as a cellular stress sensor, responding to a multitude of oxidative and energetic events, including reactive oxygen species, tumor necrosis factor alpha stimulation, endoplasmic reticulum stress, increases in intracellular calcium concentration, and reactive lipid electrophiles. Upon challenge by any of these stressors, ASK1 activates MAPK kinases (MAP2Ks) via phosphorylation, leading to even further downstream signaling changes in MAPKs such as p38 and c-JUN N-terminal kinases (JNKs). This signaling cascade ultimately results in activation of the stress response and apoptosis. ASK1 enzymatic activity is regulated by protein-protein interactions. Here we show that ASK1 is part of a dynamic multi-protein

signalosome, the components of which vary based on the type of stress encountered. We show all of the ASK1 interacting proteins detected in ASK complex dynamics, compared to proteins which significantly increased in abundance with increasing HNE concentration. ASK1 is also known to be regulated at the level of post-translational modifications, in which phosphorylation of specific ASK1 residues confers increased or decreased activation. The conditions that result in phosphorylation of specific ASK1 sites remain poorly understood. We have found that different *in vitro* treatments result in activation at varying phosphorylation sites. Regarding differential stress sensing phosphorylation, we have shown that HNE can increase phosphorylation of Serine83 (S83) and Sernie1004 (S1004) where H_2O_2 can decrease phosphorylation of Serine83 (S83) and Sernie1004 (S1004) in a concentration dependent manner. Using these newly identified, treatment-specific sites, ongoing experiments employ CRISPR to investigate the role of such post-translational events in oxidative stress signaling. Future experiments are aimed at further understanding the structural constituents of ASK1 necessary for its role in apoptotic signaling in models of oxidative stress, energetic stress, and ischemia, which encompasses both energetic and oxidative components.

Abstract: The transcriptional mechanism by which stroke induces the reduction of the neuroprotective Na^{+}-Ca^{2+} exchanger isoform 3 (NCX3) is still unclear. Here, we investigated the role of the histone deacetylases (HDACs) in regulating NCX3 in cortical neurons treated with different HDAC inhibitors (HDACi). Trichostatin A, a pan-inhibitor, and MC1568, a class IIA HDACi, significantly increased NCX3 promoter activity, gene and protein expression, whereas MS275, a class I HDACi, had no significant effect. Interestingly, in neurons transiently overexpressing or knocking-down for HDAC4 and HDAC5 NCX3 mRNA and protein levels were down-regulated or increased, respectively. However HDAC7 and 9 had no reliable effect. Furthermore, by Chromatin Immunoprecipitation (ChIP) assay we found that HDAC4 and HDAC5 binding and acetylation of histone protein H3 were reduced or up-regulated after MC1568 treatment. Immunoprecipitations experiments demonstrated also that HDAC4 and HDAC5 are bound to the transcriptional repressor Downstream Regulatory Element Antagonist Modulator (DREAM) and that DREAM knockdown by small interfering RNA (siRNA) transfection prevented HDAC4 and HDAC5 binding to the NCX3 promoter. Moreover, in MC1568 treated neurons site direct mutagenesis of DREAM sequence on ncx3 promoter, corroborated the hypothesis that HDACi-induced NCX3 gene transcription is achieved by DREAM. Furthermore, we found that transient middle cerebral artery occlusion (tMCAO) increased the protein expression of DREAM, HDAC 4 and 5, that in turn, by deacetylating ncx3 gene promoter, determines its down-regulation. Moreover, tMCAO-induced NCX3 reduction was prevented when DREAM, HDAC4 and HDAC5 were silenced by intracerebroventricular (icv) injection of siRNAs for DREAM, HDAC4 and HDAC5. In addition, in neurons silenced with siRNA of DREAM, HDAC4 and HDAC5 and subjected to (OGD) (3 h) plus reoxygenation (RX) (48 h), the neurodetrimental effect of anoxia was counteracted by preventing NCX3 mRNA and protein downregulation. Collectively, our findings suggest DREAM/HDAC4/HDAC5 complex as a new transcriptional repressor machinery that reduces ncx3 transcription in brain after stroke. In addition we identify that the blocking of HDAC4 and HDAC5 could represent a new therapeutic strategy in stroke treatment.

Title: A comprehensive analysis of the redox modulation of the adaptive genetic response to hypoxia in neurons: implications for brain protection and repair

Authors: *A. KUMAR[1], M. VAISH[2], A. A. STARKOV[3], I. GAZARYAN[1], S. S. KARUPPAGOUNDER[1], R. R. RATAN[1];
[1]Burke-Cornell Med. Res. Inst., White Plains, NY; [2]Dept. of Pharmacol. & Syst. Therapeut., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Metazoans have evolved an elegant adaptive program to compensate for hypoxia via a key family of transcription factors, called the hypoxia inducible factors. Under normoxic conditions, the most well studied member of this family, Hif1α is hydroxylated at proline 402 and 564 of its oxygen dependent domain (ODD), leading to its ubiquitination and degradation. Under hypoxic conditions, Hif1α gets stabilized, dimerizes with its partner (Hif-1β) and activates the expression of an array of genes involved in compensating for a discrepancy in oxygen demand and supply. A pervasive but still controversial theory holds that hypoxia activates Hif1α via a mitochondrial peroxide messenger (hydrogen peroxide) that leads to the inhibition of the HIF prolyl hydroxylases, oxygen sensors that directly regulate HIF stability. Other studies have implicated superoxide, lipid peroxides, decrease in oxygen or even decreases in ROS to the hypoxic adaptive response. To reconcile these apparently conflicting observations, we first assessed the response of endogenous antioxidants to hypoxia, as an indirect way to understand the possibility of change in the level of oxidants under hypoxia. Steady state levels of endogenous antioxidants didn't change under hypoxia. Then, in order to understand whether ROS is really involved in hypoxic stabilization of Hif-1α or not, we systematically manipulated the level of ROS in human neuroblastoma cells via adenoviral delivery of a host of antioxidant enzymes including MnSOD, GPX1, GPX4, Catalase and peroxiredoxin 3 (Prdx3) and studied the effect of forced expression on HIF-1 stabilization in normoxia or hypoxia. We examined the effect of these manipulations also on the expression of Hif1α target genes, p21 and enolase 2. Some antioxidants enzymes such as MnSOD (targets Mitochondrial SOD) and GPX4 (targets lipid peroxides) didn't change HIF levels or transcriptional activity. However, GPX1 (targets peroxide) led to a significant decrease in HIF levels and activity while other antioxidants such as Catalase and Prdx3 resulted in a significant increase in HIF levels and activity. A similar trend of change in the stabilization of Hif-1α in mouse primary cortical neurons was confirmed. We conclude that the stabilization of Hif-1α is unrelated to the changes in the level of specific ROS under hypoxia, but that HIF activity can be modulated via specific antioxidant enzymes. The effect of these enzymes is likely redox dependent but experiments are ongoing to establish this connection.

Title: Rapid and reversible F-actin reorganization as a cytoskeletal hallmark of excitotoxic neuronal cell stress

Authors: B. CALABRESE[1], J. T. AUNG[1], L. HUBER[1], E. R. MORENO[1], R. POWERS[1], Y. ZHANG[1], H. N. HIGGS[2], *S. L. HALPAIN[3,1];

Abstract: Excess glutamate represents a cellular stress condition that potentially underlies circuit disruption in disorders ranging from acute injury and neurodegeneration to neuropsychiatric disorders. ER and mitochondria fragmentation are two hallmarks of cellular stress in neuronal and non-neuronal cells. Indeed, when we incubate cultured neurons with the glutamate agonist N-methyl-D-aspartate (NMDA) for 5 min, a condition that elicits a form of stress called cytotoxic edema, both organelles undergo extensive fragmentation and/or swelling. We found that bath-applied NMDA also induces a dramatic relocalization of filamentous actin within the somatodendritic domain of a majority of neurons. F-actin is rapidly depleted from dendritic spines and aberrantly aggregates in bundles within the dendrite shaft. Blocking protein synthesis did not prevent this “actinification” of the somatodendritic domain, indicating that pre-existing actin generates these filaments. Either ATP depletion or inhibition of actin polymerization by cytochalasin D (cytoD) prevented the F-actin reorganization, implying that it is an energy-dependent process requiring barbed end actin polymerization, rather than translocation and aggregation of F-actin. This NMDA-induced somatodendritic actin assembly is formin-mediated, not Arp2/3 mediated. We identified inverted formin 2 (INF2) as playing a critical role in this “actinification” of the soma/dendrite, since either shRNA-mediated knockdown or expression of a dominant negative form of INF2 prevented NMDA-induced actinification. Moreover, overexpression of INF2 increased the sensitivity of neurons to actinification. Once induced, somatodendritic F-actin bundles are highly stable, since incubation for several minutes with the G-actin sequestering compound latrunculin A fails to dissipate them,

indicating slow turnover. However, somatodendritic actinification spontaneously reverses once the NMDA receptor activation ceases. Therefore, we propose that this dramatic F-actin reorganization is a pro-survival mechanism, similar to the previously described ER and mitochondria fragmentation, potentially relevant to neurological conditions characterized by excessive depolarization and NMDA receptor hyperactivity.

Title: Wnt7a in post-stroke angiogenesis: a novel target for stroke repair?

Authors: *H. ZHAO[1], T. B. LENGNING[2], A. J. BRUMM[1], M. MACHNIKI[1], S. T. CARMICHAEL[1];
[1]Neurol., UCLA, Los Angeles, CA; [2]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Stroke is a leading cause of adult disability, but despite its prevalence current treatments do not provide long-term recovery. Stroke itself induces a wide-range of repair mechanisms, including the proliferation and long-distance migration of immature neurons (neuroblasts) from the subventricular zone (SVZ) to peri-infarct tissue, a process termed post-stroke neurogenesis. These neuroblasts localize to and migrate along angiogenic blood vessels, forming a neurovascular niche in the peri-infarct zone. The reciprocal signaling between neuroblasts and endothelial cells has not been clearly characterized. Understanding these endogenous signaling systems may provide novel targets for pharmaceutical intervention to enhance functional recovery.
In genome-wide expression profiling studies, we compared FACS isolated peri-infarct neuroblasts and neuroblasts from the olfactory bulb. We then identified Wnt7A as a candidate signaling gene that is down-regulated in stroke-responsive neuroblasts. Wnt7A induces endothelial cell migration in vitro and is important in vascular development (Daneman, *et. al*);

however, its role in adult angiogenesis and in stroke repair is not well understood. Based on these findings, Wnt7A may play a key role in the neurovascular niche by promoting neuronal differentiation as well as angiogenesis and vessel maturation. Here, we identify Wnt7A's role in post-stroke angiogenesis in a set of gain-of-function (GOF) and loss-of-function (LOF) studies in the photothrombotic stroke model. Lentiviruses for overexpression and microRNA-mediated knockdown were injected into young adult mice into the peri-infarct cortex, a site for the neurovascular niche that supports post-stroke neurogenesis. At 14 and 42 days after stroke, we found that Wnt7A GOF results in increased vessel density (determined using CD31-positive endothelial cell volume/area). Moreover, CD31/EdU co-labeling indicated an increase in endothelial cell proliferation. We also observed that Wnt7A GOF increases the number of newborn endothelial cells expressing BBB-specific glucose transporter 1 ($GLUT1^{+}/EdU^{+}$) and stimulates overall GLUT1 expression after PT stroke. We are in the process of establishing whether Wnt7A LOF impairs post-stroke endothelial cell proliferation and maturation and whether this would affect overall vessel volume in peri-lesional tissue. Based on our results, overexpression of Wnt7A promotes early angiogenic events (i.e. EC proliferation), enhances the expression of BBB-specific transporters (i.e. GLUT1), and results in morphological changes that persist at least for 7 weeks after stroke (i.e. vessel density).

Title: Molecular mechanism of hypoxia-induced axon degeneration in cultured cerebellar slices

Authors: *Y. CUI[1], B. G. KIM[2];
[1]Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Ajou university Sch. of Med., Suwon, Korea, Republic of

Abstract: Subcortical ischemic vascular dementia is caused by chromic ischemia due to narrowing of small blood vessels supplying the white matter. The pathological changes of ischemic white matter degeneration include axonal degeneration, demyelination, and glial activation. However, it is not fully understood how chronic ischemia leads to the white matter pathologies. In this study we aimed to develop an *in vitro* model of ischemic white matter degeneration using cultured cerebellar slices. Cerebellar slices were obtained from postnatal day 12 mice and cultured for 12 days *in vitro*. At this time point, subcortical white matter axon bundles survived with exuberant myelination. Most of surviving axons from cerebellar cortices were positive with purkinje cell marker calbindin-D28k. The cultured cerebellar slices were exposed to 2% hypoxic condition for 48 hours beginning at 10 day *in vitro*. Hypoxic insult resulted in axons with beading appearances consisting of focal swelling and constriction. In contrast, myelin basic protein expression was preserved even at the site of severe axonal damages. Moreover, there was no significant decrease or loss of oligodendrocytes, suggesting that axonal structures are more vulnerable to hypoxia than myelin ensheathment. Electron micrographs showed accumulation of lysosome-like structures in the axoplasm after hypoxia. Consistent with the EM findings, lysosomal-associated membrane protein 1 (LAMP1) immunereactivity was significantly increased in the white matter in a hypoxic condition. The AMPA/kainate receptor antagonist NBQX, calpain inhibitor ALLN and MDL28170, and lysosomal protease inhibitor pepstatin A, significantly attenuated hypoxia-induced beading appearances. Our slice model could be utilized to explore molecular mechanisms of ischemia-induced axon degeneration. Axonal degeneration following hypoxia is likely to involve multiple pathways, such as AMPA receptor, calpain proteolysis and lysosomal proteases.

Title: Still not identified: The channel driving spreading depolarization during ischemia

Authors: *P. J. GAGOLEWICZ, K. TRESIDDER, R. D. ANDREW, K7L 2G8; Queen's Univ., Kingston, ON, Canada

Abstract: Higher CNS neurons undergo a propagating anoxic depolarization (AD) during ischemia that causes acute neuronal injury. There is no consensus as to the origin of the large inward current driving AD. Various scenarios include excess glutamate release or accumulation, open voltage-gated Na^+channels or open pannexin, ASIC, P2X7 or TRPM7 channels. To address this question, we monitored AD in live brain slices during 10 min of O_2/glucose deprivation (OGD) at 35^{o}C using two techniques: 1) AD imaged as a wave of increased light transmittance (LT) propagating across neocortex; 2) sudden AD onset in whole-cell patch recordings from neocortical pyramidal neurons. LT imaging showed an intact propagating AD front despite slice pre-treatment with one of 2 mixtures of blockers in artificial CSF. Blocker `mix 1` contained: 1 uM TTX, 10 mM TEA, 1 mM kynurenic acid, 10 uM nifedipine, 100 uM carbenoxolone/500 uM probenicide [pannexin blockers] and 100 uM picrotoxin. Blocker `mix 2` contained: 100 uM amiloride [ASICs], 2 uM BBG [P2X7], 2 uM FTY720 [TRPM7] and 100 uM CSB [glutamate uptake]. Whole-cell patch recordings from pyramidal neurons showed that OGD induced AD within 5.5 to 8.5 min (n=10, panel A). Pre-treatment with `mix 1` merely delayed AD onset (9.2 to 12 min, n=8, panel B). Mix 2 had no effect on onset (6 to 8 min, n=7). We conclude that the usual channel suspects do not drive AD. Is there an alternative? Like OGD, 10-100 nM palytoxin evokes a spreading AD-like event as imaged in 12 slices. An abrupt depolarization evoked by 50-100 nM palytoxin in pyramidal cell recordings (n=7, panel C) was only delayed by pre-treatment with mix 1 (panel D) similar to OGD. Mix 2 was without effect (n=7). Because palytoxin converts the Na/K pump into an *open cationic channel*, ischemia might elicit a similar pump conversion that drives AD and subsequent acute neuronal damage.

Title: Role of nuclear class III histone deacetylases in differentially affected brain areas following transient global cerebral ischemia

Authors: A. B. WAHUL[1], P. JHELUM[1], R. KORABOINA[1], *A. KUMAR[2], S. CHAKRAVARTY[1];
[1]Dept. of Chem. Biol., Indian Inst. of Chem. Technol., Hyderabad, India; [2]CSIR- Ctr. For Cell. and Mol. Biol. (CCMB), Hyderabad, India

Abstract: Transient global cerebral ischemia is the result of cardiac arrest, which finally leads to broad range of neurological and emotional dysfunction, including cognitive ones. To understand the details of the molecular events underlying ischemia-induced damage and repair, we performed bilateral common carotid arterial occlusion (BCCAo) in adult CD1 male mice for 6-7 minutes, followed by reperfusion. Animals were sacrificed at 24, 72 and 120 h post ischemia and reperfusion, to uncover the molecular mechanisms involved in damage as well as neurogenesis that ensues. After ischemic insult, each animal was assessed for motor coordination as well as grip strength functionality. Visual memory was also analyzed using novel object recognition (NOR) test. To evaluate the degree of damage in three different affected brain areas in mice subjected to BCCAo, micro-dissected samples from cortex, striatum and hippocampus were processed for molecular as well as histochemical investigations. The neurobehavior assessment showed loss of motor co-ordination as well as grip strength functionality at early time point, which slowly recovered over time 72 h, but the visual memory functionality remained affected even 72 hours post-ischemic insult. Further, there was significant loss of synaptic connectivity at early time point, as confirmed by the Western blot analysis. For molecular mechanisms the genes investigated were (i) Hypoxia Inducing factors (HIF 1 &2), hypoxia markers (ii) Vascular Endothelial Growth Factor (VEGF), angiogenic markers, (iii) Neuroglial damage markers (Aqp4, neurabin2, GFAP), (iv) inflammatory markers (IL1α and IL6). Finally, we studied the epigenetic regulation of few of these genes by NAD-dependent class III HDACs called Sirtuins, in particular the nuclear ones i.e. Sirt1, 2, 6 and 7, in the etiopathology as well as recovery. The outcome of the study yielded better insight into the molecular mechanisms underlying neural damage and recovery following BCCAo.

Title: Endogenous lipid electrophiles mediate ischemic tolerance in brain via Nrf2

Authors: T. YANG[1], Y. SUN[1], L. MAO[2], B. SUN[2], Y. GAO[1,3], S. H. GRAHAM[1], J. CHEN[1,3], *F. ZHANG[1];

Abstract: Introduction: Ischemic stroke is the leading cause of long-term disability and third-leading cause of death. Though FDA approved tPA for restoring the blood flow, no medicine is available for the purpose of neuroprotection. Ischemic preconditioning (IPC) is a promising approach for protecting against ischemic injury; however, the underlying protective mechanisms are not clear. Recent studies suggested that nuclear factor erythroid 2 related factor 2 (Nrf2) may underlie the protective mechanism of IPC. This study aims at confirming the role of Nrf2 in IPC and investigating how Nrf2 is activated following IPC. Methods: In vivo, middle cerebral artery occlusion (MCAO) was induced in male C57BL/6J wild type (WT) and Nrf2 knockout mice, 12 min for IPC and 60 min for stroke with an interval of 3 days. In vitro, oxygen-glucose deprivation was applied to rat primary neuronal cultures, 12 min for preconditioning and 60 min for ischemic condition with an interval of one day. Results: In mice, IPC significantly reduced neurological dysfunction and infarct volumes compared to control group. The protection depended on Nrf2, as IPC induced Nrf2 nuclear translocation and upregulation of its target genes on PCR arrays, and Nrf2 knockout abolished the protection of IPC. Similar results were observed in vitro, confirming the key role of Nrf2 in IPC. To identify the endogenous inducers of Nrf2, we performed Western dot blots to measure the levels of 4-hydroxy-nonenal (4-HNE), a lipid electrophiles and the end-product of lipid peroxidation of omega-6 polyunsaturated fatty acids. We found that IPC increased the level of 4-HNE in the brain via mild oxidative stress. In exploring the role of 4-HNE in IPC, we found that 4-HNE alone activated Nrf2 in neuronal

cultures and in brain tissue, and increased the expression of heme oxygenase 1 (HO-1), a target enzyme of Nrf2. In addition, IPC-mediated protection was aborted by the treatment of N-acetylcysteine (NAC), a compound that can neutralizes electrophiles. Taken together, our data suggest that lipid electrophiles induced by IPC could exhibit an endogenous neuroprotective effects against stroke via the activation of Nrf2 pathway. Conclusion: Our findings suggested a novel mechanism of ischemic tolerance, in which lipid electrophiles act as key mediators. IPC induced mild oxidative stress in the brain, leading to the generation of lipid electrophiles; these electrophiles then activate Nrf2 pathway, protecting the brain against stroke.

Title: Activation of the phb-oma1-opa1 pathway is an early mitochondrial event in neuronal ischemia

Authors: *C. J. ANDERSON, P. ZHOU, G. MANFREDI, C. IADECOLA;
Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Mitochondrial structure is critical for neuronal health. Abnormal mitochondrial structure has been reported in ischemic brain injury and alterations in key mitochondrial structure regulators have been identified. However, the molecular mechanisms that lead to these alterations in ischemia remain to be elucidated. Therefore, we sought to gain insight into molecular determinants of mitochondrial structural changes in ischemic injury. Prohibitin (PHB), an inner mitochondrial membrane (IMM) protein that forms large heteromeric complexes, is essential for mitochondrial structure (PLoS Genet., 8:11, 2012). Previously, we demonstrated that overexpression of PHB protects neurons from ischemic cell death (Stroke, 45:4, 2014) and loss of PHB increases neuronal susceptibility to injury (J. Neurosci., 32:583, 2012). PHB regulates levels of membrane-bound isoforms of OPA1, an IMM protein required for mitochondrial fusion and cristae structure, by preventing its cleavage by the metalloprotease OMA1. We observed that mitochondria become fragmented in primary cortical neurons after 2hrs oxygen-glucose deprivation (OGD), resulting in a 40% reduction of average length, which

persisted throughout OGD (4hrs). Using native gel electrophoresis, we observed that the PHB complex is destabilized by OGD, seen as a reduction in PHB complex size. Consistent with the hypothesis that a role of PHB is to stabilize OPA1, we observed an increase in OPA1 processing of long isoforms 2hrs after OGD, concomitant with mitochondrial fragmentation. Furthermore, we observed an increase in OMA1 activation using an OMA1-FLAG construct. To directly demonstrate the role of OMA1-dependent OPA1 processing in OGD-induced neuronal cell death, we created an OPA1 construct lacking the S1 processing site responsible for cleavage by OMA1 in low ΔΨm conditions (OPA1-ΔS1). Neurons expressing OPA1-ΔS1 were significantly protected from OGD-induced death compared to vector expressing neurons. Interestingly, OPA1-ΔS1 expression did not mitigate mitochondrial fragmentation in OGD. This suggests that in OGD, OPA1-ΔS1 does not protect neurons by maintaining mitochondrial network morphology. In order to understand how PHB controls this pathway we studied the interaction of PHB and OPA1 in N2a cells. Upon treatment with the ΔΨm-dissipating protonophore CCCP, the interaction of PHB and OPA1 decreased, which may indicate a role for PHB in the regulation of OPA1 processing by physical interaction. Together, these data suggest that the PHB-OMA1-OPA1 pathway participates in early mitochondrial damage in OGD, possibly by regulating IMM structure independently of fission and fusion dynamics.

Title: Absence of Nrf2 preferentially aggravates the early-stage of reactive astrogliosis contributing to the inflammation associated cerebral ischemic damage under hypoxia

Authors: ***L. LIU**[1], M. VOLLMER[1], M. CARSON[1], S. DORE[1,2];
[1]Anesthesiology, Ctr. for Translational Res. in Neurodegenerative Dis., [2]Neurology, Psychiatry, Pharmaceutics, Psychology, and Neurosci., Univ. of Florida Col. of Med., Gainesville, FL

Abstract: Protracted neuroinflammation has been recognized as a pivotal mechanism of secondary brain injury progression following ischemic stroke. Astrocytes are emerging as crucial

regulators of CNS inflammatory response that exert either powerful proinflammatory potential or potent protective anti-inflammatory function. Accumulated evidence indicates that the transcriptional factor Nrf2 and antioxidant response element (ARE) pathways play a vital role in the cellular defense against oxidative stress, inflammation, and cell death via upregulating cytoprotective genes encoding for phase II defense enzymes and antioxidant stress proteins. However, the underlying regulatory mechanism of the Nrf2 pathway in the CNS remains inconclusive. Interestingly, Nrf2/ARE-regulated genes are preferentially activated in astrocytes, thereby having more efficient cytoprotection defenses than neurons. Here, through testing in a hypoxic/ischemic (H/I) mice model, we show that Nrf2 can function as a modulator of reactive astrogliosis that links inflammation in the early stage of ischemic stroke to subsequent brain injury. We found that at 24h after H/I, cerebral infarct size, edema volume, and the resultant functional neurological deficit were significantly increased in Nrf2 knockout mice compared to wild-type controls. To further determine which cells appear to be the most preferentially activated in a spatiotemporal pattern by this Nrf2/ARE pathway contributing to ischemic injury, we investigated, in the very early stage of ischemic injury following H/I, the characteristic changes in brain cells, including neuron loss and degeneration, as well as reactive astrogliosis and microglia/macrophage activation. 12h after H/I, as we expected, the mice lacking Nrf2 exhibited much more severe neuronal death, and more remarkable reactive astrogliosis and microglia activation. Notably, 6h after H/I, Nrf2 ablation dramatically triggered obvious reactive astrogliosis and microglia activation in the striatum. However, neuronal loss did not show an obvious difference between groups through either Cresyl violet or NeuN staining, whereas lack of Nrf2 resulted in relatively high synaptic damage compared to wild-type controls, which might lead to the functional deficit. Indeed, the functional evaluation showed an obviously severe neurological deficit in Nrf2 knockout mice 6h after H/I. Our findings indicate a neuroprotective role of Nrf2 pathway against hypoxia-associated brain diseases, and the Nrf2-dependent cytoprotective response occurs preferentially in astrocytes, providing new insight into the unique pathways involved in the CNS and neurological disorders.

Title: Human acid-sensing ion channel 1a (ASIC1a) exhibits higher levels of surface trafficking than mouse ASIC1a

Authors: *Y. XU[1,3], Y.-Q. JIANG[2,4], J. WU[2,5], M. HE[2], Y. HU[5], J. XU[3], W. G. RUSYNIAK[6], M. LIN[2], X.-M. ZHA[2];

Abstract: ASICs are a family of proton-gated cation channels which are mainly expressed in the nervous system. In the brain, the main ASICs contributing to acid-activated currents are ASIC1a, ASIC2a, and ASIC2b. ASIC1a is more pH sensitive and starts to be activated at pH≤7.2, In contrast, ASIC2 mainly plays a modulatory role. ASICs are important for synaptic function, and are one main contributor to acidosis-related neuronal injury. Previous ASIC studies were mainly performed in rodents, and we know little about ASICs in humans. To facilitate the translational targeting of ASICs, it is important to understand the differences between mouse and human ASICs. In our previous studies, we have found that human ASIC1a and mouse ASIC1a exhibit differences in current and their effect on spine remodeling. These data indicate that the two homologs, though sharing 98% amino acid identity, differ in their contribution to acidosis-induced responses. The objective of this study is to determine 1) the molecular mechanism underlying differential function of human and mouse ASIC1a, and 2) their contribution to acidosis-induced neuronal injury. We compared acutely dissected human and mouse brain tissue, and found that human brain expressed lower levels of ASIC2b. Further, since ASIC1a is the key subunit determining acid-activated currents, we focused on ASIC1a and studied the trafficking of the two homologs in heterologous cells. Human ASIC1a exhibited higher surface trafficking, which correlated with an increase in *N*-glycosylation. Inhibiting *N*-glycosylation with tunicamycin reduced surface trafficking of human and mouse ASIC1a to a similar level. Previous studies showed that the interaction between the wrist region and the first transmembrane domain is important for efficient glycosylation and trafficking of ASIC1a. We examined the amino acid sequence of the homologs and found that two amino acids within these two regions, amino acids 70 (His in human; Cys in mouse) and 285 (Pro in human; Ser in mouse), differ between human and mouse ASIC1a. To test whether these two amino acids determine differential trafficking of the two ASIC1a homologs, we generated swapping mutants of human and mouse ASIC1a. Swapping amino acid 70 had little effect. In contrast, the mouse S285P mutant exhibited increased *N*-glycosylation, elevated surface level, and higher acid-activated current. The human P285S mutant had the opposed effect. These results reveal the molecular basis for elevated trafficking and activity of human ASIC1a, and further indicate that acidosis has a bigger impact on neuronal injury in human neurons.

Title: Suppressive effect of orexin-A through vagus nerve on the development of post-ischemic glucose intolerance and increase of inflammatory factors

Authors: *S. HARADA, Y. NOZAKI, S. TOKUYAMA;
Kobe Gakuin Univ., Kobe, Japan

Abstract: We have previously found that the development of post-ischemic glucose intolerance is one of the triggers of ischemic neuronal damage. Orexin-A (a neuropeptide in the hypothalamus) plays an important role in many physiological functions, including the regulation of glucose metabolism. We have reported that the vagus nerve plays an important role in the recovery of post-ischemic glucose intolerance and mediates a neuroprotective effect by hypothalamic orexin-A. In addition, orexin neuron projects from hypothalamus to medulla oblongata, nuclei originis of vagus nerve. Recently, it was reported that cerebral ischemia can activate hepatic inflammatory factors and is associated with the development of hepatic insulin resistance by activation of sympathetic nerve. The aim of this study was to determine the involvement of orexin-A and vagus nerve on the cerebral ischemia-induced inflammatory factors in liver.

Male ddY mice were subjected to middle cerebral artery occlusion (MCAO) for 2 h. The hepatic vagotomy mice created to selectively transect at the hepatic branch vagus nerve. Neuronal damage was estimated by histological and behavioral analyses. Expression of each protein levels was analyzed by western blot and immunofluorescence staining.

Intrahypothalamic orexin-A (5 pmol/mouse) administration significantly suppressed the development of post-ischemic glucose intolerance and neuronal damage on day 1 and 3, respectively after MCAO. MCAO-induced decrease of hepatic insulin receptors and increase of hepatic gluconeogenic enzymes on day 1 after was reversed to control levels by orexin-A. This effect was reversed by hepatic vagotomy. In the liver, MCAO-induced increase in F4/80 (a kupper cells marker), TNF-α and IL-1β on day 1 was recovered to control levels by OXA, and which was reversed by hepatic vagotomy.

These results suggest that the orexin-A and vagus nerve may play an important role in the regulation of post-ischemic elevated hepatic inflammatory factors.

Title: Following oxygen-glucose deprivation/reperfusion, nuclear translocation of annexin 1 induces neuronal apoptosis by regulating Bid expression via p53 binding

Authors: ***X. LI**, Y. ZHAO, Q. XIA, L. ZHENG, L. LIU, B. ZHAO, J. SHI;
Dept. of Neurobiology, Tongji Med. Col., Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: As a Ca^{2+}-and phospholipid-binding protein, annexin 1 (ANXA1) performs different roles depending on its subcellular localization. Our previous data have suggested that the nuclear translocation of ANXA1 is involved in neuronal apoptosis after ischemic stroke. As the mechanism and function of ANXA1 nuclear migration remain unclear, it is important to clarify how ANXA1 performs its role as an apoptosis "regulator" in the nucleus. Here, we report that importazole (IPZ), an importin β-specific inhibitor, decreased ANXA1 nuclear accumulation and reduced the rate of neuronal death induced by nuclear ANXA1 migration after oxygen-glucose deprivation/reoxygenation (OGD/R). Notably, ANXA1 interacted with the *Bid* promoter directly; however; this interaction could be partially blocked by the p53 inhibitor pifithrin (PFT)-α. Accordingly, ANXA1 was shown to interact with p53 in the nucleus and this interaction was enhanced following OGD/R. A luciferase reporter assay revealed that ANXA1 was involved in the regulation of p53-mediated transcriptional activation after OGD/R. Consistent with this finding, the nuclear translocation of ANXA1 after OGD/R up-regulated the expression of Bid, which was impeded by IPZ, *ANXA1* shRNA, or PFT-α. Finally, cell-survival testing demonstrated that silencing ANXA1 could improve the rate of cell survival and decrease the expression of both cleaved caspase-3 and cleaved poly ADP-ribose polymerase. These data suggested that importin β-dependent nuclear ANXA1 migration participates in the OGD/R-dependent induction of neuronal apoptosis. ANXA1 interacts with p53 and promotes p53 transcriptional activity, which in turn regulates Bid expression. Silencing ANXA1 decreases the expression of Bid and suppresses caspase-3 pathway activation, thus improving cell survival after OGD/R. Overall, these observations provide a more comprehensive understanding of ANXA1 function in cell apoptosis after OGD/R, suggesting the potential for a previously unidentified treatment strategy in minimizing apoptosis after ischemic stroke.

Title: Cerebral ischemia-mediated phosphorylation of GSK-3〈β〉 induced neurogenesis in rats

Authors: ***K. KISOH**, H. HAYASHI, M. ASADA, T. ITO, M. ARAI, B. YUAN, N. TAKAGI; Applied Biochem., Tokyo Univ. Pharm. and Life Sci., Tokyo, Japan

Abstract: Cerebral ischemia is one of the leading causes of death and disability. Therapy against cerebral ischemia is limited. In particular, the therapeutic agents for the treatment during chronic stage of cerebral ischemia are used to prevent of recurrence of stroke. Neurogenesis is expected as new therapeutic approach currently, because it is focused on regenerating damaged neural circuits by development of stem cell research. It is transiently enhanced as one of endogenous regenerative abilities in the subventricular zone (SVZ) of lateral ventricle and the subgranular zone (SGZ) of hippocampal dentate gyrus (DG) in the damaged brain after cerebral ischemia. However, mechanisms of neurogenesis after cerebral ischemia remain to be fully clarified. The aim of this study is to elucidate the mechanism of neurogenesis after cerebral ischemia. Cerebral ischemia was produced by the injection of 700 microspheres into right internal carotid artery of the rat in this study. At first, we examined cell proliferation and differentiation in dentate gyrus (DG) of the hippocampus on day 7 after microsphere-induced cerebral embolism (ME). Ki67-positive proliferated cells in ipsilateral DG were increased compared to those in contralateral DG. These cells also expressed DCX, which is an immature neural marker. In addition, NeuroD, proneural bHLH transcription factor, was expressed in cells in granule cell layer of DG and the number of NeuroD-expressed cells in ipsilateral DG after ME was increased compared to that of contralateral DG on day 7 after ME. We next demonstrated that Akt/GSK-3〈β〉/〈β〉-catenin signaling, which is involved in neurogenesis and regulate expression of NeuroD, was promoted on day 7 after ME. Our present data suggested that NeuroD expression on day 7 after ME might have been caused by Akt/GSK-3〈β〉/〈β〉-catenin signaling pathway, including increase in phosphorylation of GSK-3〈β〉. As indicated changes of Akt/GSK-3〈β〉/〈β〉-catenin signaling pathway, we further examined that the levels of IGF-1 and BDNF are involved in this process, which are closely related to neurogenesis via PI3K/Akt patheway. Contrary to expectations, levels of these growth factors were significantly decreased on day 7 after ME.

These results suggest that ME-induced cell proliferation and differentiation are involved in Akt/GSK-3〈β〉/〈β〉-catenin signaling in IGF-1 and BDNF-independent manners at this time point.

Title: Dna methylation and hydroxymethylation patterns in mouse brain following experimental stroke.

Authors: *K. MORRIS, R. VEMUGANTI;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Mounting evidence over the past decade reveals that epigenetic factors play a major role in the pathophysiology of ischemic injury in the brain. Cerebral ischemia has been shown to alter the methylation and hydroxymethylation of DNA which are interrelated epigenetic processes associated with the repression or activation of transcription, respectively. Inhibition of DNA methyltransferases provides robust protection against ischemic injury. Alternatively, inhibition of a Ten-eleven translocation (TET) dioxygenase, an enzyme that converts methylated DNA to hydroxymethylated DNA was shown to increase infarct volume following transient middle cerebral artery occlusion (MCAO) in adult rodents. We presently determined the effect of transient MCAO on DNA methylation and hydroxymethylation in mouse brain. C57BL/6J male mice were subjected to 60 min of MCAO and the cortex, striatum, and hippocampus were harvested at 5 min, 3h, 6h and 24h of reperfusion. Dot blot analyses of DNA showed significant increases in DNA methylation at 5 min, 3h and 6 h of reperfusion in the cortex, and at 6h of reperfusion in the hippocampus. DNA hydroxymethylation was also increased in the cortex at 5 min of reperfusion, whereas remained unaltered in the hippocampus and striatum. We also assessed the expression of the DNA methyltransferases (DNMT1, DNMT3a, and DNMT3b) and the methyl dioxygenases (TET1, TET2, and TET3). Following transient MCAO, DNMT3a and DNMT3b were significantly increased in both cortex and striatum. Whereas, TET1 was increased in the cortex while TET3 was increased in the striatum. Overall these data indicate the

changing temporal landscape of DNA methylation and hydroxymethylation following cerebral ischemia. These results may be important for enhancing the efficacy of potential stroke therapeutic targets that effect DNA methylation. Funded by NIH.

Title: Mitochondrial Complex I-mediated bioenergetic failure in acute ischemic brain injury

Authors: *A. KAHL[1], A. STEPANOVA[2], C. KONRAD[1], G. MANFREDI[1], P. ZHOU[1], A. GALKIN[2], C. IADECOLA[1];
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Sch. of Biol. Sci., Queen's Univ. Belfast, Belfast, United Kingdom

Abstract: Mitochondrial energy production in the brain fails rapidly at the onset of ischemia and is only restored by timely reperfusion. The loss of cerebral blood flow leads to decreased oxygen levels and energy crisis in the ischemic area, initiating a sequence of pathophysiological events that after reoxygenation lead to ischemia/reperfusion (IR) damage (Neuron 67:181, 2010). Mitochondria play a key role in ischemic brain injury. Oxidative stress and bioenergetic failure have been proposed as early events in IR damage (Cell Metab. 23:254, 2016). However, the biochemical and molecular mechanisms of mitochondria damage in IR remain to be elucidated. We studied IR-induced changes of mitochondrial respiratory function in a mouse model of focal ischemia induced by transient occlusion of the middle cerebral artery (MCA). Reestablishing cerebral blood flow after MCA occlusion resulted in a significant decline (50±6.2% of sham control, mean±SEM; $p<0.05$; n=5/group) in ADP-stimulated respiration measured in tissue homogenates from the ischemic area. The decline was followed by a recovery of mitochondrial oxygen consumption at one hour after reperfusion (85±2.3% of sham control; $p>0.05$; n=5). After the transient restoration in mitochondrial function, a secondary gradual decline in respiration occurred during the following 4-24 hours (55±7.8% of sham control; $p<0.05$; n=5, at 24h). Mitochondrial respiratory control ratio (phosphsorylating:non-phosphorylating respiration), a parameter reflecting the integrity of the mitochondrial membrane, did not change during the first 12 hours of reperfusion, suggesting that opening of the permeability transition pore was

unlikely to be the underlying cause for the respiratory decline in this time period. Functional analysis of individual respiratory chain complexes indicated that reduced mitochondrial respiration was associated with a decline in mitochondrial complex I activity. *In vitro* treatment of post-ischemic mitochondrial fractions with a thiol reducing agent partially recovered complex I activity at early, but not at late, time points after reperfusion. These data suggest that early reversible post-translational modifications of complex I were followed by irreversible enzyme deficiency. Our results suggest a central role of complex I impairment in the bioenergetic failure initiating ischemic brain injury. Modulating complex I-dependent bioenergetic failure could be an effective approach to prevent subsequent detrimental events in the IR cascade, ultimately reducing brain damage after stroke.

Title: The role of developmental transcription factors in post-stroke axonal sprouting

Authors: *C. A. SCHWEPPE, M. MACHNICKI, S. T. CARMICHAEL;
Univ. of California Los Angeles, Los Angeles, CA

Abstract: The ability of the nervous system to repair itself following injury is a remarkable phenomenon, but central nervous system endogenous repair mechanisms are incomplete. Ischemic stroke produces a limited process of neural repair, characterized by axonal sprouting and cortical reorganization in the cortex adjacent to the infarct (peri-infarct region). Previously, our lab has used transcriptional profiling of single sprouting neurons during the period of post-stroke axonal sprouting to identify their unique gene expression profile, a post-stroke sprouting neuron transcriptome. Within this transcriptome dataset are a number of transcription factors known to play a role in cortical development that are differentially regulated in sprouting neurons following stroke. Developmental transcription factors present an intriguing target for study due to their inherent ability to act as master regulators of genes responsible for neuronal growth. As such, a number of these differentially regulated developmental transcription factors have been investigated for their ability to regulate axonal sprouting following stroke.

Transcription factor targets were initially screened for their ability to promote axonal outgrowth following lentiviral overexpression and knockdown in mouse primary cortical neuron cultures. To test the ability of these targets to promote post-stroke axonal sprouting in vivo, adult C57BL/6 mice received a cortical stroke via middle cerebral artery occlusion followed by viral delivery of expression vectors. Relative axonal sprouting was evaluated via BDA tracing of connections in the peri-infarct region. The results of these studies begin to explore the role of development-associated transcription factors in neural regenerative processes in the adult cerebral cortex.

Title: Cerebroprotection by hesperetin against ischemic brain injury via restoration of tryptophan-modulating enzymes

Authors: *W. LEE, S. KIM, C. KIM;
Pusan Natl. Univ. Sch. of Med., Yangsan, Gyeongsangnam-Do, Korea, Republic of

Abstract: Indoleamine 2,3-dioxygenase (IDO) and tryptophanyl-tRNA synthetase (TrpRS) are tryptophan-modulating enzymes involved in L-tryptophan catabolism and its use in protein synthesis, respectively, and are associated with the neuroinflammation and immune response to acute cerebral ischemia. Hesperetin, a citrus flavanone, is known to help prevent tissue damage from oxidative stress in the brain. In this study we investigated the mechanisms involved in cerebroprotective action of heseperetin in connection with the tryptophan-modulating enzymes. Male C57BL/6 mice were anesthetized and subjected to photothrombotic cortical ischemia. Hesperetin was administered i.p. 1 h after ischemic insult. Posttreatment with hesperetin significantly reduced the infarct size including infarct area and volume. Ischemic insult markedly altered the tryptophan-modulating enzymes, i.e. an increase in the expression of IDO and a simultaneous decrease in that of TrpRS. Hesperetin significantly decreased the expressions of IDO, CD11b, CD11c, p-JAK2 and p-STAT1 via increasing the expression of TrpRS. Hesperetin significantly restored the tryptophan-modulating enzymes, inhibiting JAK/STAT signaling

activation. These results suggest that the cerebroprotective effects of hesperetin might be associated with the increase in the TrpRS expression as well as the suppression of the IDO expression.

Title: mir-29a differentially regulates cell survival in astrocytes from cornu ammonis-1 and dentate gyrus by targeting VDAC1

Authors: ***C. STARY**[1], X. SUN[1], Y. OUYANG[1], L. LI[1,2], R. GIFFARD[1];
[1]Anesthesia, Stanford Univ., Stanford, CA; [2]Anesthesia, Zhujiang Hospital, Southern Med. Univ., Guangzhou, China

Abstract: Neurons in the cornu ammonis 1 (CA1) region of the hippocampus are selectively vulnerable to transient cerebral ischemia, while neurons in the dentate gyrus (DG) are more resistant. This effect is mediated by local astrocyte function, and may be related to differences in subregional hippocampal expression of miR-29a. In the present study we investigated the role of miR-29a on cell survival in hippocampal astrocytes cultured selectively from CA1 and DG in response to extended glucose deprivation (GD) injury. We observed that CA1 astrocytes exhibited a higher degree of cell death and a correspondingly greater decrease in miR-29a following injury versus astrocytes from DG. A reciprocal change was observed in expression of the mitochondrial voltage dependent cation channel-1 (VDAC1), a regulator of mitochondria and target of miR-29a. In both CA1 and DG astrocytes, increasing levels of miR-29a by transfection with mimic decreased VDAC1 expression and improved cell survival following injury. Knockdown of VDAC1 expression with small interfering RNA resulted in improved survival from GD injury in both CA1 and DG astrocytes. Finally, we observed that the protective effect

of miR-29a was eliminated by inhibition of miR-29a/VDAC1 binding. These findings suggest that the selective vulnerability of the CA1 to transient cerebral ischemia may be due in part to a limited miR-29a response in CA1 astrocytes. This effect results in a relative increase in VDAC1-mediated cellular dysfunction in CA1 astrocytes. These findings may provide insight for post-resuscitation interventions aimed at preventing hippocampal injury following global cerebral ischemia.

Title: Ischemia/reperfusion injury leads to accumulation of insoluble protein aggregates with components similar to neurodegenerative diseases

Authors: *K. HOCHRAINER[1], A. KAHL[1], K. JACKMAN[1], J. BASKAR[1], S. ZHANG[2], J. ANRATHER[1], C. IADECOLA[1];
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Inst. of Biotech. and Life Sci. Biotechnologies, Cornell Univ., Ithaca, NY

Abstract: Brain injury is frequently associated with the accumulation of ubiquitin-containing insoluble protein aggregates (Ross and Poirier, 2004). We have recently discovered that cerebral ischemia leads to a drastic increase in ubiquitin-rich inclusions analogous to other neurological disorders (Hochrainer et al, 2012; Hochrainer et al, 2015). To gain a better understanding of the biological significance of post-ischemic aggregates we asked what other proteins in addition to ubiquitin migrate to protein aggregates after stroke. Mice underwent middle cerebral artery occlusion or sham-surgery (n=8/ group). After one-hour reperfusion, when ubiquitin is maximally detected in aggregates, mice were sacrificed and insoluble proteins, as determined by their resistance to 2% Triton X-100 solubilization, were obtained from ischemic neocortices. Isolated proteins were digested with trypsin and identified by nanoLC-MS/MS (n=4, each 2 pooled sham and ischemia animals). Relative amounts of proteins detected in sham and ischemia

groups were quantified for each run using label-free quantification (MaxQuant). Ischemia versus sham fold change was determined and mean values were calculated across all 4 runs. Out of 541 identified proteins, 197 were significantly increased in the insoluble aggregate fraction after ischemia/reperfusion (fold change 1.21 - $6.24x10^7$). As anticipated, ubiquitin was among the most prevalent proteins ($5.83x10^7 \pm 2.91x10^7$-fold induction). Stroke-induced insoluble proteins were examined for Gene Ontology enrichment by the DAVID database (https://david.ncifcrf.gov). Ischemia/reperfusion almost exclusively promoted the aggregation of proteins regulating RNA/protein synthesis and signal transduction ($P<0.001$), while it either reduced or did not affect insoluble proteins associated with membranes, cytoskeleton and macromolecular complexes. Finally, stroke-dependent aggregated proteins were analyzed for functional association networks via the STRING database (http://string-db.org) and the 2 largest clusters were examined for identity of proteins. Remarkably, we found in these clusters a notable number of RNA-binding proteins with known relation to neurodegenerative diseases, especially ALS and FTD, among them Tdp43, Fus, Hnrnpa1, Hnrnpa3, Sfpq and Srsf1. Our data support a novel and previously unrecognized molecular overlap between neurodegeneration and ischemic stroke. Although aggregation of these proteins is believed to be detrimental in neurodegenerative diseases, it remains to be established how the accumulation of these proteins affects cell viability and outcome after cerebral ischemia/reperfusion.

Title: Myeloid differentiation primary response protein 88 protects cerebral ischemia via a non-inflammatory mechanism

Authors: *J. REN, Y. HE, K. QIAN, Y. SHEN, Y.-D. ZHOU;
Dept. of Neurobio., Mailbox 22, Zhejiang Univ. Sch. of Med., Zhejiang, China

Abstract: Toll-like receptors (TLR) are a group of pattern recognition receptors which play a critical role in the innate immune system. Myeloid differentiation primary response protein 88 (MyD88) is one of the key molecules recruited by the toll-like receptors. Existing evidence

shows that TLR/MyD88-mediated inflammatory processes within the brain might contribute to brain ischemic injury. However, knocking out MyD88 aggravates brain ischemic injury. In the present study, we explored the mechanism underlying MyD88-mediated protection against brain ischemia. We found that MyD88 expression level was lower in hippocampal CA1 area than in CA3 and cortical regions in C57BL/6 mice. The expression level of MyD88 correlates well to its protection against transient forebrain ischemia-induced neurodegeneration, suggesting MyD88 is an endogenous pro-survival molecule in the brain. MyD88 deficiency led to enhanced ischemic injury in a manner independent of the pro-inflammatory pathway. Notably, MyD88 stabilized brain ischemia-induced desphoshorylation of CaMKII in the brain. The binding of MyD88 to protein phosphatase 1 (PP1) was significantly enhanced following oxygen glucose deprivation (OGD) treatment in vitro, suggesting that the MyD88 stabilizes CaMKII dephosphorylation via PP1. Taken together, we establish an interaction between MyD88 and CaMKII in brain ischemia tolerance, and provide a fresh insight into the basic and clinical research of cerebral ischemia.

Title: Cold-inducible RNA-binding motif protein 3 (RBM3) protects neural cells against hypoxic-ischemic (HI) injury and is involved in stemness maintenance of neural stem progenitor cells (NSPC)

Authors: X. ZHU[1], C. BREGERE[2], R. GUZMAN[1], *J. P. KAPFHAMMER[3], S. WELLMANN[1];
[1]Univ. Childern´s Hosp. Basel (UKBB), Basel, Switzerland; [2]Dept. of Biomedicine, Univ. of Basel, Basel, Switzerland; [3]Univ. Basel, 4056 Basel, Switzerland

Abstract: Moderate hypothermia is a potent therapeutic tool to ameliorate hypoxic-ischemic (HI) brain injury. RNA-binding motif protein 3 (RBM3) belongs to a small group of proteins, whose expression is elevated during hypothermia while global protein translation is suppressed. Recently, RBM3 has been identified as a positive effector in hypothermia-mediated neuroprotection against HI injury, and is potentially involved in neurogenesis in euthermic condition. However, the underlying molecular mechanisms remain largely unknown.
We took advantage of an *ex vivo* organotypic hippocampal slice culture (OHSC) model from postnatal day 3 C57BL7/J mice, and challenged OHSC with oxygen-glucose deprivation (OGD)

to mimic HI injury. We observed that moderate hypothermia (32°C) significantly reduces OGD-induced neuronal cell death, and meanwhile increases RBM3 expression level, particularly in dentate gyrus (DG) where postnatal neurogenesis occurs.
Therefore, we have looked at expression levels of RBM3 in cultured NSPCs. We found high RBM3 expression in proliferating NSPCs which decreased dramatically when cells were stimulated to differentiate. Doublecortin, a marker for neuroblasts and immature neurons, was simultaneously upregulated. These results indicate that RBM3 may play an important role in the maintenance of NSPC stemness. Previously we performed an interactome screening and discovered protein interactions between RBM3 and oncofetal protein IMP family members, which are known to regulate NSPC properties and fetal neural development. Here we demonstrated that IMP1, IMP2 and IMP3 are abundant in NSPCs but diminish with differentiation, similar to the expression pattern of RBM3. Among the three IMP proteins, only IMP2 is expressed in postnatal brain. We confirmed the interaction of RBM3 and IMP2 *in vitro* and *in vivo*, by co-immunoprecipitation (CoIP) and proximity ligation assay (PLA), respectively. In summary, RBM3 may play a key role in hypothermia-mediated brain protection against HI injury, and is involved in regulating NSPC self-renewal by interacting with oncofetal protein IMP2.

Title: Targeting MAPK phosphorylation sites of the Connexin43 C-terminal tail provides neuroprotection in stroke

Authors: *M. FREITAS-ANDRADE[1], N. WANG[2], J. BECHBERGER[1], P. D. LAMPE[3], L. LEYBAERT[2], C. C. NAUS[1];

[1]Cell. & Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada; [2]Basic Med. Sci., Ghent Univ., Ghent, Belgium; [3]Div. of Publ. Hlth. Sci., Fred Hutchinson Cancer Res. Ctr., Seattle, WA

Abstract: Connexin43 (Cx43) gap junction (GJ) channels directly bridge the cytoplasm between coupled astrocytes, and allow for direct intercellular signaling. However, Cx43 channels also exist on their own as single membrane hemichannels that connect the cell cytoplasm to the extracellular milieu. In brain injury, Cx43 GJ channels are largely associated with protective mechanisms while hemichannels are linked to deleterious effects. The cytoplasmic C-terminal region is a key factor in Cx43 function with putative phosphorylation sites specific to different kinases that directly mediate channel and hemichannel activity. The mitogen activated protein kinase (MAPK) has been linked with regulating Cx43 channel function. The goal of this study was to determine whether the MAPK phosphorylation sites of Cx43 are critical in stroke outcome.

We subjected wild-type (WT) and mutant (MK4) mice, with mutations within the Cx43 C-terminal that include the MAPK site Cx43(S255/262/279/282A), to permanent middle cerebral artery occlusion (pMCAO). After 4 days of recovery, brain sections were histologically evaluated for infarct volume and were correlated with behavioral outcomes. Immunofluorescent analysis of astrocyte reactivity, microglial activation and apoptosis were performed. Electrophysiological analysis of Cx43 hemichannel activity as well as Cx43 GJ coupling studies were performed in WT and MK4 astrocytes.

A significant decrease in infarct volume was measured in MK4 mice. In the penumbra, an increase in astrocyte reactivity as well as a decrease in microglial activation was observed in the MK4 mice, compared with WT animals. Consistent with the infarct volume data, a significant reduction in cell death was also observed in MK4 mice; this was correlated with significant improvement in behavioral performance. In contrast to WT astrocytes, MK4 astrocytes displayed a reduction in Cx43 hemichannel activity and an increase in GJ channel coupling. This unique channel characteristic is associated with the neuroprotective phenotype of MK4 animals to stroke. This was confirmed by injecting ischemic mice with TAT-GAP19, a nonapeptide derived from the cytoplasmic loop of Cx43 and previously shown to inhibit hemichannel activity without affecting GJ coupling (Abudara, V., et al. (2014), Front Cell Neurosci 8: 306; Wang et al., (2013) Basic Res Cardiol, 108: 309). Similarly to the MK4 phenotype, those mice treated with TAT-GAP19 showed a significant reduction in infarct volume compared to non-treated mice. Taken together, understanding the molecular mechanisms associated with Cx43 channel function in stroke, opens up new avenues for therapeutic intervention.

Title: Sesn3 and Post-Ischemia Seizures in Diabetes

Authors: *Z. C. XU, Z. LEI, L. XIA, Z. SHI;
Indiana Univ. Med. Ctr., Indianapolis, IN

Abstract: Seizures are the most common neurological sequelaee of stroke. Diabetes mellitus has been identified as an independent predictor of acute seizures in stroke patients. The mechanisms of post-stroke seizures under diabetic condition remain unclear. Recent studies indicated that epilepsy could be mediated by energy metabolism related proteins such as Sestrin3 (Sesn3). The present study attempted to reveal the contribution of Sesn3 to seizure generation in diabetic condition after ischemia.
Transient global ischemia was produced in adult Wistar rats mice. Diabetes was induced by i.p. injection of 50 mg/kg streptozotocin (STZ). The seizure activity was defined by the Racine scale III-V. The neuronal death in the brain was determined by hematoxylin-eosin staining. The expression levels of Sesn3 were analyzed by Western blotting and immunohistochemistry. The neuronal excitability was recorded with electrophysiological approaches.
The blood glucose levels was >300 mg/dL in animals one week after STZ injection. The seizure rate significantly increased from zero of naive animals to 100% in diabetic rats 24 hr after 15 min ischemia. No obvious neuronal damage was observed in hippocampus and cerebral cortex one day after ischemia. Sesn3 expression in hippocampus was significantly increased in diabetic animals with post-ischemia seizures. The potassium currents were decreased and neuronal excitability increased in these animals. The seizure rate was decreased from 50% of wild type mice to 15% in Sesn3 knockout mice after 15 min ischemia. The above results indicate that increase of Sesn3 expression might be responsible to post-ischemia seizure in diabetic animals.

Title: Deficiency of Perlecan, a basement membrane heparan sulfate proteoglycan, leads to the blood-brain barrier deterioration in a mouse ischemic stroke model

Authors: *K. NAKAMURA[1,3], P. ZHANG[1], T. IKEUCHI[1], C. RHODES[1], D. MAHBOUBI[1], Y. CHIBA[1], T. AGO[3], Y.-S. MUKOUYAMA[2], Y. YAMADA[1];

Abstract: Ischemic stroke is a leading cause of death and disability. The pathological process of ischemic stroke is worsened by the disruption of blood-brain barrier (BBB). The BBB is a highly selective permeability barrier formed by brain endothelial cells and covered by basement membranes (BMs), pericytes, and the end-feet of astrocytes. The expression of platelet-derived growth factor receptor β (PDGFRβ), a marker of pericyte, is increased around the ischemic lesion for the maintenance of the BBB and the involvement in the repair process. Here we focus on Perlecan, the major heparan sulfate proteoglycan in the BMs, which is preferentially expressed in endothelial cells in the brain. Previous studies demonstrate that Perlecan interacts with extracellular matrix, growth factors, and receptors, implicating various cellular activities and tissue homeostasis. However, the role of Perlecan in the BBB breakdown and the subsequent repair process after ischemic stroke remains unclear.
To elucidate the role of Perlecan in the brain vasculature, we used conditional *perlecan*-deficient (*Perlecan*$^{-/-}$-Tg) mice. The BBB formation and function in the brain vasculature appeared to be unaffected in *Perlecan*$^{-/-}$-Tg mice. However, under the ischemic stroke model produced by a transient middle cerebral artery occlusion, *Perlecan*$^{-/-}$-Tg mice exhibited larger infarct volumes and more BBB leakage than control mice on post-surgery day (PSD) 2. Moreover, *Perlecan*$^{-/-}$-Tg mice had less PDGFRβ-positive pericytes around the ischemic lesion on PSD 3 to 7, suggesting that the Perlecan deficiency results in defective pericyte activation during the repair process. Combined, these results suggest that Perlecan is required for the endothelial cell-pericyte integrity in the BBB maintenance and the pericyte activation in the BBB repair process after ischemic stroke.

Title: Alternatively activated brain-infiltrating macrophages facilitate recovery from collagenase-induced intracerebral hemorrhage

Authors: *W. CHO[1], H. MIN[1], Y. JANG[1], I.-H. CHO[2], S.-W. YU[3], S. LEE[4], S. LEE[1]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Kyung Hee Univ., Seoul, Korea, Republic of; [3]Daegu Gyeongbuk Inst. of Sci. and Technol., Daegu, Korea, Republic of; [4]Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Intracerebral hemorrhage (ICH) is one of the major causes of stroke. After onset of ICH, massive infiltration of macrophages is detected in the peri-hematoma regions. Still, the function of these macrophages in ICH has not been completely elucidated. In a collagenase-induced ICH model, CX3CR1+ macrophages accumulated in the peri-hematoma region. Characterization of these macrophages revealed expression of alternatively activated (M2) macrophage markers. In the macrophage-depleted mice, ICH-induced brain lesion volume was larger and neurological deficits were more severe compared to those of control mice, indicating a protective role of these macrophages in ICH. In the ICH-injured brain, mannose receptor-expressing macrophages increased at a delayed time point after ICH, indicating M2 polarization of the brain-infiltrating macrophages in the brain microenvironment. To explore this possibility, bone marrow-derived macrophages (BMDM) were co-cultured with mouse brain glial cells and then tested for activation phenotype. Upon co-culture with glia, the number of mannose receptor-positive M2 macrophages was significantly increased. Furthermore, treatment with glia-conditioned media increased the number of BMDM of M2 phenotype. In this study, our data suggest that brain-infiltrating macrophages after ICH are polarized to the M2 phenotype by brain glial cells and thereby contribute to recovery from ICH injury.

Title: St2/il-33 signaling restricting acute ischemic brain injury involves switching microglia/macrophage polarization

Authors: *Q. YE, Y. YANG, H. ZHANG, J. WANG, G. WANG, J. CHEN, X. HU, X. HU; Neurol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: BACKGROUND AND PURPOSE: ST2/IL33 signaling is involved in immune regulation and inflammatory responses. It has been shown that both IL33 and ST2 are expressed in CNS and may play an important role in recovery after spinal cord injury. Recent study documented an increase in blood ST2 expression after stroke. The exact roles of ST2 in the ischemic brain injury, however, are not explored. **METHODS:** C57/BL6 wild type (WT) and ST2-KO mice were subjected to 60-minute transient cerebral ischemia (tMCAO) or distal permanent MCAO (dMCAO). The expression of ST2 and IL-33 in the ischemic brain were measured at different time points after tMCAO using RT-PCR. Brain infarct was quantified using TTC staining and MAP2 immunostaing. Neurobehavioral tests were performed up to 7 days after tMCAO. The expression of ST2 on CNS cells was assessed by flow cytometry analysis. For experiments with ST2 activation, IL-33 was injected intracerebroventricularly (i.c.v.) into WT mice right after the induction of tMCAO. **RESULTS:** In WT mice, the mRNA expression of ST2 in the ischemic brain exhibited a delayed elevation 7d after tMCAO, while the mRNA expression of IL-33 was transiently increased 1d after tMCAO. The deficiency of ST2 resulted in enlarged Infarct volume 3d after tMCAO or dMCAO and aggravated neurological deficits lasted out to 7d. Further study showed that i.c.v. injection of IL-33 at the time of reperfusion attenuated the severity of brain infarct in WT mice, suggesting that central activation of ST2 could protect against acute ischemic brain injury. Furthermore, immunofluorescent staining shows reduced microglia/macrophage polarization towards M2 phenotype in ST2 deficient mice. In vitro results confirm the direct effect of IL-33 of microglial polarization under physiological conditions or upon ischemic neuronal death. **CONCLUSIONS:** ST2/IL-33 signaling plays essential role in restricting acute ischemic brain injury. Such protective effect of ST2/IL-33 involves a shift of microglia/macrophage polarization towards M2 phenotype. Our study may provide a new therapeutic target for stroke treatment.

Title: Rod microglia induced by traumatic brain injury are resident cells that align with blood vessels adjacent to damaged neurons

Authors: *K. G. WITCHER[1], B. N. BENNER[1], M. M. MUCCIGROSSO[1], D. B. MCKIM[1], A. M. FENN[1], J. LIFSHITZ[3], D. S. EIFERMAN[2], J. P. GODBOUT[1];

Abstract: Traumatic brain injury (TBI) elicits immediate neuroinflammation that contributes to acute cognitive, motor, and affective disturbances. Although acute impairments resolve after mild to moderate TBI, inflammatory processes persist and may underlie neuropsychiatric and cognitive complications that arise long after injury. Microglia, the innate immune cells resident to the brain, are key mediators of acute and chronic inflammation. We have previously reported that methylene blue (MB), an antioxidant and anti-inflammatory agent, reduces microglia-mediated neuroinflammation after midline fluid percussion injury, a murine model of diffuse TBI. This was associated with improved recovery of motor coordination 7 days post-injury (dpi). In examining microglia morphology 7 dpi, we found that MB intervention prevented TBI-induced formation of rod microglia in the cortex. Although the formation of rod microglia after FPI has been observed, their origin and role in pathophysiology is unclear. Here we show novel data that rod microglia are in close proximity to axotomized (ATF-3+) neurons 7 dpi and form trains along nearby blood vessels. Furthermore, both rod microglia and nearby activated microglia upregulate CD45. We confirmed that CD45+ rod microglia originate from resident CNS cells (unlabeled in GFP bone marrow chimeras), but not through proliferation (unlabeled by BrdU). Overall, these findings suggest that TBI drives resident microglia to take on a rod morphology, align with blood vessels proximal to damaged cortical neurons, and that this process can be prevented by anti-inflammatory intervention. One possible interpretation is that

the rod morphology facilitates movement of microglia along blood vessels toward sites of neuronal injury.

Abstract: Traumatic brain injury (TBI) is a risk factor for developing Alzheimer's Disease (AD), and occurs when the brain is mechanically loaded by an external force. Unfortunately, we do not yet understand why individuals develop AD following TBI. In light of the heterogeneous and complex neuronal architecture within the brain, and the focal and diffuse nature of traumatic lesions, we hypothesized that the geometry and orientation of axons and dendrites relative to the directionality of traumatic impact will dictate the severity of their structural changes and injury-induced AD phenotypes. This study details our initial deployment of a new *ex-vivo* cell injury model, which we used to probe morphological and biochemical phenotypes following rapid unidirectional deformation of human neurons derived from induced pluripotent stem cells (iPSC). Human iPSC-derived neuronal progenitor cells (NPCs) were either i) seeded and directly differentiated into neurons within stretching devices; ii) differentiated into neurons in standard culture plates, prior to seeding within devices after dissociation; or iii) differentiated into neurons in standard culture plates, prior to dissociation and FACS-sorting to enrich for a neuronal population. In all experimental groups, at time points up to 24 hours, we compared the response

of unstretched cells to those subjected to 1 or 50 cycles of 24% stretch followed by release. We found that neurites aligned along the axis of stretch experienced immediate and significantly more frequent and more severe structural changes in response to stretch, as defined by residual neurite waviness upon release (likely created by the inelastic lengthening of axons during stretch). How neurite length and thickness influence the severity of stretch-induced morphological changes was also determined. As a first step in addressing whether our mechanical injury model induces AD-related phenotypes, we used ELISA-based and immunocytochemistry assays to quantify accumulation of secreted amyloid beta peptide and changes in tau phosphorylation, two classical AD hallmarks, in response to rapid stretch. Our study demonstrates the feasibility of a powerful model system and represents the first steps towards developing a deeper mechanistic understanding of the linkage between TBI and AD.

Title: Fibrinogen regulates adult neural stem/precursor cell differentiation into astrocytes via BMP receptor signaling

Authors: ***C. SCHACHTRUP**[1], S. SCHILDGE[2], L. POUS[2], C. BOHRER[2], K. MAMMADZADA[2], D. PFEIFER[3], K. SCHACHTRUP[4], K. AKASSOGLOU[5,6];

Abstract: Subventricular zone (SVZ)-derived neural stem/precursor cells (NSPCs) have the potential to contribute to brain repair upon CNS injury or disease. However, the majority of SVZ-derived NSPCs differentiate into glial cells or stay in a precursor state instead of differentiating into functionally integrated neurons. This hindrance of neuronal regeneration is mainly attributed to changes in the NSPC environment. Identification of the extracellular factors driving NSPC differentiation and characterizing the contribution of SVZ-derived newborn cells to brain repair is essential to harness endogenous NSPCs for therapeutic goals. Here, we show that the blood protein fibrinogen drives NSPC differentiation into astrocytes via activation of the BMP receptor signaling pathway. After cortical injury, we could show that fibrinogen is deposited not only in the cortical lesion area, but also rapidly in the NSPC microenvironment within the SVZ niche. Interestingly, in fibrinogen knockout mice, the total number of SVZ-derived newborn astrocytes was reduced by 50 % in the body of the cortical lesion center. Accordingly, stereotactic injection of fibrinogen into the mouse cortex resulted in a 30 % increase in the total number of SVZ-derived astrocytes, revealing a specific role for fibrinogen driving adult NSPC differentiation into astrocytes. Fibrinogen-mediated differentiation of NSPCs into astrocytes is reversed by blocking β1 integrin-mediated BMP receptor recruitment into lipid rafts or by blocking phosphorylation of the BMP receptor. Microarray and protein expression analyses of fibrinogen-induced NSPCs differentiating into newborn astrocytes revealed a distinct astrocyte signature compared to resident cortical astrocytes, with a potential beneficial function after brain repair. These results identify fibrinogen as a novel environmental factor of adult NSPCs that induces BMP receptor signaling leading to NSPC differentiation into astrocytes after traumatic brain injury.

Title: Molecular, cellular, and behavioral improvements after treatment of rodent traumatic brain injury with human mesenchymal stem cells.

Authors: *C. W. LEVENSON, A. DARKAZALLI, C. VIED;
Florida State Univ. Col. of Med., Tallahassee, FL

Abstract: Mesenchymal stem cells have emerged as a promising therapy to reduce secondary injury and cognitive deficits associated with traumatic brain injury (TBI). To identify mechanisms responsible for the efficacy of stem cell-based therapies, we employed a rodent model of TBI (controlled cortical impact), combined with behavioral testing, high throughput RNA sequencing (RNAseq), and an examination of the role of endogenous neural progenitor cells after treatment with $1x10^6$ intravenously delivered adult human bone marrow-derived mesenchymal stem cells (hMSC). RNAseq and KEGG pathway analysis revealed that TBI altered the abundance of almost 7000 mRNAs regulating pathways involved in metabolism, neuronal plasticity, receptor-mediated cell signaling, and neurodegenerative diseases including Parkinson's and Alzheimer's. hMSC treatment normalized 50% of these TBI-disrupted genes, with some pathways exhibiting 100% normalization by this cell-based therapy. We also investigated a possible role for hMSC in the role and regulation of endogenous neural progenitor cells that arise from in the lateral end of the subventricular zone (SVZ). Stereological analysis revealed that within 48h, TBI produced a 52% ($p \leq 0.05$) increase in the number of proliferating cells in the SVZ. Treatment with hMSC resulted in a further 74% ($p < 0.001$) increase in proliferation. Consistent with human studies, TBI resulted in depression-like behaviors as measured by a 54% ($p \leq 0.05$) decrease in saccharin preference scores. Treatment with hMSC fully prevented TBI-associated depression. TBI was also found to produce a 73% ($p \leq 0.05$) decrease in novel object interaction time, indicating impaired working memory that was similarly prevented by hMSC treatment. To test the hypothesis that hMSC efficacy is dependent cell proliferation in the SVZ, precision X-ray irradiation was used to selectively eliminate mitosis in the SVZ prior to hMSC treatment. The ability of hMSC to prevent TBI-associated depression and working memory impairment was eliminated when proliferation in the SVZ was inhibited by targeted irradiation, suggesting a key role for these cells in the efficacy of hMSC in this model. Together this work not only shows that hMSC may be an effective treatment option for TBI-induced depression and cognitive deficits, but also identifies a number of novel molecular targets for the development of new therapeutic approaches.

Title: Characterization and modulation of stem-like cells after a controlled cortical impact injury in mice

Authors: *B. R. DESOUSA[1], A. AHMED[1,2], M. SPURLOCK[1], S. GAJAVELLI[1], R. BULLOCK[1];
[1]Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Dept. of Neurosurg., Univ. Hosp. Southampton, Southampton, United Kingdom

Abstract: Traumatic Brain Injury (TBI) often leads to disability among survivors as the brain fails to regenerate. Ethical and immune compatibility issues limit the use of exogenous cell transplant approaches. Promoting regeneration of injured nervous system via endogenous neural stem cells (NSCs) is becoming possible. To harness these cells for repair they have to exit quiescence and be driven toward neuronal and glial lineages. In uninjured cortex such cells are absent, as evidenced by proliferative potential under in vitro conditions. In contrast, cortical glial fibrillary acidic protein (GFAP) cells/reactive astrocytes acquire stem properties following injury. Studies have linked the stem cell response of the astrocytes to the Sonic Hedgehog (SHH) signaling pathway. We hypothesized that (1) controlled cortical impact (CCI) injury will modify the activated stem-like cells in the cortex and (2) that modulation of the SHH pathway will alter functional outcome. In this study, we show that stem-like cells in the cortical parenchyma are activated following CCI injury, and the quantity of such cells can be modulated through the SHH signaling pathway. Activation of cortical cells was determined using a Neurosphere stemness assay and immunohistochemistry to assess the proliferative and differentiating potential for these cells. We showed that a significant number of neurospheres, or stem-like cells, were produced at 3 and 7 days post-injury (DPI). These stem-like cells were also shown to have the capacity to become neurons, oligodendrocytes, and astrocytes. We also show that upregulation of the SHH signaling pathway improves function after cortical injury. Animals were treated with a modulator of the SHH signaling pathway, either Smoothened agonist (SAG) or Cyclopamine (SHH antagonist), and motor function was assessed using the Rotarod performance test. Mixed ANOVA analysis suggests a significant effect at 3, 7, 14, and 28 DPI when treated with SAG, but not Cyclopamine, as the animals were able to remain on the rotating rod for a longer period of time when treated with SAG. From this study, we determined that (1) stem-like cells are activated after CCI injury in the cortex with the most being activated at 3 DPI, and that (2) modulation of the SHH signaling pathway with SAG improved motor function at 3, 7, 14, and 28 DPI.

Title: Neural stem cell transplants promote cortical reorganization after traumatic brain injury

Authors: *C. P. ADDINGTON, S. E. STABENFELDT, J. A. KLEIM;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Traumatic brain injury (TBI) afflicts over 1.7 million Americans and leads to 52,000 deaths annually. TBI is characterized by a primary, mechanical insult that leads to an expansive secondary, biochemical injury that is largely responsible for long-term deficit associated with TBI. Despite the prevalence of TBI and associated impairments, there are currently no clinical therapies that directly address the secondary injury of TBI. Preclinical studies have used stem cells to mitigate the deleterious effects of TBI with moderate success; however, the mechanism of benefit of cell therapies after TBI remains unclear. We have used intracortical microstimulation to investigate the capacity of neural progenitor/stem cell (NPSC) transplants to modulate cortical motor map plasticity in a rat model of TBI. We observed NPSC transplants to promote significant preservation of forelimb motor map areas at subacute time points after TBI compared to vehicle-receiving controls ($p=0.0227$ at 7 days after TBI). However, the ratio of distal to proximal forelimb representation is widely varied in NSPC-mediated motor map recovery. These data indicate that stem cell therapies may represent a mechanism for promoting functional reorganization within residual cortical tissue after TBI.

Title: Microglial proliferation after stroke is indirectly controlled by ETB_R signaling in reactive astrocytes.

Authors: J. J. MCINNIS, M. D. LECOMTE, *J. L. SPEES;
Med., Univ. of Vermont, Colchester, VT

Abstract: During central nervous system injuries such as stroke, the glial response includes both reactive astrocytes ($GFAP^+$) and activated microglia ($CD11b^+$). Within the injury environment, paracrine effectors released by reactive astrocytes and activated microglia are thought to cross-activate both glial cell types. In culture, many factors secreted by glial cells are reported to promote glial activation in an autocrine/paracrine manner. However, few studies have clearly demonstrated such reactive astrocyte/microglial interactions *in vivo*. Previous work from our lab demonstrated a Notch1-STAT3- ETB_R signaling axis that controls reactive astrocyte proliferation after brain injury. In addition to proliferation, this signaling axis may also control reactive astrocyte function(s). Here we show that disruption of ETB_R signaling in astrocytes using inducible, conditional knockout (cKO) mice (GFAP-$CreER^{TM}$-ETB_R-cKO), leads to a significant reduction in microglial proliferation in the peri-infarct area after stroke as measured by $CD11b^+/Ki67^+$ cells. Through proteomic studies on ETB_R-cKO astrocytes, we are currently performing screens to identify factors released by proliferating reactive astrocytes that regulate microglial activation and proliferation.

Title: Modulation of microglial polarization and phagocytosis by hemoglobin in an *Ex vivo* model of intracerebral hemorrhage

Authors: *Q. LI, X. LAN, X. HAN, J. WANG;
Anesthesiol. & Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Background and Purpose: Microglia are activated in the peri-hematoma region after intracerebral hemorrhage (ICH). The classically activated microglia (M1) release inflammatory factors, whereas alternatively activated microglia (M2) carry out anti-inflammatory functions and phagocytize hematoma and debris. We aimed to investigate whether hemoglobin regulates

polarization of and phagocytosis by microglia in an *ex vivo* model of ICH. **Methods:** Hemoglobin (Hb), a main metabolite of blood, was used to mimic ICH *ex vivo*. We treated organotypic hippocampal slice cultures (OHSCs) with Hb (20 μM) or vehicle for 16 h and collected tissue to examine the protein/mRNA levels of M1 (CD11b, iNOS, and CD16/32) and M2 (Arg1, IL-10) markers and examine cytokines and chemokines in the conditioned media. We also treated OHSCs with Hb or vehicle for 16 h and performed a phagocytosis assay using fluorescent-conjugated latex beads or aged red blood cells from GFP-UBC mice. **Results:** In cultured mouse OHSCs, Hb induced *CD11b, iNOS,* and *Arg1* ($p<0.05$) mRNA expression; induced CD11b, CD16/32, and Arg1 protein expression; and enhanced the expression/secretion of IL-10 ($p<0.05$) and other M1 markers (IL-6 and TNF-α, $p<0.05$). In a cytokine/chemokine array performed using Hb- or vehicle-treated media from OHSCs, multiple inflammation related cytokines/chemokines were increased by Hb, as well as the anti-inflammation factor IL-10. In addition, we found that treating OHSCs with Hb increased microglial phagocytosis ($p<0.05$). **Conclusion:** Hb treatment *ex vivo* induced overexpression of pro- and anti-inflammatory factors and increased phagocytosis of microglia. OHSCs can be used as an *ex vivo* platform to study microglial polarization and phagocytosis after ICH.

Title: Anxiety-related and depression-like behaviors following mild traumatic brain injury in adolescent rats are dependent on sex and estrous cycle

Authors: *L. L. KRAFJACK[1], R. RAGHUPATHI[2];
[2]Neurobio. & Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Following mild traumatic brain injury (TBI), high school and collegiate-aged female athletes tend to report more emotional symptoms than male athletes. Thirty five-day-old male and female rats were used to model mild TBI in the adolescent human. Rats were anesthetized and directly impacted on the skull using a 5mm metal tip just behind bregma over the midline suture (2mm depth, 5.5m/s velocity); sham-injured rats were anesthetized, but not injured. Injury resulted in similar percentages (90% of males, 85% of females) of skull fractures and righting

reflex times in male (473 ± 28 sec) and female (463 ± 20 sec) rats, which was significantly different ($p<0.05$) than their sham-injured, age-matched counterparts (male, 269 ± 28 sec; female, 270 ± 28 sec). Brain-injured male and female rats were evaluated for anxiety-related and depression-like behaviors using the elevated plus maze (EPM) and forced swim test (FST), respectively, at 6 weeks. Male rats did not exhibit any changes in open arm time in the EPM or immobility time in the FST at 6 weeks post-injury. Vaginal cytology was performed to determine the phase of the estrous cycle females rats were in at the time of behavioral testing. During the estrus phase, when circulating levels of estradiol and progesterone are low, brain-injured female rats spent more time in the open arm of the EPM compared to their phase-matched, sham-injured counterparts. During the proestrus phase, when circulating estradiol is high, brain- injured animals exhibited decreased open arm time, suggestive of an anxiety-related phenotype. Open arm time in the EPM during the diestrus phase, when circulating levels of progesterone are high, did not differ between sham- and brain-injured rats. Brain-injured rats also exhibited increased immobility in the forced swim test during the estrus and diestrus phases, suggestive of a depression-like phenotype, but immobility time did not differ between sham and brain-injured rats during the proestrus phase. Injured brains were evaluated for neuronal damage (NeuN), neurodegeneration (FluoroJade), astrocytic (GFAP) and microglial (Iba1) reactivity at 6 weeks post-injury. Immunoreactivities for NeuN, GFAP, or Iba1 were not different between sham- and brain-injured animals at 6 weeks post-injury suggestive of the mild nature of the trauma. In contrast, both male and female brain-injured rats exhibited a similar degree of axonal degeneration in the corpus callosum. Taken together, these data suggest that female rats may be more vulnerable to anxiety-related and depression-like symptoms following mild TBI and that future behavioral analyses using female rats in TBI should take the estrous cycle into account.

Title: Changes in cortical activity may underlie motor deficits and seizure susceptibility following traumatic brain injury in the neonate rat

Authors: *L. A. HANLON[1], J. W. HUH[2], R. RAGHUPATHI[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) in infants results in long-lasting deficits in cognition and motor function that are associated with structural alterations in the brain such as atrophy and ex vacuo ventriculomegaly. Both the cognitive deficits and the cellular pathologies have been replicated in a rat model of infant TBI. Furthermore, closed head impact over the left parietal cortex of 11-day-old rats produced sustained neurodegeneration and microglial reactivity in the injured cortex that preceded the cortical atrophy and enlargement of the lateral ventricles at 4 weeks post-injury. To investigate whether these pathologies affected neuronal activity, evoked field potentials (EFPs) were recorded at 3, 7, and 21 days post-injury by stimulating cells in layers 2/3 and recording from cells in layer 5 of the motor cortex in slices from the injured hemisphere. At 3 days post-injury, the amplitudes of the EFPs were significantly smaller in brain-injured animals (45%, $p<0.05$ compared to sham-injured controls). This hypoactivity was transient because at 7 and 21 days post-injury, the amplitudes of the EFPs of brain-injured animals were indistinguishable from those in the sham-injured, age-matched counterparts. Interestingly, post-injury administration of the antibiotic minocycline (45mg/kg/injection, 2x/day for 3 days) rescued the cortical hypoactivity at 3 days post-injury, but did not have any effect on injury-induced spatial learning and memory deficits on days 11-15 post-injury. Whereas the swim speeds of brain- and sham-injured animals were not different, a closer investigation using a straight-path swim task at 28 days post-injury revealed that brain-injured animals used the forelimb contralateral to the impact side to a significantly greater extent compared to sham-injured rats ($p<0.05$) . This deficit in motor control was preceded by a 104% increase in the amplitude of the EFP compared to sham-injured controls within the forelimb motor cortex - a region remote from the impact site wherein neurodegeneration or microglial reactivity were not observed. Additionally, brain-injured animals demonstrated at 14% decrease in their latencies to seize compared to sham-injured rats indicative of an increase in seizure susceptibility at 6 weeks post-injury. Both behavioral and neuronal activity deficits were independent of the sex of the brain-injured animal. Collectively, these data provide evidence of the complex underpinnings of the functional deficits observed in the immature brain in the acute and chronic post-traumatic periods.

Title: Mild traumatic brain injury in adolescent rats results in sex-specific cognitive deficits

Authors: *R. RAGHUPATHI, L. L. KRAFJACK;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Following mild traumatic brain injury (TBI), girls perform more poorly on visual memory tasks and take longer to recover from their symptoms than their male counterparts. Thirty five-day-old male and female rats were used to model mild TBI in the adolescent human. Rats were anesthetized and impacted on the exposed skull using a 5mm metal tip just behind bregma over the midline suture (2mm depth, 5.5m/s velocity); sham-injured rats were anesthetized, but not injured. Injury resulted in similar percentages (90% of males, 85% of females) of skull fractures; righting reflex times in male (485 ± 18 sec) and female (471 ± 18 sec) brain-injured rats was significantly different than their sham-injured counterparts (male, 307 ± 23 sec; female, 286 ± 28 sec, $p<0.05$). Neither male nor female brain-injured rats exhibited deficits in spatial working memory in a Morris water maze-based task on days 4-7 post-injury. Brain-injured male rats did not exhibit deficits in novel object recognition (NOR) at 3, 8, or 28 days using either a 1hr or 24hr interval between the habituation and the testing trials. In contrast, brain-injured female rats exhibited a short term memory deficit in NOR at 3 days post-injury using the 1hr interval ($p<0.01$), but this deficit was no longer present at 8 days. Brain-injured female rats also exhibited a long term memory deficit in NOR using a 24hr interval at both 3 and 8 days ($p<0.01$), but this deficit was no longer present at 28 days. Injured brains were evaluated for neuronal damage (NeuN), neurodegeneration (FluoroJade), astrocytic (GFAP) and microglial (Iba1) reactivity, and blood brain barrier damage (IgG extravasation) at 3 and 8 days post-injury. NeuN immunoreactivity was unchanged in the brain-injured rats compared to their age-matched, sham-injured counterparts; no evidence of IgG extravasation at either 3 or 8 days was present suggesting that the blood-brain barrier was intact. Both male and female brain-injured rats exhibited similar degrees of axonal degeneration in the retrosplenial cortex and corpus callosum. Increased microglial reactivity was observed in the retrosplenial cortex and corpus callosum of both male and female brain-injured rats at 3 days post-injury ($p<0.01$), but returned to sham-injured levels by 8 days. Increased astrocytic reactivity was observed at 8 days post-injury in the retrosplenial cortex ($p<0.01$) and corpus callosum ($p<0.01$) in female rats only. Collectively, these data suggest that specific cognitive deficits following mTBI may be more prevalent in female rats, and that cellular pathologies may not be indicative of behavioral alterations.

Title: Depletion of microglia immediately following traumatic brain injury in the neonate rat: Implications for cellular and behavioral pathology.

Authors: *J. W. HUH[1], L. HANLON[2], R. RAGHUPATHI[2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: In the immature rat brain, traumatic brain injury (TBI) results in cell death, impaired axonal transport (IAT) and axonal degeneration which are accompanied by activation of microglia. Eleven-day-old rat pups received an impact to the intact skull centered over the left parietal cortex; 24 hours later, both sham-injured and brain-injured animals received intra-cortical and intra-thalamic injections of either liposome-encapsulated sodium clodronate (which depletes microglia) or empty liposomes and brains were histologically evaluated at 3, 15, and 35 days post-injury. Clodronate depleted microglia in the cortex, white matter, and thalamus, and also decreased astrocyte density. In sham-injured animals, microglia and astrocyte densities were returned to sham-injured levels by 14 days post-injury. In brain-injured animals that received clodronate, were decreased up to 35 days post-injury compared to brain-injured animals that received the empty liposomes, suggestive of a deficit in repopulation. This sustained decrease in glia was accompanied by an increase in Fluoro Jade B-positive (FJB+) profiles in both the cortex and thalamus of clodronate-treated brain-injured animals at 3 ($p<0.001$), 14 ($p<0.01$), and 35 days post-injury, suggestive of a lack of clearance of degenerating cells. Clodronate administration had no effect on injury-induced IAT or axonal degeneration at 3 days post-injury suggesting that glia may not be involved in axonal injury. Clodronate-treated sham- and brain-injured animals and empty liposome-treated brain-injured animals were unable to perform the spatial learning task in the acute post injury period (days 10-14) as efficiently as sham-injured animals treated with the empty liposomes ($p=0.08$), implicating a role for glial cells in the development of the circuitry necessary for learning. In the chronic post-injury period (days 28-32), all brain-injured animals had spatial learning deficits ($p<0.05$) and clodronate-treated sham-injured animals were indistinguishable from sham-injured animals that received the empty liposomes. Collectively, these data suggest that microglia may predominantly play a phagocytic role in post-injury pathology. It remains to be seen, however, whether this lack of clearance has any effect on functional outcomes in the chronic post-injury period.

Title: Microglia and infiltrating peripheral macrophages express different inflammatory markers after experimental permanent brain ischemia

Authors: ***J. G. ZARRUK**, A. D. GREENHALGH, S. DAVID;
Ctr. for Res. in Neurosci., McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Microglia and macrophages from the peripheral circulation contribute importantly to the inflammatory response after ischemic stroke. Recent studies have examined macrophage/microglia polarization in brain ischemia, however these studies have not distinguished between microglia and infiltrating macrophages. We used the LysM-EGFP knockin mouse in which myeloid cells (monocyte-derived macrophages and neutrophils) are tagged with EGFP which distinguishes them from microglia at sites of CNS damage. This was combined with immunostaining for P2ry12, a microglia specific marker. We studied the expression of pro-inflammatory and anti-inflammatory markers after a permanent Middle Cerebral Artery Occlusion (pMCAO). Immunostaining 3 days post-pMCAO brains with P2ry12, Iba-1, EGFP confirmed that the EGFP+/Iba-1+ cells were macrophages, while P2ry12+/Iba-1+ microglia did not express EGFP. The peak of EGFP+ myeloid cell infiltration was 72h post-ischemia and these cells were distributed evenly within the lesion core. FACS analysis showed that a significantly higher percentage of microglia expressed TNF-α at 3 and 7 days post-pMCAO compared with infiltrating macrophages. We then isolated microglia from infiltrating macrophages using FACS-sorting 72h post-ischemia to quantify the mRNA expression of pro and anti-inflammatory markers. We confirmed the purity of the extraction by quantifying *fcrls* (microglia specific gene) expression. Compared to microglia, infiltrating macrophages upregulated the expression of arginase-1 and Ym1 by 1000-fold, and the expression of CD206 by 10-fold. There was also a 100-fold increase in the expression of IL1-β in macrophages and no differences in TNF-α mRNA expression at this time point. Although MIP-1α was downregulated in ipsilateral microglia compared to contralateral microglia, a higher percentage of microglia

expressed this pro-inflammatory marker compared with macrophages. Finally, we confirmed by immunofluorescence that arginase-1 was only expressed in macrophages 72h post-pMCAO. These data show differences in the inflammatory expression profile between microglia and infiltrating macrophages after permanent brain ischemia. These results also show that microglia have a more proinflammatory profile as compared to macrophages suggesting that these two cell types play different and complementary roles after cerebral ischemic lesion.

Title: Insulin-like growth factor1 overexpression mediates long-term survival and migration of immature neurons in the hippocampus following TBI

Authors: *E. LITTLEJOHN[1], S. K. MADATHIL[2], T. STEWART[1], K. SAATMAN[1]; [1]SCoBIRC, Univ. of Kentucky, Lexington, KY; [2]Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: The pathology associated with traumatic brain injury (TBI) manifests in motor and cognitive dysfunction following injury. Immature neurons residing in the neurogenic niche of the dentate gyrus (DG) in the hippocampus are particularly vulnerable to TBI. The inability to restore this population of hippocampal immature neurons following TBI has been causally linked to cognitive impairment. We have shown that elevating brain levels of IGF-1 stimulates hippocampal neurogenesis, enhancing the recovery of immature neuron numbers after severe TBI in mice. However, little is known about the effectiveness of IGF-1 to promote long-term survival or appropriate development of neurons born after injury. To this end, astrocyte-specific

IGF-1 conditionally overexpressing mice (IGF-1 TG) and wild-type (WT) mice received controlled cortical impact (n=9/genotype) or sham (n= 2/genotype) injury and 50 mg/kg BrdU (i.p.) twice daily for 7 days following TBI. At six weeks following injury IGF-1 significantly increased $NeuN^+/BrdU^+$ cell density in the granule cell layer. IGF-1 appropriately restricted the localization of these cells primarily to the inner 1/3 of the granule cell layer and restored the proportion of post-trauma proliferated cells that are $NeuN^+$ to a level equivalent to sham. The signaling mechanism through which IGF-1 modulates brain plasticity in the setting of TBI remains unclear. In the nervous system, PI3-K/Akt signaling predominates in mediating many of IGF-1 functions. Akt activation results in the phosphorylation of multiple downstream signaling molecules including mammalian target of rapamycin (mTOR). We hypothesized that increased brain levels of IGF-1 would potentiate posttraumatic activation of the mTOR signaling pathway, a pathway associated with growth and differentiation. To this end, IGF-1 TG and WT mice received CCI (n=8/genotype) or sham (n= 3/genotype) injuries. At 72hrs following injury, immunohistochemical labeling of pS6, a downstream effector of mTOR, was quantified in the granule cell layer, molecular layer, and the hilus of the dentate gyrus. Analysis of pS6 at the injury epicenter suggests that IGF-1 stimulates activity of the mTOR pathway following TBI. These data show that IGF-1 affects long-term survival and localization of posttrauma-born neurons. Further work is required to determine if this is appropriate or maladaptive and if mTOR is required for these effects.

Title: Co-ultra pealut enhances neuronal recovery after a moderate traumatic brain injury

Authors: *S. CUZZOCREA, I. PATERNITI, M. CAMPOLO, R. CRUPI, M. CORDARO, G. BRUSCHETTA, R. SIRACUSA, E. ESPOSITO;
Univ. of Messina, Messina, Italy

Abstract: Traumatic brain injury (TBI) is a major health problem worldwide. Currently, there is no effective treatment to improve neural structural repair and functional recovery. Recently, has been demonstrated that hippocampal injury-induced neurogenesis is one mechanism underlying endogenous repair following TBI. The aim of this study was to evaluate the neuro-regenerative

properties co-ultra PEALut (constituted by the association of palmitoylethanolamide (PEA), with the flavonoid luteolin (Lut)) in a mouse model of TBI until 7 days. TBI was induced in mice by the controlled cortical impact (CCI), one of the most common models of TBI; the mice were orally administered co-ultra PEALut (1mg/Kg) 1h after trauma and daily for 72h and 7d. A conspicuous neurogenesis was seen in mice 72h and 7d after trauma. Co-ultra PEALut treatment stimulated neuronal reconstitution process restoring the basal level of new neurons (by BrdU staining) and mature neurons (by doublecortin staining). Moreover this positive effect was associated with an important upregulation of neurotrophic factors (BDNF and NT-3), ultimately leading to improvement in memory recall on behavioral testing (Morris water maze test). Co-ultra PEALut could represent a therapeutic potential of augmenting the endogenous repair response for treating TBI.

Title: Effect of Nano Pulsed Laser Therapy (NPLT) on neurogenesis in a rat model of traumatic brain injury

Authors: *E. MOCCIARO[1,3], R. ESENALIEV[2], I. PETROV[2], Y. Y. PETROV[2], M. O. PARSLEY[1], D. S. DEWITT[1], D. S. PROUGH[1], M. A. MICCI[1];
[1]Anesthesiol., [2]Ctr. for Biomed. Engin., Univ. of Texas Med. Br., Galveston, TX; [3]Exptl. Biomedicine and Clin. Neurosci., Univ. of Palermo, Palermo, Italy

Abstract: Background: Traumatic brain injury (TBI) is a chronic disease that occurs after a head trauma and results in neurological dysfunctions. Neurobiology, in the last few years, has focused on the study of “neurogenesis” subverting the old thinking of the inability of the brain to replace neurons. It is now well accepted that in the adult brain, new neurons are continuously generated in the subventricular zone of the lateral ventricles and in the dentate gyrus of the hippocampus (an area of the brain involved in learning and memory and mostly affected by TBI). In previous studies we have shown that transcranial delivery of Nano-Pulsed Laser Therapy (SPLT), that combines the benefits of near-infrared laser light (808 nm) and of

ultrasound waves (generated with each short high-energy laser pulse within the tissue), is neuroprotective in a rat model of TBI (blast-induced neurotrauma; BINT). The aim of this work was to study the ability of NPLT to stimulate the proliferation and neuronal differentiation of hippocampal NSC in a rat model of TBI. **Methods:** For the *in vivo* studies, anesthetized adult male Sprague-Dawley rats were subjected to BINT or Sham injury. NPLT was applied 1 hour after BINT for 5 minutes. Proliferation of NSC in the hippocampus was studied using BrdU incorporation. In *in vitro* studies, hippocampal-derived NSC (Hipp-NSC), isolated from adult rat brains, were cultured and treated with nano pulse near-infrared laser light (NIL) alone or ultrasound (US) alone for 5 minutes. Proliferation was assayed using the MTS assay 1 and 2 days post-treatment. For differentiation studies, after US treatment, Hipp-NSC were plated onto poly-ornithine/laminin-coated plates and cultured for 7 days. The expression of neuronal (βIII-tubulin) and glial (GFAP) markers was assayed by immunofluorescence analysis. **Results:** NPLT increases the number of proliferating (BrdU+) Hipp-NSC in the hippocampus 7 days after BINT as compared to Sham rats. *In vitro*, US stimulation increased Hipp-NSC proliferation in a dose-dependent manner, and decreased the expression of neuronal markers but not of glial markers. NIL stimulation alone did not affect Hipp-NSC proliferation. **Conclusion:** Our results show that NPLT increases proliferation of NSC after BINT via generation of ultrasound waves, while NIL is likely to increase their neuronal differentiation.

Title: Combined stem cell therapy for white matter stroke

Authors: *D. R. MILLER[1], J. A. MAZZITELLI[1], I. L. LLORENTE[1], W. E. LOWRY[2], J. CINKORNPUMIN[2], S. T. CARMICHAEL[1];
[1]Neurol., [2]Mol. Cell Developmental Biol., UCLA, Los Angeles, CA

Abstract: Stroke is currently the most prevalent neurological disease. Up to 800,000 people a year experience a first-time stroke and few completely recover. Subcortical white matter stroke (WMS) constitutes up to 30% of all stroke subtypes and is the second leading cause of dementia. Using a subcortical WMS mouse model with a large infarct area that mimics the larger white matter lesions seen in moderate to advanced human white matter ischemia on immunodeficient

NSG mice, the model is amenable to human cell transplantation. Two different cell lines were simultaneously injected into the infarct area: human induced pluripotent stem cells (iPSCs) - Neuronal progentitor cells (NPCs) as well as human iPSCs - glial enriched progenitor cells (GEPsa). iPSC GEPs produce immature glial cells and are therefore suited for WMS treatment. iPS cells were virally transduced with fluorescent reporters. Cells were injected 7 days after the stroke during the subacute stage in one injection of 100 000 cell/µl using a 1:1 ratio of iPS-NPCs and iPS-GEPs (50 000 each cell/µl). Immunohistochemistical staining was used to track the location, proliferation, and migration of the cells. Additionally, motor behavior was assessed using two different tasks. The gridwalking test assesses gait by placing animals on a mesh floor and measuring precision of foot placement. The cylinder test assesses spontaneous forelimb use and motor control during exploratory behavior. Axonal tracing of the fluorescent reporter expression indicated an increase of axons in the infarct area coming from both endogenous neurons and from the transplanted NPCs. Behavioral data showed an increase in motor function for the stem/progenitor cell transplantation group relative to the stroke group. These studies suggest that the transplantation of stem/progenitor cells in a combined therapy in moderate to advanced white matter stroke, as seen in vascular dementia, may provide a therapy to promote white matter repair and recovery.

Title: Modified MSCs enhance functional recovery and neuroplasticity in chronic stroke via mechanisms involving angiogenesis, neurogenesis and anti-fibrosis.

Authors: *S. MARASINI, S.-W. YOO, D. CHANG, Y.-D. LEE, S.-S. KIM, H. SUH-KIM; Sch. of Medicine, Ajou Univ., Suwon, Korea, Republic of

Abstract: Stroke is a dominant cause of sensorimotor disability. Due to a limited or partial spontaneous functional recovery, stroke survivors often suffer from sensory-motor dysfunctions and various degrees of paralysis for several subsequent years. We previously reported that in acute phase of stroke, mesenchymal stem cells ameliorated stroke damage via several ways

involving immunomodulation and neuroprotection. In this study, we found that MSCs were unable to exert similar beneficial effect when transplanted in the chronic phase. This inability of MSCs in the treatment of chronic stroke could be attributed to the presence of unfavorable tissue environment. We genetically modified MSCs using adenovirus encoding several genes and transplanted in chronic stroke brain. Treatment with genetically modified MSCs significantly improved the behavioral and histological deficits when assessed with sensory-motor function tests and MRI respectively. Immunohistochemical analyses indicated that transplantation of those genetically modified stem cells rejuvenated the microenvironment of the damaged brain tissue and activated the quiescent endogenous neural stem cells in a transgenic mouse model where neural stem/progenitor cells can be detected as EGFP. We also obtained similar results in vitro studies indicating those cells exerted proangiogenic effects. Our genetically modified MSCs, satisfied the STEP3 guidelines suggested for preclinical studies by FDA and NIH (2014), might provide a potential therapeutic strategy for the treatment of chronic stroke.

Title: Cell maturity plays a role in cell survival following transplantation into the stroke-injured brain

Authors: ***S. PAYNE**[1,2], P. ANANDAKUMARAN[2], M. COOKE[2], B. VARGA[6], C. MORSHEAD[3,4], A. NAGY[6], M. SHOICHET[1,2,5];

Abstract: Worldwide 15 million people will suffer from a stroke each year, and up to two-thirds of survivors will experience life-long functional deficits. Despite the high prevalence of stroke, no clinical treatment exists that can replace lost cells and restore function. Recent regenerative

medicine strategies have focused on the transplantation of an exogenous population of cells to both provide local support to neurons of the brain and replace lost cells by integrating into the existing circuitry. While a promising strategy, most cells delivered to the brain fail to integrate into the host tissue, and usually perish. In order to address these issues, we investigated the use of a hydrogel delivery vehicle coupled with human induced pluripotent stem cell (iPSC)-derived cortical neural precursor cells (NPCs) of varying maturity for delivery into the rat stroke-injured brain. To increase cell survival following transplantation, our lab developed a hydrogel composed of hyaluronan and methylcellulose (HAMC) and demonstrated its ability to improve cell delivery and increase survival in models of spinal cord injury, retinal regeneration, and stroke. A population of human neuroepithelial cells (hNECs) was derived from iPSCs and then differentiated towards a neuronal lineage in vitro. Cell maturation over time was characterized using immunocytochemical staining for sox2, nestin, doublecortin, β-III tubulin, and MAP2. To determine the effect of cell maturity on survival in the stroke-injured brain, three time points of differentiation were chosen that displayed significant difference in neuronal marker expression in vitro: no differentiation (day 0), committed (day 16) and immature (day 32). First, the in vitro survival of these cells in HAMC was tested and it was determined that HAMC does not adversely affect cell survival. Next, rats were given a stroke in the motor cortex through injection of endothelin-1. One week following injury hNEC-derived cells were stereotactically injected into the injury site and, after 7 days, animals were sacrificed for immunohistochemical analysis. Both committed (d16) and undifferentiated (d0) neuronal cells had the highest number of cells present after 7 days, which was not due to differences in cell proliferation. The cell phenotype was also characterized for each group and it was found that the committed cell group contained the highest number of β-III tubulin positive cells. In ongoing studies, we are evaluating long-term cell survival and functional locomotor recovery.

Title: Gpr161 regulates the adult neural stem cell neurogenesis post-traumatic injury

Authors: *M. ABABON[1], K. RONDEL[2], S. TENG[3], J. ALDER[3], P. MATTESON[2], J. MILLONIG[2,3];
[1]Ctr. For Advanced Biotech. and Med. Rut, Piscataway, NJ; [2]Ctr. For Advanced Biotech. and Med. Rutgers Univ., Piscataway, NJ; [3]Rutgers University-RWJMS, Piscataway, NJ

Abstract: Brain damage from injury, stroke and neurodegenerative diseases is irreversible, with no known treatment. Adult neural stem cells proliferate in response to injury including traumatic brain injury (TBI). Others have shown that inhibiting this response worsens the injury, while enhancing it improves cognitive recovery. Stimulating these stem cells is then a possible therapeutic strategy for brain injury. Understanding the molecular mechanisms regulating their neurogenesis will help develop therapeutics to aid repair after injury. We demonstrated that Gpr161, an orphan G protein coupled receptor (GPCR) is expressed in these adult CNS stem cell populations. Our previous work has shown that Gpr161 regulates retinoic acid (RA) signaling, which is required during adult neurogenesis in the hippocampal subgranular zone (SGZ). We then tested the hypothesis that Gpr161 regulates adult neurogenesis. First, *in vitro* lentiviral knockdown and overexpression of Gpr161 directly in adult-derived neurosphere cultures were performed. Gpr161 knockdown does not affect proliferation (EdU labeling) but increased the number of apoptotic cells (activated caspase-3 staining) ($p < 0.001$).Gpr161 overexpression resulted in a significant increase in EdU+ cells ($p < 0.001$) and decrease in activated caspase-3 + cells ($p < 0.05$).*In vivo,* lentiviral knockdown of Gpr161 in the SGZ decreased EdU ($p < 0.01$) and Dcx (neuronal differentiation marker) ($p = 0.06$) staining, and increased activated caspase-3 staining post-TBI. On the other hand, Gpr161 overexpression increased EdU+ ($p < 0.001$) and Dcx+ cells post-injury. To investigate the signaling pathway, we hypothesize that Gpr161 regulates adult neurogenesis through crosstalk between cAMP and RA signaling: Gpr161 activates cAMP and subsequent protein kinase A (PKA) phosphorylation of RA receptor alpha (RARa), increasing RARa nuclear translocation and transactivation activity, and increasing downstream RA signaling. Through immunocytochemistry for phosphorylated RARa (phosphoRARa) in our neurosphere cultures, we observed a decrease in nuclear staining of phosphoRARa in the knockdown ($p < 0.001$) and an increase in the overexpression ($p < 0.001$). Our results demonstrate that Gpr161, possibly through downstream cAMP and RA signaling, is both necessary and sufficient to regulate neurogenesis of adult neural stem cells in response to injury. Currently, 50-60% of available drugs target GPCRs, making them the most important family of pharmaceutical targets. Based on our study, Gpr161 may be a potential pharmaceutical target to treat brain damage.

Title: The next generation of autologous bone marrow stromal cell transplantation for stroke; MSC2.0

Authors: *H. SHICHINOHE, C. TAN, S. OH, T. ABUMIYA, N. NAKAYAMA, K. KAZUMATA, K. HOUKIN;
Hokkaido Univ., Sapporo, Japan

Abstract: Background and purpose - Recent studies have elucidated that the bone marrow stromal cells (BMSCs) have therapeutic potential against stroke. Some clinical trials have been starting up in practice. We aimed to evolve the autologous BMSC transplantation for stroke into the next generation. **Materials and methods-** Human BMSCs were cultured with human platelet lysate (hPL) instead of fetal calf serum (FCS). They were labeled with superparamagnetic iron oxide (SPIO). Rat ischemic stroke models were made and $5x10^5$ cells were injected into the ipsilateral striatum stereotactically 7 days post-insult. Behavioral analysis, MRI for cell tracking, ^{18}F-FDG PET, and ^{123}I-Iomazenil SPECT were performed. The animals were sacrificed 5 to 8 weeks post-transplantation and histological analysis was performed. **Results-** There was no difference in the surface markers and cell proliferation between hPL and FCS. Although rotarod test showed that motor function deteriorated in rats suffered from permanent MCAo, BMSC-hPL transplantation enhanced recovery of the motor function, significantly. MRI demonstrated that SPIO-BMSCs aggressively migrated towards the lesion. Moreover, ^{18}F-FDG PET and ^{123}I-Iomazenil SPECT showed that BMSC transplantation promoted recovery of the glucose utilization and the binding potential of iomazenil in the peri-infarct area, respectively. Histological analysis supported the findings on MRI and showed the inclination for neural differentiation of donor cells. **Conclusion**- The hPL may be valuable and safe in expanding BMSCs. The application of bio-imaging techniques is also valuable for BMSC transplantation for stroke. Now we prepare the novel clinical trial against stroke, Research on advanced intervention using novel bone marrow stem cell (RAINBOW) study. The present results are translated into the optimal design of the trial.

Title: Stem cell-based therapies for white matter stroke: neuronal vs glial progenitor cell treatment

Authors: *I. L. LLORENTE[1], D. R. MILLER[2], J. A. MAZZITELLI[2], J. CINKORNPUMIN[3], W. E. LOWRY[3], S. T. CARMICHAEL[2];
[1]Neurol., Univ. of California , Los Angeles, Los Angeles, CA; [2]Neurol., [3]Molecular, Cell and Developmental Biol., UCLA, Los Angeles, CA

Abstract: Subcortical white matter stroke (WMS) constitutes up to 30% of all strokes subtypes. There is no medical therapy that promotes recovery in this disease. Human induced pluripotent stem cells (IPSs) have shown benefit in some pre-clinical stroke models, but have never been tested in white matter stroke. In this study two stem/progenitor cell lines were used: human iPS-neuronal progenitor cells (NPCs) and human iPS-glial enriched progenitor cells (GEPs)-this cell line is differentiated from an iPS-NPC line into an immature glial cell. iPS-GEPs may be uniquely suited to repairing the brain after white matter stroke, as they produces immature glial cells that may both stimulate the injured cerebral white matter, and differentiate into replacement cells that have been lost in the stroke. We tested the effects of iPS-NPC and iPS-GEP transplantation in NSG mice in a subacute stage (7 days post-stroke) and performed tissue, MRI and behavioral outcome measures up to 6 months after transplantation. Both stem/progenitor cell lines presented a good engraftment and survival after 2 months. iPS-NPCs and iPS-GEPs behave very differently after transplantation. iPS-GEPs migrate widely in white matter after transplant, white the iPS-NPCs remained clustered in the infarct area. iPS-GEPs treatment stimulated endogenous neurogenesis, defined as the production of new neurons and glial cells, at a level 4 times than that seen with iPS-NPCs. Both iPS-NPC and iPS-GEP treatment led to remyelination in the stroke area 2 months post-transplantation (assessed by MBP staining). Motor testing showed iPS-GEPs uniquely improved motor recovery after stroke compared to the stroke-alone and stroke+iPS-NPCs. This white matter repair can be tracked in the living animal in real time with MRI, providing a biomarker for brain repair with this cell line in this disease. These findings suggest that transplanted iPS- progenitor cells could potentially replace lost cells and circuitry in ways that are unique to the subtype of the iPS- progenitor: GEP vs NPC.

Title: To enhance the efficiency of delivery and engraftment of stem cells in a rat chronic stroke model

Authors: D.-R. CHO, D. CHANG, *H. K. SUH-KIM, G.-H. KIM, J. YOON, S.-S. KIM; Dept. of Anat., Ajou Univ, Sch. Med., Suwon, Korea, Republic of

Abstract: Mesenchymal stem cells (MSCs) have been reported to improve the recovery from ischemic stroke. However, MSCs have not been recognized clinically because their therapeutic effects were not demonstrated clearly, especially in chronic stroke patients. Moreover, routes and procedures for transplantation of MSCs have not been established. In our previous study, we showed that the transplantation of neurally-induced MSCs by introducing Neurogenin1 (MSC/Ngn1) dramatically improved the stroke outcome compared to the parental MSCs in an acute stroke model. In this study, we investigated whether MSC/Ngn1 cells were advantageous in a chronic stroke model compared to the parental MSCs. We also developed a transplantation procedure, which was less invasive than the intracranial injection while allowing an efficient engraftment of transplanted cells. We will discuss the results from experiments utilizing hyperosmotic agents to facilitate the infiltration of transplanted cells toward the infarcted area in a chronic stroke model. We propose that as a pre-clinical evidence, our results can be extended to the future clinical field for safe administration of functionally enhanced stem cells to the chronic stroke patients.

Title: Probing the stroke vasculome with endothelial progenitor cells

Authors: *S. A. ACOSTA, V. DE ALVARENGA GUEDES, J. LEE, Y. KANEKO, C. V. BORLONGAN;
Universty of South Florida, Tampa, FL

Abstract: Stroke is the number one cause of disability in the adult population and the fourth leading cause of death in the United States. Currently, the therapeutic interventions are limited with only one FDA- approved drug for ischemic stroke; namely tissue plasminogen activator or tPA. Recent novel findings revealed that cerebral endothelium can secrete molecules that may regulate disease processes following ischemic stroke; namely inflammation-associated vasculome. In the present in vitro study, we evaluated the therapeutic effect of endothelial progenitor cells on the inflammation-associated stroke vasculome. Briefly, human endothelial cells (HEN6) were prepared and grown for 10 days. qRT-PCR analysis of the expression of specific stroke vasculome genes revealed that under ambient condition, basal levels of BRM, IκB, foxf1, and ITIH-5 could be detected (compared to non-endothelial cells NT2N acting as control), but following oxygen glucose deprivation (OGD), there were significant elevations in all 4 inflammation-associated stroke vasculome genes (P's<0.05 vs. respective level of each gene in ambient condition). Interestingly, co-culture of HEN6 with human EPCs (1:1 ratio) during the OGD treatment significantly blocked the elevations of BRM, IκB, and foxf1 (P's<0.05 vs. respective level of each gene in OGD condition), but not ITIH-5 (P>0.05). Next, employing the knockdown/antisense technology, silencing the inflammation-associated stroke vasculome gene, IκB, as opposed to scrambled knockdown, blocked the EPC-mediated protection of HEN6 against OGD (P's<0.0 vs. OGD or OGD+ IκB knockdown). These results implicate a close interaction between EPCs and stroke vasculome, which appear to be therapeutically modulating the inflammatory insult after stroke.

Title: What role do immune cells play in preterm newborn brain injury?

Authors: *X. ZHANG[1,2], D. JABIN[1], K. ZHOU[3], A. NAZMI[1], A.-M. ALBERTSSON[1], K. SOBOTKA[1], C. ZHU[3], H. HAGBERG[1,4,5], C. MALLARD[1], X. WANG[1];
[1]Perinatal Ctr., Goeteborg, Sweden; [2]The Third Affiliated Hosp. of Zhengzhou Univ., Dept. of Pediatrics, Zhengzhou, China; [3]Ctr. for Brain Repair and Rehabil., Gothenborg, Sweden; [4]Sahlgrenska Acad., Dept. of Obstetrics and Gynecology, Gothenburg, Sweden; [5]King's Col., Dept. of Perinatal Imaging and Hlth., London, United Kingdom

Abstract: Background/Objective Infants with sepsis have increased incidence of cerebral palsy, white-matter injury, and brain abnormalities, and these are especially common in low birthweight newborn infants. It is now accepted that immune cells derived from the systemic circulation are a key feature of many diseases of the central nervous system. The aim of this study was to investigate whether or not immune cells contribute to the development of preterm brain injury using a mouse model of sepsis. **Methods** C57BL/6J (wild-type), T-cell receptor delta knockout (deltaTCRKO), and T-cell receptor beta knockout (betaTCRKO) mice were subcutaneously administrated sterile saline or lipopolysaccharide (LPS) (5 mg/kg) at postnatal day (PND) 2. Pups were sacrificed at PND12, and their brains were collected. Brain sections were stained for myelin basic protein, which is the brain white-matter marker. Motor function and anxiety were evaluated at PND 26-30, which is comparable to human teenage years, using Digi Gait analysis and an elevated plus maze. **Results** LPS causes the loss of brain white matter volume in wild-type mice and tissue loss in the betaTCRKO mice compared with their saline-treated groups. However, deltaTCRKO mice did not have any white-matter tissue loss after LPS compared to the controls. The different treatments and genotypes had no effect on anxiety behavior in the mice as determined with the elevated plus maze. Digi Gait analysis showed that there were increases in stance, stride, and stride length and a decrease in stride frequency after LPS treatment in the wild-type and betaTCRKO mice, but no such effect was observed in the deltaTCRKO mice. **Conclusions** 1. LPS causes sepsis-induced damage to the white matter in the

brain. 2. Gamma/delta T cells, but not alpha/beta T cells, contribute to sepsis-induced brain injury and mild motor abnormalities in early life of mice.

Title: Hyperactive effect of BrdU on an endothelin 1 induced stroke model of rat

Authors: ***H. H. CHAN**[1,2], J. COOPERRIDER[2], H. PARK[2], J. T. GALE[2], K. B. BAKER[2], A. G. MACHADO[2];
[2]Neurosciences, [1]Cleveland Clin., Cleveland, OH

Abstract: Introduction:
5-bromo-2'-dexoyuridine (BrdU) is often used to label newly-divided cells in the context of experimental research. However, several studies suggest that BrdU may produce unwanted side effects; including changes in animal behavior that might impact behavioral assays and healthy cell function in postnatal animals. In this study, we investigated the effect of BrdU on locomotor behavior as well as GABAergic and glutamatergic neurotransmission in a rodent model of ischemic stroke.
Method:
Ischemic strokes were induced in adult rats using 6 injections of 800pmol endothelin 1 into the left motor cortex. 50mg/kg BrdU was intraperitoneally injected over 5 days beginning 2 weeks post-stroke, while stroke control animals received only saline. Locomotor activity was evaluated by videotaping the rats in their home cages for 30 min, beginning one hour after BrdU injection. Rats were sacrificed 6 weeks after stroke induction. The glutamatergic and GABAergic tract integrity in the perilesional cortex and striatum was analyzed by immunohistochemistry.
Result:
BrdU-treated rats showed increase locomotor activity than control animals ($p<0.05$). Furthermore, there was a greater reduction of GABAergic signal in the perilesional cortex and striatum of BrdU-treated animals, while the magnitude of the observed reduction in

glutamatergic signal did not differ between BrdU-treated and untreated animals.
Conclusion:
These findings suggest that BrdU induces a hyperlocomotor effect in rats, possibly due to a selective degeneration of GABAergic innervation in both perilesional motor cortex and striatum.

Title: Comparison of the therapeutic effects of BMSCs derived from normal or T1DM rats and the role of T1DM-miR145 in the treatment of ischemic stroke

Authors: ***A. ZACHAREK**[1], C. CUI[3,2], M. CHOPP[2], P. VENKAT[2], T. YAN[2], R. NING[2], P. YU[2], J. CHEN[2];
[1]Neurol., Henry Ford Hosp., Novi, MI; [2]Henry Ford Hosp., Detroit, MI; [3]The Affiliated Hosp. of Xuzhou Med. Col., Xuzhou, China

Abstract: Background: Treatment of stroke with bone-marrow-stromal cells (BMSCs) derived from normal rats (Nor-BMSCs) at 24h after stroke onset improves functional recovery in non-DM rats, but not in type-one DM (T1DM) rats. In the present study, we tested the therapeutic effects and mechanisms of action when treating T1DM stroke with BMSCs derived from DM rats (DM-BMSCs) or Nor-BMSCs. The potential role of microRNA-145 (miR-145) in mediating the enhanced DM-BMSC treatment induced benefits was also investigated.
Methods: T1DM rats underwent 2 hours of middle cerebral artery occlusion (MCAo) and were treated 24 hours later with (n=8/group, 5×10^6 cells, i.v.) 1) Phosphate Buffered Saline (PBS); 2)

Nor-BMSCs; 3) DM-BMSCs; 4) DM-BMSCs with miR-145 over-expression (miR-145+/+DM-BMSCs); 5) Nor-BMSCs with miR-145 knockdown (miR-145-/-Nor-BMSC). Evaluation of functional outcome, vascular and white matter remodeling and microRNA expression, and in-vitro studies were performed.
Results: Compared with Nor-BMSCs or PBS control, treatment of stroke in T1DM rats with DM-BMSCs significantly improved functional outcome, decreased serum miR-145 expression, as well as increased expression of miR-145 target genes, adenosine triphosphate-binding cassette transporter 1 (ABCA1) and insulin-like growth factor 1 receptor (IGFR1). DM-BMSCs increased vascular remodeling, identified by cerebral vascular density and cerebral artery density, increased Bielschowsky silver (axon marker) and Luxol fast blue (myelin marker) expression in the ischemic border zone (IBZ) compared to PBS treated T1DM-MCAo rats. We also found that DM-BMSCs exhibited decreased miR-145 expression and increased BMSC survival compared with Nor-BMSCs. DM-BMSCs conditioned medium significantly decrease smooth muscle cell (SMC) and oligodendrocyte (OL) cell death compared to Nor-BMSCs conditioned medium in vitro. In vivo, miR-145+/+DM-BMSCs significantly increased blood serum miR-145 expression and decreased brain ABCA1 and IGFR1 expression as well as attenuated DM-BMSCs induced neurorestorative effects in T1DM-MCAo rats**.** miR-145-/-Nor-BMSC treatment of stroke in T1DM rats significantly improved functional outcome compared to PBS or Nor-BMSCs treated T1DM-MCAo rats, respectively.
Conclusion: Treatment of stroke in T1-DM rats with DM-BMSCs significantly increased neurovascular remodeling and improved neurological recovery compared with Nor-BMSC and PBS treated T1-DM rats. DM-BMSCs exhibit decreased miR-145 expression compared to Nor-BMSCs. The miR-145/ABCA1/IGFR1 pathway may contribute to the enhanced functional and neurorestorative effects of DM-BMSCs in T1DM stroke rats.

Title: Mesenchymal stem cell MRI tracking of intraarterial and intravenous therapy in cerebral ischemia.

Authors: *T. SOBRINO[1], B. ARGIBAY[2], E. LOPEZ-ARIAS[2], U. HIMMELREICH[4], C. CORREA-PAZ[2], I. LOPEZ-LOUREIRO[3], M. PEREZ-MATO[3], R. IGLESIAS-REY[3], J. RIVAS[5], J. CASTILLO[3], F. CAMPOS[3];

Inst. of Santiago de Compostela, Santiago de Compostela, Spain; [4]Biomed. MRI, Dept. of Imaging and Pathology., KULeuven, Leuven, Belgium; [5]Applied Physics Dept. - Campus Vida, Univ. de Santiago de Compostela, Santiago de Compostela, Spain

Abstract: Rationale: Mesenchymal stem cells (MSCs) represent a promising clinical therapy for ischemic stroke; however, critical parameters, such as the most effective administration route, remain unclear. Intravenous (i.v.) and intraarterial (i.a.) delivery routes, most frequently used for cell administration, have yielded varied outcomes across studies, presumably due to the unknown distribution of MSCs. In this regard, cell tagging by contrast agents (CAs), coupled with magnetic resonance imaging (MRI) analysis, represents a powerful technique to accomplish this challenge.
Objective: In this study, dextran-coated superparamagnetic nanoparticles (D-MNPs) were synthesized as CAs and validated for cell tracking in MRI. Secondly, the protocol for i.a. cell administration was optimized to improve efficiency and safety. The cellular biodistribution of MSCs after i.a. and i.v. administration was also investigated. Finally, the therapeutic effects of MSCs administered via both routes were compared in an animal model of ischemic stroke.
Methods and Results: MSCs labeled with D-MNPs were detected in the brain by magnetic resonance (MR) T_2*weighted images after i.a. injection (**Figure 1**). Transmission electron microscopy (TEM) showed cells not only in small cerebral vessels, but also in the brain parenchyma. However, after i.v. administration, cells were localized exclusively to the lungs. I.A. administration was not found to be more advantageous than i.v. administration, as cerebral edema and cerebral lesions increased following i.a. delivery.

Conclusions: i.a. administration represents an efficient strategy to engraft MSCs in the brain after an ischemic stroke; however, this method of delivery presents the risk of cerebral lesions, without greater benefits than i.v. after ischemic stroke.
Figure 1 Legend: MR T2* weighted images of one ischemic animal injected (IA) with 0.25x106 D-MNPs labeled MSCs at different time-points.

Title: The NINDS Repository: a large public collection of biomaterials for neurological disease research.

Authors: C. A. PEREZ[1], *S. G. HEIL[1], J. SANTANA[1], A. GREEN[1], A. AMBERSON[1], R. ZHANG[2];
[1]NINDS Repository, Coriell Inst. For Med. Res., Camden, NJ; [2]NIH-NINDS, Bethesda, MD

Abstract: Neurological disorders are a serious health concern that presents massive challenges to healthcare systems globally and their multifactorial pathological mechanisms are not completely understood. The National Institute of Neurological Disorders and Stroke (NINDS) - part of the USA National Institutes of Health (NIH)- sponsors the NINDS Repository which was established in 2002 at the Coriell Institute for Medical Research with the mission of supporting the identification of the genetic risks and causes for neurological disorders. The NINDS Repository collects blood samples as well as de-identified clinical data from a diverse patient population diagnosed with cerebrovascular diseases, Parkinsonism, motor neuron diseases, epilepsy, Tourette syndrome, Dystonia, and neurologically normal controls. The collection features patient-derived DNA and cell lines including many samples annotated with well-defined mutations. Since the NINDS Repository inception, biomaterials and clinical data from more than 46,000 individuals have been received. More than 38,000 unique samples are available through an online catalog at http://catalog.coriell.org/1/NINDS and since 2003 more than 40,000 samples have been distributed to investigators worldwide.The NINDS Repository aims to standardize the collection and processing across all samples while protecting patient safety and privacy. In an effort to ensure the quality of these valuable biological resources, the NINDS Repository has established well validated standard operating procedures (SOPs) for the collection, reception, processing, storage, and worldwide distribution of biological specimens. These SOPs include rigorous quality control assessments for each sample type. The NINDS Repository aims to provide rapid feedback to sample submitters regarding sample integrity and appearance at the time of receipt and status after completion of all required in-house processing. Essential to all this is a customized secure and highly user-integrated biobanking laboratory information management system, including sample-data association by cross-referencing with other NIH resources such as dbGaP.The development of such a centralized collection of human biospecimens and their associated de-identified clinical data allows the NINDS Repository to provide a vital resource for research designed to discover and validate genetic and molecular biomarkers relevant for the study and treatment of neurological disorders prevalent in our society.

Title: The effect of hyperbaric oxygen therapy on blood biomarkers and functional impairments following an ischemic stroke

Authors: *E. ROSARIO[1], S. KAPLAN[2], S. ROSENBERG[2];
[1]Res. Inst., Casa Colina Hosp. and Centers For Healthcare, Pomona, CA; [2]Casa Colina Hosp. and Centers for Healthcare, Pomona, CA

Abstract: Objective: While research suggests a benefit of hyperbaric oxygen therapy (HBOT) for neurologic injury, controlled clinical trials have not been able to clearly define the benefits. The objective of this study was to investigate the mechanistic and functional effects of hyperbaric oxygen therapy (HBOT) in the treatment of ischemic stroke.
Methods: Subjects were included in this study if they had suffered an ischemic stroke approximately 12-month ago and exhibited some functional impairments. Using a within subject design a baseline for current functional abilities was established over a 3-month period for all subjects. Each subject then received two 4-week periods of HBOT for a total of 40, 90-minute treatments over a 12-week period. Subjects completed a battery of assessments including cognitive, physical, speech, and quality of life measures, and had blood drawn for biochemical analysis of biomarker expression levels six times over the 9-month total duration of the study.
Results: We found improvements in cognition and executive function as well as physical abilities specifically, improved gait. Participants reported improved sleep and quality of life following HBOT treatment. We also saw changes in serum levels of biomarkers for inflammation and neural recovery. In the functional domains where improvement was observed following HBOT treatment, the improvements were maintained up to 3 months following the last treatment. However, the physiological biomarkers showed a pattern of more transient changes following HBOT treatment.
Conclusions: Findings from this study support the use of HBOT as a potential intervention following stroke, even after patients have plateaued in recovery. In addition these finding suggest the potential value of monitoring blood based inflammatory and neural markers as indicators of a physiological response to treatment.

Title: System biology reveals genomic-wide alterations linking brain trauma with neurological disorders

Authors: *F. GOMEZ-PINILLA[1,2,3], Y. MENG[1], X. YANG[1];
[1]Integrative Biol. and Physiol., [2]Brain Injury Res. Ctr., [3]Dept. Neurosurg., UCLA, Los Angeles, CA

Abstract: The complexity of the pathology of traumatic brain injury (TBI) involving multiple components poses pressing challenges for development of effective methods to diagnose the pathology and to develop therapeutics. We carried out a systems biology study using next generation sequencing and integrative genomics analyses to determine how TBI affects networks of genes that could characterize main events in the pathology, and how these signatures could serve as biomarkers of mild TBI (mTBI). We found that mTBI promoted reprogramming of important aspects of gene regulation (DNA methylation, transcript abundance, alternative splicing, and organization of genes in networks), which have the potential to alter the course of brain homeostasis and disease. We also analyzed leukocytes to trace homologies between central and peripheral events, and found homology between hippocampus and blood at gene-, pathway-, and network levels. Transcriptomic signatures in the hippocampus overlap with those in leukocytes, and that these signatures correspond to curated functional categories related to vascularity, cell integrity, and immune response. mTBI also elicited select methylomic changes in hippocampus and leukocytes that colocalized with the respective transcriptomic signature genes. We also found that mTBI promotes specific changes in the organization of genes in networks, under the regulatory control of key driver genes such as *Anxa2* and *Ogn*. Gene networks identified in our rodent model of mTBI overlapped with candidate causal genes in human gene-wide association studies (GWAS) for several neurodegenerative diseases such as Alzheimer's disease, bipolar disorder, autism, cognitive performance, PTSD, and psychiatric disorders, which are proposed long-term sequel of mTBI. The overall results support the potential of our novel unbiased strategy to diagnose and to treat mTBI. In addition, our approach has the promise to get insightful information to elucidate one of the most intriguing aspects of

mTBI, which is why many patients become vulnerable to a range of neurological disorders such as CTE, Alzheimer's, and psychiatric.

Title: Cardiovascular changes in the Wistar rats after the traumatic brain injury.

Authors: *V. C. CHITRAVANSHI[1], H. N. SAPRU[2];
[1]Neurolog. Surgery, Rutgers The State Univ. of New Jersey, Newark, NJ; [2]Neurosurg., Rutgers-NJMS, Rutgers State Univ. of NJ, Newark, NJ

Abstract: Cardiovascular complications often accompany traumatic brain injury (TBI) and their negative impact on the recovery of these patients is well documented. There are no reports in the literature regarding the alterations in brain areas controlling cardiovascular function in TBI. In this study we investigated the effects of mild (0.1-1 atmospheres), moderate (1.5-2.2 atmospheres) and severe (2.8-3.6 atmospheres) traumatic brain injury (TBI) on systemic blood pressure (BP), and heart rate (HR). Alterations induced by TBI in the responses elicited by chemical stimulation of the medial subnucleus of nucleus tractus solitarius (mNTS), caudal ventrolateral medullary depressor area (CVLM) and rostral ventrolateral medullary pressor area (RVLM) were also studied. The experiments were done in adult, male Wistar rats, weighing 325-350 gm, anesthetized with either isoflurane or urethane. Fluid percussion was applied to induce TBI. Application of severe, moderate and mild TBI resulted in 100%, 33% and 10% mortality, respectively. The rats were unconscious for 12.4 ± 3.9 min and 4.6 ± 1.6 min after application of moderate and mild TBI, respectively. Application of moderate and mild TBI resulted in apnea for 8.2 ± 2.8 and 1.8 ± 1.1 sec, respectively. The decreases in mean arterial pressure (MAP) elicited by application of moderate TBI were 29.8 ± 3.4, 14.2 ± 5.4, 29.1 ± 7.9, 42.6 ± 7.1, 43.3 ± 3.4 and 51.4 ± 10.2 (mmHg) after 5, 30, 60, 120, 240 and 360 min of injury, respectively. The decreases in HR elicited by moderate TBI were 30.6 ± 10.4, 72.4 ± 28.6, 84.3 ± 29.1, 98.1 ± 32.7, 103 ± 31.6 and 134.6 ± 54 (bpm), respectively, at the same time points. The decreases in MAP elicited by mild TBI were 24.8 ± 3.4, 9.6 ± 5.7, 20 ± 4.8, 38 ± 6.3, 38 ± 8.6 and 49.3 ± 5.1 (mmHg) at the same time points. HR decreases elicited by mild TBI at corresponding time points

were 25.8 ± 10.9, 65.6 ± 28.8, 80.8 ± 28.8, 79.3 ± 30.5, 85.3 ± 30.2 and 92.8 ± 29.6 (bpm), respectively. These results indicate that both moderate and mild TBI elicit decreases in MAP and HR.

Title: Changes of hippocampal autophagy and lysosome function after traumatic brain injury

Authors: E. LI[1], Y. YIN[1,2], G. SUN[1], I. ATTARWALA[1], G. BEGUM[1], H. YAN[3,4], K. KISELYOV[5], E. DIXON[3], *D. SUN[1,4];

Center, Univ. of Pittsburgh, Pittsburgh, PA; [4]Veterans Affairs Pittsburgh Hlth. Care Syst., Geriatric Research, Education, and Clin. Ctr., Pittsburgh, PA; [5]Biol. Sci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) triggers ER stress and toxic protein accumulation (unfolded, and misfolded, or protein aggregates). Impaired autophagy flux and lysosomal function decrease autophagic clearance of damaged organelles and toxic macromolecules and contribute to neuronal death after TBI. We previously reported that post-injury administration of docosahexaenoic acid (DHA) reduces ER stress and improves neurological function after TBI. In this study, we investigated whether administration of DHA improves autophagy flux in the hippocampus after TBI. TBI was induced by cortical contusion injury in Sprague Dawley rats, which received DHA (16mg/kg in DMSO) or vehicle DMSO (1 ml/kg) daily interperitonial administration with an initial dose at 15 minutes after the injury. Changes of autophagy and lysosomal function in hippocampal tissues at 3 days after TBI were evaluated by Western blot analysis. First, TBI triggered significant accumulation of ubiquinated protein (4.1 ± 1.2 fold, $p < 0.05$) and SQSTM1/p62 (sequestosome 1) expression (19.8 ± 9.1 fold, $p < 0.05$). In addition, there was a 3.8 ± 1.2 fold increase ($p < 0.05$) in LAMP1 (lysosomal-associated membrane protein 1) expression but significant decrease in cathepsin D protein level (0.41 ± 0.15 fold; $p <$

0.01) in the injured hippocampus. In contrast, no differences between the contralateral and ipsilateral cathepsin D protein expression ($p > 0.05$) were detected in the DHA-treated hippocampus. Moreover, there is a trend that post-injury DHA administration maintains a higher hippocampal LAMP1 and SQSTM1/p62 expression. Taken together, our study suggests that TBI activates autophagy but decreased hippocampal autophagy flux and lysosomal functions. Post-injury DHA administration reduces ER stress and improves lysosomal function, which could collectively facilitate tissue repair, demonstrating its therapeutic potential to ameliorate TBI-induced injury.

Title: Long-term functional outcomes are associated with synaptic and axonal loss in the hippocampus following traumatic brain injury: Relationship to neurodegenerative disease.

Authors: *L. E. COLLINS, A. ARULSAMY, J. TENG, C. VAN DEN HEUVEL, F. CORRIGAN;
Univ. of Adelaide, Adelaide, Australia

Abstract: Background: Traumatic brain injury (TBI) is a leading cause of disability and death worldwide, affecting as many as 54-60 million people annually. While much previous research has focused on impairment immediately following injury, TBI is also recognized as a significant risk factor for the development of dementia and Alzheimer's disease. Alarmingly, the risk of developing dementia has been shown to be increased at least 2-fold and 4-fold in patients who have suffered moderate and severe TBI, respectively. Despite growing awareness of the relationship between TBI and dementia, however, the brain mechanisms that may account for this relationship are currently unknown. Recently, it has been proposed that structural damage caused by axonal injury in TBI may interact with neuroinflammation in the pathogenesis of dementia.

Objective: The objective of the current study was to investigate the persistent post-TBI neuroinflammatory response and how it mediates the development of neurodegeneration and functional impairment.
Methods and Materials: Sprague-Dawley rats (n= 10/group) underwent either sham surgery or an experimental model of moderate-severe TBI. At 1-month and 3-months post-injury, rats completed a functional battery testing motor function, depressive-like behaviour, anxiety and cognition. Following testing, Western blot analysis was conducted to assess the protein expression of a range of inflammatory, neurodegenerative and oxidative stress markers.
Results: At both 1 and 3-months post injury, depressive-like behavior was significantly increased in TBI animals compared to shams. Additionally, at 3-months post-injury, TBI animals exhibited significant cognitive impairment. While markers of synaptic integrity and astrocyte expression both appeared to be significantly decreased in the frontal lobe at 1-month post-injury, this effect was no longer seen by 3-months post injury. Interestingly, while hippocampal tissue appeared normal, with the exception of an elevation of astrocyte expression, at 1-month post-injury, by 3-months post-injury, both synaptic and axonal integrity were reduced, and expression of the apoptotic marker active caspase-3 was significantly increased.
Conclusion: While transient changes to synaptic integrity of the frontal cortex are observed acutely following TBI, persistent neurodegenerative changes within the hippocampus do not appear until the chronic phase of injury, concomitant with the emergence of cognitive decline. Understanding specific brain mechanisms that may link TBI to dementia is a critical first step in developing novel treatment strategies for long-term complications of TBI.

Title: Decreased synaptic insulin responsiveness in the hippocampus of traumatic brain injured rats

Authors: *W. FRANKLIN[1], G. TAGLIALATELA[2];
[2]Mitchell Ctr. for Neurodegenerative Diseases, Dept. of Neurol., [1]UTMB At Galveston, Galveston, TX

Abstract: Alterations of insulin signaling in neurons have been linked to many disorders including Alzheimer's disease (AD). Decreased insulin signaling increases synaptic sensitivity to amyloid beta (Aβ), a toxic protein in AD, thus contributing to the cognitive decline that characterizes this neurodegenerative disorder. Traumatic brain injury (TBI) is a risk factor for later development of AD, although the mechanisms contributing to this increased risk are unknown. To determine whether decreased insulin responsiveness in TBI animals is playing a role in the synaptic vulnerability to AD pathology, we developed a method for studying the insulin responsiveness at the synaptic level. We isolated functional synaptosomes from frozen rodent brain tissue and exposed them to insulin in the presence of ATP to detect insulin receptor (IR) phosphorylation (activation). Using this method coupled to Western blot analysis, we were able to detect insulin-driven phosphorylation of the synaptic IR, proportionate to the known extent of insulin responsiveness/resistance of the input samples. After optimizing this method, we analyzed synaptosomal insulin responsiveness in the hippocampi of SHAM and TBI animals that underwent a lateral fluid percussion injury. Our results indicate that there is decreased insulin responsiveness 2 days post injury that is exacerbated by 7 days, primarily in the hippocampus of the injured hemisphere. In conclusion, we were able to detect acute dysregulation in synaptic insulin responsiveness in the brain of rats after traumatic brain injury warranting further experiments to look at chronic alterations and downstream elements. These initial results further suggest that synaptic insulin resistance may occur as a consequence of TBI, a condition that is know to sensitize synapses to the dysfunctional impact of Aβ oligomeric species and thus increase susceptibility to AD-related cognitive decline.

Title: A novel quantitative multianalyte immunoassay to detect peripheral blood biomarkers following traumatic brain injury

Authors: M. ANDERSON, *G. HICKEY, I. O'BRIEN, P. YOUNGE, L. LEONG;
Bio-Techne Inc, Minneapolis, MN

Abstract: Traumatic Brain Injury (TBI) is a worldwide health concern that affects about 10 million people globally every year. The majority of TBI cases are classified as mild, and many of these individuals do not exhibit any visible physical signs of head trauma, making it difficult to

identify TBI. Early detection of TBI is crucial in order to limit the primary and secondary brain damage that may occur following head trauma. Thus, there is a need for the early detection and measurement of circulating biomarkers that reflect a traumatized state. Research has been conducted to identify potential markers of TBI in cerebral spinal fluid (CSF). However, because of the invasiveness in obtaining CSF samples, CNS-specific markers of TBI in peripheral blood need to be discovered. Unfortunately, most standard immunoassays do not have the sensitivity to detect markers of neural cell damage and neuroinflammation in the peripheral blood.
The Simple Plex™ (ProteinSimple) assay is a novel, quantitative, multianalyte immunoassay platform that delivers high precision and accuracy while using less than 25 μL of sample. This highly sensitive platform measures up to four analytes simultaneously from a single, small sample with results generated in just over an hour. The microfluidic-based system allows parallel single analyte quantification and reduces the non-specific antibody interactions often observed in other traditional multiplex platforms. The whole process is automated within a single cartridge, thus removing potential user variability. The Simple Plex™ assay was employed to look at several proposed TBI markers in serum samples from individuals diagnosed with TBI. Our study suggests that this platform may represent a highly efficient method for detecting and quantifying markers of neural cell damage and neuroinflammation in the peripheral blood following TBI.

Title: Integrated genomic approaches identify changes in interconnected networks and major pathways following traumatic brain injury in young and aged APOE3 and APOE4 mice

Authors: *E. L. CASTRANIO[1], A. MOUNIER[1], C. M. WOLFE[1], J. SCHUG[2], N. F. FITZ[1], R. KOLDAMOVA[1], I. LEFTEROV[1];
[1]Envrn. and Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept. of Genet., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) is a leading cause of death and disability in army personnel and general population. Expression of human Apolipoprotein E (APOE) modulates inflammatory response in an isoform specific manner, with APOE4 isoform eliciting a stronger pro-inflammatory response, suggesting a possible mechanism for worse outcome following TBI and in AD. We hypothesized that inheritance of APOE4 would lead to worse cognitive outcome and higher inflammatory gene expression following TBI with age as an additive factor for worsened outcome. This study uses mice with targeted replacement of endogenous *Apoe* by human cDNA for expression of APOE3 (E3) and APOE4 (E4). Young adult, 3 month old, and aged, 9 month old mice, received either a controlled cortical impact (CCI) brain injury or a craniotomy in the left hemisphere. In young mice, TBI groups performed significantly worse than sham ($p<0.05$) in Morris Water Maze (MWM), regardless of genotype. In aged mice, performance in MWM was significantly different between sham and TBI groups in E3, but not in E4 mice. To investigate the molecular mechanisms underlying this effect, we performed genome-wide differential gene expression analysis using RNA-seq on libraries generated from cortices and hippocampal tissues of mice from all groups and applied weighted gene-coexpression network analyses (WGCNA). In the co-expression networks, we were most interested in WGCNA modules that were significantly differentially expressed between groups, such as sham vs TBI, E3 vs E4, or young vs aged. The module most significantly related to TBI is brown, with a consensus for gene up-regulation at $p = 1e\text{-}10$. The annotation in the module demonstrated genes strongly enriched for GO terms “Immune response” and “inflammatory response”. Hub genes are the most highly connected genes within the module network, and of interest were Tyrobp, Clu and Axl. A representation of gene connectivity for the brown module, was built using Cytoscape and included *Trem2, Cx3cr1* and *Abca1*. We validated these genes using RT-QPCR expression assays, and confirmed that TBI caused significant upregulation of their gene expression. The results of our study indicate that TBI worsens cognitive deficits in an age specific manner, with E4 mice displaying a basal cognitive deficit that becomes more apparent in aged mice. Additionally, TBI increases expression of inflammatory genes related to a microglial response to injury.

Title: Acute ischemic stroke was not associated with circulating interleukin-1 and tumor necrosis factor, but did result in post-stroke depression

Authors: S. NORTON[1], R. GLASS[1], S. MANN[1], M. MOCCIO[2], A. ZIMMERMAN[3], N. FIEDLER[4], R. CONTRADA[1], M. MENZA[3], H. LEVENTHAL[1], J. MCKINNEY[6], *A. W. KUSNECOV[5];

Abstract: Acute ischemic stroke (AIS) has been associated with elevations in circulating inflammatory cytokines. In addition, a subset of AIS patients can develop clinically significant depression (post-stroke depression [PSD]), which can compromise recovery and increase recurrence of stroke. The cytokines, interleukin-1β (IL-1β), tumor necrosis factor α (TNFα), and interleukin-6 (IL-6) are known to have neuromodulatory effects, including the induction of behavioral changes similar to depressive symptomatology. Moreover, increased circulating levels of these cytokines – in particular, IL-6 - have been observed in depressed individuals. Therefore, it is possible that the development of PSD may similarly be associated with increased levels of inflammatory cytokines. In the current study, we recruited 25 AIS patients and assessed executive cognition, clinical depression, and circulating IL-1β, TNFα and IL-6. Each of these variables was measured at three time points following admission for AIS: (i) 1-2 days, (ii) 5-7 days, and (iii) 90 days. Depression was assessed throughout using the Hamilton Depression Scale and Beck Depression Inventory, as well as a structured diagnostic interview for depression (SCID) on Day 90. Cognitive function, including executive function, was measured using the RBANS, Stroop, and Trail Making Tasks. Additional repeated measures of functional and neurological status were obtained using the modified Rankin Scale (mRS) and the National Institute of Health Stroke Scale (NIHSS). Only non-aphasic patients who scored mild-to-moderate on the NIHSS were included. Of those patients that completed all three time points (n=22), seven showed detectable levels of plasma IL-6 within seven days of AIS. A further three patients (13.6%) showed evidence for PSD at Day 90, but none of these had detectable IL-6 at any time point. Contrary to expectations, no patients, at any time point, had detectable plasma

levels of TNFα or IL-1β. Based on evidence that IL-6 may be neuroprotective in animal studies of stroke, the current findings, although based on a small cohort of patients, lend themselves to the novel hypothesis that failure to generate plasma IL-6 elevations after AIS is associated with PSD. Analysis of cognitive and neurological functioning data is ongoing to determine if this relationship holds for other parameters.

Title: A new model to determine the specific and synergetic effects of comorbidities on stroke treatment and outcome

Authors: *T. I. NATHANIEL[1,2], T. COCHRAN[2], J. CHAVES[2], E. FULMER[2], C. SOSA[2], M. FREDWALL[2];
[1]Biomed. Sci., Univ. of South Carolina, Greenville, SC; [2]Univ. of South Carolina Sch. of Med., Greenville, SC

Abstract: Background. Recombinant tissue plasminogen activator (rt-PA) is an effective treatment for patients with acute ischemic stroke. However, the proportion of patients with a stroke treated with rt-PA is incredibly low. This is partly attributed to the role of comorbid conditions as the cause or the consequence of acute ischemic stroke. The specific clinical effect and relationship between comorbidities in stroke, rt-PA treatment and outcome is not known. We investigate this issue in the current study.
Method. First, we characterized comorbidities in an acute ischemic stroke population from a stroke registry, and identified non-cerebrovascular risk factors (comorbidities) that differentiate rt-PA receiving and non-receiving patients. Next, we used matlab programing to develop a new model to determine specific clinical relationships between comorbidities, rt-PA treatment and outcome.
Result. Our model identified how individual and synergetic effects of specific comorbidities (carotid stenosis, congestive heart failure, history of stroke or severity among others) significantly ($P<0.001$) affect rt-PA use and treatment outcome in an individual patient and the stroke population.

Conclusion. Treatment of patients with acute ischemic stroke with rt-PA is dependent on several exclusion criteria. For the first time, we developed a model that can be used to establish the specific and synergetic clinical effects of comorbidities in the use of rt-PA and outcome. This model will play a key role in helping clinicians to make clinical decision in the use of rt-PA and expand its benefits.

Title: Deficiency of mir-126 exacerbates white matter damage and blood-brain barrier dysfunction after stroke

Authors: *P. YU, C. CUI, M. CHOPP, A. ZACHAREK, P. VENKAT, J. CHEN;
Henry Ford Hosp., Detroit, MI

Abstract: MicroRNAs (miRs) are small non-coding RNA molecules, which regulate gene expression and translation. MiR-126 is primarily expressed in endothelial cells (ECs) and plays a crucial role in regulating the function of ECs, angiogenesis and vascular integrity. In central nervous system (CNS), ATP binding cassette subfamily A member 1 (ABCA1) mediates cholesterol transport, and promotes vascular and axonal/white matter (WM) remodeling after stroke. We hypothesize that inhibition of miR-126 decreases ABCA1 expression, and increases neurological functional deficit, neurovascular and WM damage after stroke. Adult specific conditional EC miR-126 knockout (miR-126$^{EC-/-}$) mice and floxed non miR-126 knockout control (miR-126$^{fl/fl}$) mice were subjected to permanent distal middle cerebral artery occlusion (dMCAo) and were euthanized 4 days after dMCAo. A battery of neurological and cognitive functional tests was measured. To test if miR-126$^{EC-/-}$ regulates vascular and WM changes,

Bielschowsky silver (an axon marker) and Luxol fast blue (a myelin marker), tight junction protein ZO-1, vascular endothelial growth factor (VEGF) and albumin staining were performed. Western blot and PCR were employed to measure miR-126 targets expression in the ischemic brain. Primary cortical neuron (PCN)-axonal outgrowth effects of miR-126 were measured in vitro. miR-126$^{EC-/-}$ mice exhibit significantly increased neurological and cognitive functional deficits after stroke measured by foot-fault, modified neurological severity score and cognitive and odor tests compared to miR-126$^{fl/fl}$ stroke mice. MiR-126$^{EC-/-}$ mice exhibit decreased brain miR-126 and ABCA1 gene expression and significantly increased miR-126 targets, e.g. phosphoinositol-3 kinase regulatory subunit 2, sprouty-related, EVH1 domain containing 1, Monocyte Chemotactic Protein-1 and VEGF protein levels in the ischemic brain compared to miR-126$^{fl/fl}$ stroke mice. MiR-126$^{EC-/-}$ mice also showed significantly decreased axon, myelin density and ZO-1 expression in the ischemic boundary zone and increased BBB leakage compared to WT miR-126$^{fl/fl}$ control stroke mice. In vitro, PCN coculture with mouse brain endothelial cells (BECs) significantly increases axonal outgrowth. However, knockdown of miR-126 in BEC significantly decreases axonal outgrowth compared to coculture with BEC group. Deficiency of endothelial cell miR-126 increases BBB leakage and WM/axonal damage which may contribute to functional deficits after stroke. Concomitant reduction of ABCA1 and upregulation of miR-126 targets may contribute to miR-126 deficiency-induced BBB and WM/axonal damage in ischemic brain.

Title: Late stage transient global ischemia causes secondary cell death, characterized by a surge in inflammatory and apoptotic cells, to cerebellum and heart of rhesus macaque monkeys

Authors: *S. MASHKOURI, S. ACOSTA, D. NWOKOYE, Y. KANEKO, C. BORLONGAN; Dept. of Neurosurg. and Brain Repair, Univ. of South Florida, Tampa, FL

Abstract: Stroke is the number one cause of disability and co-morbidities in the adult population and the fourth leading cause of death in the United States. The major pathological consequences of stroke are neurological effects proximal to the infarction area, however, distal areas from the original injury may present pathological manifestations that further increase the risks of co-

morbidities which complicate the patient's health. Transient global ischemia (TGI) model was induced by clipping the arteries originating from the aortic arch. Previously we demonstrated that our TGI model in adult Rhesus macaques (Macaca mulatta) results in marked neuronal cell loss in the hippocampal region, specifically the cornu Ammonis (CA1) region. In the present in vivo study, we evaluated the vulnerability of the cerebellum and the heart for the potential propagation of secondary injuries in late stage TGI model in rhesus macaque monkeys. After 6 months post-injury, the brain and the hearts were harvested and analyzed using immunohistochemical techniques to target infiltrated lymphocytes, apoptosis, and cell death of both cerebellar neurons and cardiac myocyte cells. Unbiased stereological quantification showed significant purkinje cells loss in lobule III and lobule IX of the cerebellum relative to control cerebellum (*p's<0.05). Analysis of gliosis, TNF-alpha, and tunnel revealed significant increase expression in the white matter of lobule III and IX respectively compared to control cerebellum (*p's<0.05). Analysis of the heart revealed significant elevation of activated infiltrated lymphocytes, TNF-alpha, and apoptosis relative to control heart (*p's<0.05), which is indicative of cardiac myocyte damage. The marked increase in inflammatory and apoptotic markers in the cerebellum and the heart suggests a pathological link between the detrimental effects of distal secondary injuries and the development of chronic neuropathological manifestation and cardiac dysfunction. These results further extend our understanding on the propagation of chronic secondary injuries after TGI, highlighting the need to develop therapeutic interventions targeting the brain, as well as the heart, in an attempt to fully address both stroke and its related co-morbidities.

Title: Brain and heart interaction after cerebral ischemic stroke-miR-126 effects

Authors: *J. CHEN, C. CUI, X. YANG, A. ZACHAREK, J. XU, P. YU, P. VENKAT, M. CHOPP;
Henry Ford Hosp., Detroit, MI

Abstract: Background: The incidence of cardiovascular diseases are approximately three times higher in patients with neurological diseases than in patients without neurological diseases. Neurogenic stress cardiomyopathy is a well-known syndrome complicating the early phase after an acute brain injury, potentially affecting clinical outcomes. Brain injury can induce cardiac dysfunction. In this study, we investigated mechanisms underlying the effect of the brain on the heart. MiR-126 is emerging as an important factor in the pathogenesis of cardiovascular diseases and stroke. We hypothesize that the decrease of miR-126 after ischemic stroke may mediate "brain and heart interaction", and thereby contributes to cardiac dysfunction after ischemic stroke. Methods: Wild type and miR-126-/- mice were subjected to distal middle cerebral artery occlusion (dMCAo) (n=10/group). Cardiac hemodynamics and function were measured by transthoracic Doppler echocardiography. Mice were sacrificed at 28 days after dMCAo. Immunostaining in heart tissue and microRNA measurements were performed. Results: Mice subjected to stroke exhibited significantly decreased cardiac ejection fraction and increased myocyte hypertrophy and fibrosis as well as decreased cardiac capillary density compared with normal non-stroke mice ($p<0.05$). Stroked mice also exhibited significantly increased heart inflammation and oxidative stress, measured by infiltrating macrophages, 4-hydroxy-2-nonena, NADPH oxidase-2, vascular cell adhesion molecule-1 (VCAM-1), and transforming growth factor β expression compared to non-stroke animals ($p<0.05$). To elucidate the mechanisms underlying cardiac abnormality after stroke, miRNA expression and their target genes were measured. Stroke significantly decreased serum-exosome and heart tissue miR-126 expression, and thereby increased the miR-126 target gene Spred-1, VCAM-1 and monocyte chemotactic protein-1 gene and protein expression in heart tissue compared to non-stroke mice. In addition, specific conditional-knockout endothelial cell miR-126 (miR-126EC-/-) stroke mice exhibited significantly exacerbated heart dysfunction, identified by decreased ejection fraction and shortening fraction, and increased cardiomyocyte hypertrophy and cardiac fibrosis compared to non-miR-126 knockout control (miR-126fl/fl) mice ($p<0.05$). Conclusion: Stroke decreases miR-126 and increases their target gene expression as well as induces cardiac dysfunction. Decreasing miR-126 after brain ischemic stroke may mediate adverse "brain and heart interaction", and thereby contributes to cardiac dysfunction post stroke.

Title: Circulating microRNA as a biomarker of epileptogenesis and epilepsy in the rat model of temporal lobe epilepsy

Authors: *K. SZYDLOWSKA, K. NIZINSKA, A. BOT, K. LUKASIUK;
Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Epilepsy frequently develops as a result of brain insult, ex. brain injury, stroke, inflammation or status epilepticus, however currently there are no tools allowing us to predict which patients suffering from trauma will eventually develop epilepsy or how severe it is going to be. In recent years small non-coding RNAs are proposed as biomarkers for neurological diseases. Particularly microRNAs are interesting candidates, as several of them were described as changing its levels in the brain of epileptic patients and in epilepsy animal models. There is evidence suggesting that microRNAs levels are altered also in the plasma of epileptic subjects, making them attractive candidates for peripheral biomarkers of epilepsy. This study was conducted to evaluate usefulness of plasma miRNAs as biomarkers of epileptogenesis and epilepsy. In our studies we used the rat model of temporal lobe epilepsy. The status epilepticus was evoked by 25 min stimulation of the left lateral nucleus of amygdala (100-ms train of 1-ms biphasic square-wave pulses; 400 μA peak to peak, delivered at 60 Hz every 0.5). Animals were continuously video and EEG monitored for 6 months to detect spontaneous seizures. Blood was collected at 14, 30, 60, and 90 days after stimulation from tail vain. Blood plasma was separated and processed using Affymetrix miRNA 4.1 array strip microarrays. We have compared miRNA levels between sham operated (n=12) and stimulated animals (n=15); $p<0.01$ was used as a cut off. We have detected 14 miRNA differentiating between sham operated and stimulated animals at 14 days, 6 at 30 d, 16 at 60d, and 11 at 90 days. We have also compared the miRNAs levels between animals with high (30-70 seizures/day) and low (1-5 seizures/day) number of seizures. We have found differences in levels of 11 miRNA at 14 d, 7 at 30 d, 11 at 60 d and 8 at 90 d (at $p<0.01$). Levels of miRNA in plasma are altered following epileptogenic stimulus and differentiate between animals with frequent and rare seizures. miRNA may become a useful peripheral biomarker of epileptogenesis/epilepsy as well as severity of the disease. This work was supported by the FP7-HEALTH project 602102 (EPITARGET) and Polish Ministry of Science and Education grant W19/7.PR/2014.

Title: Subarachnoid hemorrhage triggers acute apnea in mice

Authors: ***E. V. GOLANOV**, G. BRITZ;
Neurosurg., Houston Methodist Hosp., Houston, TX

Abstract: Rupture of cerebral aneurysm leading to acute accumulation of blood within the subarachnoid space is known as subarachnoid hemorrhage (SAH). About 44% of SAH victims die within the first few hours following the rupture. Despite the significant progress in repairing ruptured aneurysm, the mortality following SAH remains high. While numerous studies addressed cellular and molecular damages following SAH, relatively little is known of the early events following the aneurysm rupture. We hypothesized that early events following SAH could play a crucial role in the post-ictus mortality. We explored changes in AP, heart (HR) and respiratory rate (RR), regional cerebral blood flow (rCBF) and intracranial pressure (ICP) immediately following the SAH. In spontaneously breathing C57BL adult male mice under isoflurane anesthesia, SAH was triggered by perforation of Willis circle with monofilament. After one hour of observation animals were euthanized, brains harvested, and hemorrhage was scored. Immediately following the perforation ipsilateral rCBF dropped by 75±15%, AP increased by 8±2 %, ICP increased by 102±12 %, cerebral perfusion pressure decreased by 42±7%, and HR increased by 6±3%. Immediately following the perforation, 95% of all animals (117 out of123) demonstrated dramatic decrease in RR by 69±12%, which progressed to apnea in 73% of cases. In animals, which experienced complete respiratory arrest for over 2 minutes, mechanical chest stimulation was required for “resuscitation”. Once the spontaneous respiration was reinstated, animals regained regular RR. This simple maneuver decreased mortality from 46% to 7%. No correlation between the SAH score and RR suppression was observed. No changes in RR or any other parameters were observed in animals with “sham” perforation. The lack of correlation between the size of hemorrhage and very short latency to apnea suggests the neurogenic origin of the phenomenon. Dura mater is heavily innervated by the nerve fibers endowed with TRPV1 ion channels. One hour before the perforation, capsazepine (Czp), blocker of TRPV1 channels (2 μg in 2 μl of aCSF) was injected intraventricularly. Czp failed to modify baseline parameters and acute autonomic responses to SAH. Data reveal severe respiratory

abnormalities in response to SAH. Very short latency of the apneic response and its independence from the size of the hemorrhage strongly suggest neurogenic origin of apnea. Failure of Czp to modify respiratory and other autonomic responses to SAH evidences against involvement of TRPV1 channels. Our data suggest that acute respiratory dysfunction following the ictus could be causative of the high mortality following SAH.

Title: Laminar profile underlying the propagation of CSD

Authors: *D. RAMOS[1], S. GARCIA[1], Y. FROMETA[2], J. HOW[3], J. RIERA[1], Y. MORI[4]; [1]Biomed. Engin., [2]Florida Intl. Univ., Miami, FL; [3]UCSD, San Diego, CA; [4]Univ. of Minnesota, Minneapolis, MN

Abstract: Cortical Spreading Depression (CSD) is a wave of complete neuronal depolarization that usually lasts for one to two minutes and can silence brain activity for a certain time after its occurrence. Sixty years after the initial discovery by Antonio Leão, the mechanisms for CSD propagation are still elusive. In this research project, we perform multisite recording of electric potentials to study laminar features of relevance for the CSD propagation in the cerebral cortex of rats. We perform two craniotomies on the same brain hemisphere. We drop 20-40 µL of potassium acetate (1M) on one of the craniotomies, which induces a CSD. Using an acute silicon-based electrophysiological probe, we record electric potentials from the other craniotomy while the CSD propagates through it. We perform spike sorting to determine the silencing patent of single neurons. Current source density analysis allows us to investigate disruptions in the spatial profiles of postsynaptic potentials. We perform laminar comparison of spiking rates and postsynaptic activities before, during and after a CSD. We have consistently obtained in our results a laminar propagation of CSD as can be seen in Figure 1, which shows a negative current from the supra granular layer to the infra granular layer during the CSD event. In addition, we have observed different spiking rates during the different phases of CSD as its represented in Figure 2. It is believed that with a better understanding of the mechanisms for CSD propagation is critical to create effective therapeutic strategies for related brain disorder such as epilepsy,

stroke and migraine. Our data will be useful in the future to calibrate a computational model, which is currently being developed at the University of Minnesota.

Title: Changes in the extracellular matrix following ischemic stroke in the rat

Authors: *E. M. ANDREWS, A. MEIER, T. BRUGMAN, M. PATEL;
Midwestern Univ., Downers Grove, IL

Abstract: Ischemic strokes results in immediate inflammation and neuronal cell death. The amount of functional recovery that is seen following a central nervous system (CNS) injury is limited. Recent studies have shown that chondroitin sulfate proteoglycans (CSPGs) contribute to the lack of functional plasticity due to their inhibition of neurite outgrowth. Previous research indicates that there is limited neuroplasticity (neurite outgrowth) from the uninjured contralateral hemisphere and this neuroplasticity can be enhanced with various therapeutic treatments (anti-nogo, adult human bone marrow stem cells, etc.). Astrocytes and microglia are involved in the post-ischemic inflammatory response, and contribute to the changing extracellular matrix (ECM) by both producing CSPGs and producing enzymes that can alter CSPGs and the ECM in the ischemic core and penumbra region. Alterations to CSPG expression, the ECM and the glial response may be altered in the contralateral sensorimotor cortex to allow for the limited neuroplasticity seen after injury.
In the present study, we investigated glial activation and CSPG expression in the sensorimotor cortex after an ischemic stroke in the rat, both ipsilateral and contralateral to the lesion 3, 7, 14 and 28 days post stroke. Both neurocan expression and GFAP expression increased at 14 days in the ipsilateral sensorimotor cortex. Total neurocan expression is significantly increased 14 days post stroke in the ipsilateral sensorimotor cortex as compared to control. GFAP expression (indicative of activated astrocytes) is significantly increased in the sensorimotor cortex surrounding the lesion at 14 days post stroke as compared to control. Both aggrecan and CD11b (microglia) expression are stable at 3 and 14 days post stroke as compared to controls. Western blot analysis of CSPG expression at 7 days and 28 days post injury is under investigation. CSPG distribution at all time points (3 day, 7 day, 14 day, 28 days post injury) is being analyzed via immunohistochemistry. These results may help pinpoint the best time and location of treatment to help restore function following an ischemic stroke.

Title: Memantine therapy as a tool to break the link between brain injury and Alzheimer disease: a preclinical study in humanized amyloid-beta mice

Authors: E. E. ABRAHAMSON[1,3], L. SHAO[1], S. CULVER[2], W. PALJUG[1], X. MA[2], C. E. DIXON[2], *M. D. IKONOMOVIC[1,3];

Abstract: Traumatic brain injury (TBI) results in brain accumulation of amyloid-β (Aβ) peptides and neuronal degeneration which could contribute to the risk of developing Alzheimer's disease (AD) later in life. Memantine is a clinically well-tolerated, moderate-affinity, noncompetitive glutamate receptor antagonist proven beneficial in excitotoxicity models and is one of the few currently available therapies for AD, but its utility in ameliorating Aβ- and glutamate-related excitotoxic neurodegeneration and in improving long term functional outcome after TBI has not been explored. We measured human Aβ concentration and assessed histological and behavioral outcomes after controlled cortical impact (CCI) injury in human Aβ (hAβ) knock-in mice treated with memantine hydrochloride (memantine) or vehicle (saline). Adult hAβ mice received memantine (2.5, 5, 10 mg/kg) or vehicle by intraperitoneal injection daily for 3 weeks starting 1 hr after CCI injury (depth = 1.6 mm; velocity = 6.0 m/s). Relative to naïve mice, brain concentrations of Aβ1-42 and Aβ1-40 were elevated in CCI/vehicle group. The 5 mg/kg dose of memantine significantly lowered Aβ1-42 concentration in cerebral cortex ipsilateral to injury ($p<0.01$) and reduced cortical lesion size compared to the CCI/vehicle group. CCI-induced reductions in hippocampal synaptic densities (regions CA1 and CA3) were moderately attenuated with the 2.5 and 5 mg/kg doses. CCI-induced impairment of vestibulomotor function was not improved by memantine on days 1-5 after injury, while all doses of memantine moderately attenuated deficits in novel object recognition test performance on days 9 and 10 after injury. Memantine administered at a dose of 5 mg/kg significantly ameliorated CCI-induced spatial memory impairments on the Morris water maze acquisition and probe tests (both tests $p<0.05$) on days 14-20 after injury. Collectively, these results demonstrate neuroprotective and behavioral recovery-enhancing effects of daily treatment with 5 mg/kg memantine over three weeks after severe TBI. These results provide preclinical support for use of memantine to improve outcome after TBI and to reduce the risk for AD.

Title: Analyzing chronic stroke white matter lesions using a HARDI streamline database

Authors: *T. J. HERRON[1], N. DRONKERS[3,4,5], A. U. TURKEN[2];
[1]Neurology, Res., [2]Res. & Develop., VA Northern California Hlth. Care Syst., Martinez, CA; [3]Ctr. for Aphasia & Related Disorders, VA Northern California, Martinez, CA; [4]Neurol., UC Davis, Davis, CA; [5]Neurolinguistics, Natl. Res. Univ. Higher Sch. of Econ., Moscow, Russian Federation

Abstract: We built a HARDI diffusion streamline database from 43 healthy controls for identifying likely connectivity deficits of chronic stroke patients who have lesion location masks available that specify brain damage. We verified the accuracy of the lesion mask estimated connectivity deficits in 40 stroke patients by comparison to the patients' HARDI deficits vs. age and sex matched controls. We then applied the streamline database to study a separate group of 191 left hemisphere chronic stroke subjects who suffered dysphasia and were imaged to generate hand-delineated lesion masks. We found that estimated white matter (WM) connectivity deficits contribute to explaining, along with regional gray matter (GM) damage and lesion size, behavioral speech and language deficits in the patient group.
HARDI images were processed using mrtrix to obtain 500,000 streamlines/subject, seeded at random WM and GM locations. Streamlines were partitioned in native space using the Harvard-Oxford atlas specifying 48 cortical GM locations and 7 subcortical GM locations per hemisphere. After further filtering and transformation, 6.5 million streamlines traversing 190,925 possible MNI locations were produced and classified according to which pairs of the 110 GM locations they connect. The Table shows the results of verifying the database in our 40 stroke cohort: lesion mask estimated connectivity deficits correlate well with those found directly from patient HARDI data.
When applied to the 191 patient chronic stroke cohort with lesion masks and Western Aphasia Battery (WAB) scores, we found that WM lesion size is more important than GM lesion size in predicting speech and language deficits, and that GM ROI disconnectivity is more critical than GM ROI damage, as illustrated in the Figure.

Title: Free-water and free-water corrected fractional anisotropy within the primary and secondary corticospinal tracts predict grip strength in chronic stroke.

Authors: *D. B. ARCHER, S. A. COOMBES;
Univ. of Florida, Gainesville, FL

Abstract: It is well documented that a stroke causes changes in brain structure, and that motor deficits are related to the amount of damage found within the corticospinal tracts (CSTs). Conventional diffusion MRI stroke studies often calculate measures of fractional anisotropy and diffusivity within specific regions of the CST such as the PLIC and CP. Lower FA and higher diffusivity in these regions have been associated with poorer motor function. In the current study we extend this literature by addressing four unresolved issues. 1) The single tensor model does not control for free-water, so it is not clear from these studies whether the deficits in function relate to changes in tissue and/or fluid. 2) It is not clear whether correlations between microstructure and function are limited to the PLIC and CP or extend to other regions of the CST. 3) PLIC and CP regions have been drawn across primary and secondary CSTs, and so it is not clear if microstructure in both tracts equally relate to function. 4) There is currently no consensus on whether lesions should be masked or not prior to calculating and then correlating microstructure with function. To address these issues, we calculated free-water and free-water corrected FA within every axial slice of the M1-CST and PMd-CST. We then correlated free-water and free-water corrected FA within every slice for both tracts with grip strength in twenty-three individuals post-stroke. We found that free-water and free-water corrected FA from five segments of the M1-CST and two segments of the PMd-CST predicted post-stroke grip strength ($p<0.05$, corrected). These segments were located within the CP, PLIC, and corona radiata. All segments were inputted as independent variables in a multiple regression analysis with bidirectional elimination to predict grip strength, in which we found that the optimal model ($R_{adj}^2=54.85\%$, $p<0.01$) included free-water in the M1-CST PLIC, free-water corrected FA in the the M1-CST CP, and free-water in the PMd-CST cortex. Our observations show that a data-driven approach that separately assesses tissue and free-water is robust to outliers and provides a more detailed understanding of the relationship between structure and function in chronic stroke.

Title: Changes in resting-state fMRI in acute subcortical stroke correlate with long term motor recovery

Authors: *K. AKAZAWA[1], J. XU[2], M. BRANSCHEIDT[3,4], T. KITAGO[5], P. CELNIK[3], A. LUFT[4], J. KRAKAUER[2], A. V. FARIA[1];
[1]Radiology, [2]Neurol., [3]Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD; [4]Neurol., Univ. Hosp. Zurich, Zurich, Switzerland; [5]Columbia Univ. Med. Ctr., New York, NY

Abstract: Resting-state functional MRI could potentially provide information on the mechanisms of motor acute deficits and recovery after acute stroke. Acute changes in connectivity between ipsilesional motor area and other cortical regions, and correlations between connectivity status and motor outcomes have been reported. One obstacle of studying resting fMRI in stroke is that the cortical lesion itself may be a confounder. Here, we explored the acute changes in resting fMRI and neural correlates of motor recovery in participants with subcortical strokes.

Resting fMRI, and Fugl-Meyer (FM) scores were obtained from 10 patients with supra tentorial subcortical strokes (mean age: 61.7 ± 5.44, 5 males) within 1, 4, 12, 24, and 52 weeks after stroke. Eleven age-matched healthy controls (62.7 ± 8.04, 7 males) were scanned at the same intervals. The brain segmentation and structure-based resting fMRI analysis were performed automatically in BrainGPS (www.MRICloud.org).

We first evaluated differences between patients and controls at first week, regarding resting fMRI connectivity (z-transformed Pearson correlations) between the ipsilesional precentral gyrus and 27 gyri in the ipsi- and contra-lateral frontal and parietal lobes. We then correlated the significant different connections (p-values<0.05 after Bonferroni correction) from resting fMRI with acute FM scores, and with motor recovery as measured by (FM at 24 weeks - acute FM)/acute FM. Finally, we tested the value of these connections on improving a predictive model of motor function based on acute FM scores only.

Correlations between ipsilesional precentral and ipsi and contralesional postcentral gyrus, and those between ipsilesional precentral and supramarginal gyrus were significantly different between patients and controls (p=0.014, 0.031, 0.048, respectively). This indicates that although the cortex was not directly affected, there were acute changes in connectivity between primary

motor cortex and primary sensory cortex intra and inter-hemisphere.
The acute status of connectivity between ipsilesional precentral and postcentral gyrus did not correlated with acute FM score, but it did correlated with long term (~6 months) motor recovery (r=0.825, p=0.035). As expected, the acute FM scores predicted FM scores at 6 moths, and additional resting fMRI information did not improve the model. Our results suggest that acute cortical motor-sensory connectivity may be involved in functional motor recovery, although additional connectivity measurements seem to be redundant to predict motor outcomes.

Title: Study of cerebral blood flow patterns in patients with transient neurological dysfunction assessed by arterial spin labeling perfusion MRI

Authors: *K. SUMIYOSHI;
Natl. Disaster Med. Ctr., Tachikawa, Japan

Abstract: Purpose: It can be difficult to differentiate epilepsy from other diseases that cause transient neurological dysfunction. An interictal electroencephalogram does not always provide evidence for diagnosis of epilepsy. It has been reported that perfusion changes could be detected for a time after periictal period of epilepsy using arterial spin labeling (ASL) perfusion MRI. We

aimed to examine cerebral blood flow patterns in patients with transient neurological dysfunction. **Methods:** One-hundred cases with transient neurological dysfunction were studied. Patients were imaged at a 3T MRI including ASL, and were also examined using EEG. The abnormal findings of ASL were compared with those obtained from EEG. **Results:** We found temporal changes of perfusion pattern in patients of epilepsy. On the other hand, there were almost no changes in patients of syncope. **Conclusion:** The combined use of EEG and ASL can aid the differential diagnosis of epilepsy.

Abstract: A persistent challenge in stroke neurorehabilitation research is the vast heterogeneity of the post-stroke population. Previous studies have suggested inconsistent relationships between post-stroke neuroanatomy and motor recovery based on smaller samples. However, large, diverse datasets can provide the statistical power to robustly form and evaluate these hypotheses. The ENIGMA Stroke Recovery Working Group uses innovative meta-analytic approaches to generate large datasets (goal n>3000) of neuroimaging and behavioral data, collected across multiple study sites (http://enigma.ini.usc.edu/ongoing/enigma-stroke-recovery/). Here, we present preliminary findings relating post-stroke neuroanatomy with upper limb motor impairment. Based on previous work, we hypothesize that regions of the basal ganglia should most strongly relate to motor impairment. Structural T1-weighted MRIs from over 1400 patients

across 12 sites have been committed. Data from 251 stroke patients across 8 research samples were included in this analysis. ENIGMA protocols were used to extract subcortical measures and perform quality control checks. Regression analyses examined subcortical volume as a predictor of motor impairment; additional covariates included age, sex, time since stroke, hemisphere affected, and total intracranial volume. Focal effects of each lesion on the brain volumes were manually marked and included in the model (volume=0); 10,000 permutations were used to obtain a non-parametric estimate of the statistical significance. In line with our hypotheses, we found a number of significant associations between subcortical volume and motor impairment, particularly in the basal ganglia and lateral ventricles. Importantly, individually analyzing three of the largest samples (n=37, n=34, n=27) yielded weak and inconsistent results across samples (Table 1). These preliminary results demonstrate the feasibility and utility of integrating multi-site data to study the relationship between post-stroke neuroanatomy and motor impairment. We further demonstrate the variability of findings across individual samples and the improved ability of this combined approach to more sensitively identify post-stroke brain-behavior relationships.

Table 1. Subcortical regions related to post-stroke motor behavior. Results relating subcortical regions to motor behavior are shown for the combined sample (n=251) as well as three of the largest individual sites. Beta value listed is the observed slope of the regression.

Title: Longitudinal monitoring of mesoscopic cortical activity using a fluorescent bead mouse model of small vessel disease and GCaMP6 imaging

Authors: *M. BALBI, G. SILASI, Y. SEKINO, M. VANNI, J. LEDUE, T. H. MURPHY; Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Small vessel diseases (SVDs) comprise the majority of cases of vascular dementia, itself the second most common form of dementia. Obstruction of small vessels leads to cell death from oxygen starvation and contributes to vascular dementia. These microinfarcts usually escape detection by conventional magnetic resonance imaging and are identified mostly upon postmortem examination. Reliable animal models that allow high-resolution functional imaging are needed to study brain function in SVD. Our work explores a SVD model where occlusions of small penetrating arterioles are reproduced in mice by endovascular injection of 20 μm fluorescent microspheres. Occlusions in this model have been shown to cause gross motor impairments as well as cell loss and axonal disruption throughout the brain. While the cortex itself is relatively spared from structural damage —less than 1% of occlusions result in

microinfarcts[1]— subcortical, white matter damage may disrupt cortical function. Hence we evaluated functional connectivity in the mouse cortex using genetically encoded calcium indicators. Mesoscopic functional connectivity was mapped longitudinally in awake GCaMP6 mice using transcranial wide-field calcium imaging through a bilateral chronic window implant. Spontaneous activity was recorded over 4 weeks before and 6 weeks after injection of red fluorescent microspheres (2000, 20 μm microspheres in 100μl PBS) into the left common carotid artery. Microsphere occlusions were quantified with optical coherence tomography (OCT) and changes in cerebral blood flow were assessed with laser speckle imaging. A battery of behavioral tests were performed to detect functional impairments. We assessed motor function using the clasping and neurodeficit scores (NDS). The NDS in stroke mice was significantly higher ($p=0.03$) than in sham mice. Stroke mice showed a trend to a higher clasping score, with no sham mice scoring above 0. We analyzed seed pixel correlation and standard deviation maps within somatosensory, visual, and motor cortices but no significant differences were found between sham and stroke groups. A possible interpretation of our findings is that impairments to functional circuits in subcortical structures such as the basal ganglia or thalamus affect motor function without alterations to functional connectivity in the cortex detectable at the mesoscopic scale. Analysis at the microscopic scale may bring to light more subtle relationships and provide a unifying theory spanning microscopic, mesoscopic and behavioral phenomena. Abstract: Ischemic stroke causes cell death, massive disconnections of individual neurons and disrupted functional circuits. Although functional mapping studies at macroscopic and mesoscopic scales demonstrate that plasticity within cortical regions after stroke leads to partial recovery of function after the initial injury, the role of single neurons in response to altered brain networks, or the cortical connectome, is not clear. Here we used *in vivo* two-photon calcium imaging in head-fixed freely moving adult mice to show how the response of individual neurons could affect neural network topology after stroke. Calcium dynamics were evaluated in peri-infarct motor, and more distant premotor and somatosensory cortex before and after inducing stroke in the forelimb motor cortex. These three cortical areas represent distinct circuits in relationship to the stroke (adjacent and distant) and are involved in the axonal plasticity that underlies recovery. While diminished network functional connectivity was observed for all these cortical areas, the response of functional hubs showed different signaling patterns. Based on the amplitude of change in calcium transients ($\Delta F/F$), a decrease was found only in the somatosensory cortex. Peri-infarct motor and premotor cortex exhibited a decrease in frequency whereas an increase was observed in somatosensory cortex. Applying graph theoretical analysis, our data confirmed that before stroke, cortical networks followed a high clustering pattern with heavy-tailed degree distributions. After stroke, cortical networks lose their tightly correlated firing patterns among neurons, with each area showing a distinctive pattern of loss in correlated network firing over time. Finally we evaluated mean correlation coefficients as a function of distance between neurons. Calcium transients were assessed during resting and limb motion epochs before and after stroke. We observed that the average correlation at all distances (100-400 μm) was increased during motion after inducing stroke compared to the resting state. However before stroke the average correlation was higher at resting state than during limb motion . Altogether, our data suggest that stroke disrupts network topology and causes sparse network in the areas adjacent to stroke. Furthermore, our findings are geared towards understanding recovery potential and correlation in network gain over time. Supported by the Ressler Family Foundation.
